A DICTIONARY OF APPLIED CHEMISTRY

BY

SIR EDWARD THORPE, C.B., LL.D., F.R.S.

EMERITUS PROFESSOR OF GENERAL CHEMISTRY AND DIRECTOR OF THE CHEMICAL LABORATORIES
OF THE IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY, SOUTH KENSINGTON, LONDON;
LATE PRINCIPAL OF THE GOVERNMENT LABORATORY, AND A PAST PRESIDENT OF
THE CHEMICAL SOCIETY AND OF THE SOCIETY OF CHEMICAL INDUSTRY

ASSISTED BY EMINENT CONTRIBUTORS

VOL. III.

REVISED AND ENLARGED EDITION

WITH ILLUSTRATIONS

LONGMANS, GREEN, AND CO.

A

DICTIONARY

OF

APPLIED CHEMISTRY.

EXPLOSIVES. Explosives are solid, liquid, or gaseous mixtures or chemical compounds, which by chemical action (set up in them locally by flame, by a blow, or by other means) generate suddenly large volumes of heated gas.

The rate at which the expansive force, which characterises an explosive reaction, is developed, varies considerably, and determines whether the reaction is a combustion, explosion, or detonation. These terms are purely relative, and there is no definite line of demarcation between them.

The factors determining the rapidity of an explosive reaction are the chemical nature of the explosive, its physical condition, the conditions under which it is exploded, and the method of firing.

The energetic action of an explosive largely depends on its rate of chemical change; in chemical compounds (like nitroglycerin and guncotton) the reacting atoms are in much greater proximity than are those of a mechanical mixture of solids (such as gunpowder), and in the former class the rapidity of the chemical action will be greater than in those of the latter class, composed of constituents by themselves non-explosive.

Nearly all the explosives in actual use are instances of oxidation, oxygen being supplied by a nitrate, by nitric acid, by an NO_2 group, or by a chlorate or perchlorate.

The oxidising compounds used in explosive mixtures and explosive compounds are frequently endothermic substances, the heat of decomposition contributing towards the expansion of the gaseous products of the explosion. The conditions for complete combustion of the combustible elements do not always give the maximum explosive effect; carbon burning to monoxide gives a larger evolution of gas, but less evolution of heat than on complete combustion, and the best composition for any given explosive effect has to be determined by experiment.

The physical condition of an explosive has a marked effect on its explosibility and the character of the explosion; frozen nitroglycerin

is much less sensitive than the same explosive in the liquid state, nitro explosives that have been fused and cast are less sensitive to detonation than the same explosives in the crystalline or powdered condition, and the same gunpowder mixture gives various effects according to the size of the grain.

Confinement increases the effect of all explosives; the more rapid the explosive the less the confinement necessary to obtain its maximum effect. The power of mercury fulminate is but little increased by confinement, but explosives of the gunpowder type require to be strongly confined to produce disruptive effects.

An explosive reaction may be initiated by a heated solid, a flame, by friction, by percussion, an electric spark or current, or by the concussion from another explosion. The nature of the reaction is largely conditioned by the method of firing adopted; nitroglycerin or guncotton in contact with a flame burns quite quietly in the open, but when fired by the detonation of a small initial charge of mercury fulminate, the whole mass of the explosive decomposes practically instantaneously, and detonation results.

The various explosive reactions differ considerably in the amount of impulse necessary for their initiation. To have value as an explosive, a compound or mixture must not be too sensitive to impulse. Substances like nitrogen iodide and diazotenzene nitrate are too sensitive to have practical value. The most sensitive explosives in use, such as mercury fulminate and its mixtures, are used in small quantities in caps and detonators to initiate the explosion of larger masses of less sensitive explosives, propellants or high explosives.

The value of an explosive as a propellant or high explosive depends on its density, on the quantity of gas and heat liberated, and on the velocity of the explosive reaction. For a propellant the gas and heat evolution must be high: for a high explosive it is necessary that all the factors should have a high value.

Explosives may be classified either according to their chemical composition, into explosive

mixtures or explosive compounds; according to their effect and the purpose for which they are employed, into 'high' or 'low' explosives or 'disruptives' and 'propellants'; or according to the danger in handling, transporting, and storing them.

In this article, the chemical classification is adopted, as far as possible. All the substances having explosive properties are not included, but only those that have, or may have, value for practical purposes.

EXPLOSIVE MIXTURES.

In explosive mixtures, the combustible and supporter of combustion are present in separate ingredients, which are usually not in themselves explosive. The necessary speed of reaction is ensured by extremely fine subdivision and very thorough incorporation of the ingredients, and by the oxygen being in a highly concentrated and more or less easily liberated form. An important characteristic of this class of explosives is that their effect may be varied by varying the proportions of the ingredients.

Explosive mixtures may be grouped, according to the source of their oxygen, into nitrate, chlorate, perchlorate, &c., mixtures. Only the mixtures of these oxidising substances with combustible ingredients, in themselves non-explosive, and those containing only a small proportion of an explosive compound added to improve the explosive properties of the mixture, will be considered under this heading. The mixtures of oxidising substances with explosive compounds, where the former are only of secondary importance, will be considered under the respective explosive compounds.

Nitrate Mixtures.

In the nitrates, the oxygen is in sufficiently strong combination to need a somewhat powerful disturbing agency to liberate it, so that the nitrate mixtures are not very sensitive and their action is comparatively slow.

Potassium nitrate mixtures.—Of the various nitrates used in explosive mixtures, the potassium salt is by far the best adapted for the purpose, and black powder, or gunpowder, is the most important member of this class of explosives.

Gunpowder.

Since the introduction of smokeless powders, gunpowder has been gradually superseded for

most military purposes: both as a propellant and a disruptive it is obsolescent. It is still however, very largely used in industrial mining operations, as a propellant for sporting purposes, as a bursting or opening charge for shrapnel shell, and, the smaller sizes, for subsidiary military purposes, such as for primers and igniters for large smokeless-powder charges, for fuses, and as an ingredient in certain compositions.

Ordinary black gunpowder consists of an intimate mixture of potassium nitrate, sulphur, and charcoal. The composition of the black powder used for military purposes in different countries is given in the table below.

English black gunpowders contain about 1 to 1·3 p.c. moisture.

Manufacture.—A short account only of the process of manufacture will be given, mainly that used at the Royal Gunpowder Factory, Waltham Abbey.

The Ingredients.

The *nitre* employed at Waltham Abbey is wholly Indian nitre. As imported, the 'grough' saltpetre, as it is called, has been partially purified, but contains potassium and sodium chlorides, potassium, sodium, and calcium sulphates, sand, and organic matter; the total impurities averaging about 4½ p.c. It is submitted to a simple refining process, being first dissolved by heat in the water used for washing the purified nitre of a previous operation. The liquid is heated to boiling in large refining coppers, the scum on the surface being carefully skimmed off; the temperature of the liquid is allowed to fall to 104°, and it is then filtered through bags of coarse cloth into the crystallising vessels. The temperature of the solution on entering the crystallising vessels is about 88° to 82°, the liquid is kept in constant agitation with wooden hoes, whereby, as the liquid cools, fine crystals are formed. The solution is not stirred when its temperature is lower than 32°. If the solution were left to crystallise undisturbed, large crystals would form, and would enclose mother liquor. The crystals are drawn to the side of the crystalliser, and transferred to draining frames. The drained nitre flour then receives three washings with distilled water in quantities insufficient to dissolve the nitre, each washing is succeeded by draining; after the last washing the nitre is drained all night, and is removed (except the bottom part, which is very moist) to the store bins. After about three days in store it is ready for the

COMPOSITION OF BLACK POWDER USED FOR MILITARY PURPOSES.

powder manufacture, and contains from 3 to 5 p.c. of moisture, according to the season; the water is estimated and allowed for in weighing the charges.

The waters used for washing the crystals are employed for the solution of the crude nitre; the nitre is recovered from the crystallisation mother liquors by evaporation, and is treated as crude nitre.

From Désortiaux, it appears that the agitation of the solution of nitre during crystallisation in order to obtain fine crystals is in general use on the Continent; at least, he mentions it as in use at Lille, Wetteren, and Spandau. At the refineries at Lille, Wetteren, and Spandau, he states that glue is added to the boiling solution of the crude nitre (the weight of glue being about $\frac{1}{100}$ that of the crude nitre); the glue coagulating and carrying down organic colouring matters. The process of purification was the invention of Béaume and Lavoisier, and existing processes follow theirs with slight modifications.

On the Continent, and by most private manufacturers in this country, 'artificial' or 'conversion' saltpetre, or 'German saltpetre,' as it is frequently called, is almost exclusively used. It is made by dissolving 10 parts of sodium nitrate, 'Chile saltpetre,' and 9 parts of potassium chloride, obtained from Stassfurth 'carnallite,' in mother liquors from previous operations, concentrating and crystallisation. It is refined as above.

In 1894 Hellick discovered that 'German saltpetre' frequently contained notable quantities of perchlorate, and it was stated that several accidents in powder factories coincided with the presence of a considerable percentage of perchlorate in the powder. It was subsequently shown that powder containing perchlorate was not unduly sensitive. The perchlorate is, however, not uniformly distributed in nitre, but tends to agglomerate, and the irregular shooting obtained with some foreign sporting powders, as compared with English ones, has been attributed to the contained perchlorate.

The sulphur employed at Waltham Abbey is native Sicilian sulphur, of the best quality. In Sicily, the sulphur mineral is subjected to a liqumation process, to separate the sulphur from the gangue. It still contains 3 to 4 p.c. gangue, from which it is freed by distillation. It is distilled from a large iron retort, provided with two tubes placed at right angles to each other; one tube (15 inches wide) communicates with a large dome-shaped subliming chamber, the other tube (5 inches wide) enters an iron pot which receives the distilled sulphur; this tube is jacketed for cooling with water. The tubes can be connected with the distilling vessel or cut off from it by means of valves. The distilling vessel receives its charge of sulphur, which is heated to boiling; during the earlier stages of the distillation the vapours are sent into the subliming chamber, where the sulphur condenses as 'flowers of sulphur'; later on the sulphur vapour is sent through the condenser, from which it runs into the receiver in the liquid form. It is allowed to cool somewhat, but not to its solidifying point, and is ladled into moist wooden moulds. Sulphur, of sufficient purity to be used in explosives without further treatment,

is now obtained in large quantities, by the 'Chance-Claus' process, from the calcium sulphide, which is the chief constituent of the residue formed in the manufacture of soda. Much of the sulphur used by private firms and abroad is also obtained from pyrites. The 'flowers of sulphur' are not used in the manufacture of the gunpowder, as they usually contain considerable quantities of sulphurous and sulphuric acids, but are redistilled.

The sulphur igniting in air at a low temperature—about 250° —renders the gunpowder inflammable, and, experience has shown, improves the keeping qualities of the powder. Under the influence of pressure in the manufacturing processes the sulphur flows and becomes colloidal, and cements the particles of the ingredients together. Sulphurless gunpowder is comparatively friable.

The charcoal. For making the charcoal for gunpowder, soft and light woods are chosen, as the charcoals they yield are more readily ignitable, of an average growth of from two to ten years. The wood should be cut in the spring, when it is in full vegetation, as then its bark can readily be removed; in the spring the tree is in fullest sap, but the sap is very watery, and contains but little salts in solution.

At Waltham Abbey, the woods used are: the alder buckthorn (*Rhamnus frangula*, L., improperly called dogwood), alder, and willow (*Salix alba*, L.). Dogwood charcoal is preferable for small-grain quick-burning powders; for powders of larger grain the slower alder and willow charcoals are used. The woods are grown in England, and are cut about four inches in diameter.

Désortiaux states that in France the so-called dogwood (*Rhamnus frangula*) is exclusively employed for making the charcoal for military and sporting powders; he states, however, that it is becoming increasingly difficult to procure, and that they are trying to replace it by willow, or by the wood of the spindle tree. In Germany, 'dogwood' (*R. frangula*), willow, and alder are used; in Russia, alder; in Austria, alder and hazel.

At Waltham Abbey, wood is usually kept for about three years, dogwood in thatched stacks, and willow and alder piled by cords in the open. By the method of carbonisation there followed, 25 p.c. of black charcoal should be obtained from the wood, rather more from dogwood. The wood is cut into three-foot lengths, which are split if differing much in thickness, and is packed into iron cylindrical cases called slips, 3 feet 6 inches long, and 2 feet 4 inches in diameter. The lid is fastened on, two openings (each about 4 inches in diameter) being left in the bottom of the slip. The slips are then placed in horizontal cylinders, the end of the slip with the openings going to the further end of the cylinder, in which end there are openings corresponding with those in the slips.

The cylinders are closed by tightly fitting iron doors, and are built into the wall, with furnaces underneath, so arranged as to admit of the accurate regulation of the heat throughout the operation of charring; this occupies with dogwood about 4 hours for R.F.G., and 8 hours for R.F.G.² gunpowders. The flames surround the cylinder, the heat acting as nearly as possible

on its whole surface. The gases and volatilised tar from the wood pass out through the openings in the slip and the corresponding holes in the retort, into pipes communicating with the furnace in which they are burnt; this saves a considerable amount of fuel. When the wood has been sufficiently charred, which is known by the violet colour of the flame from the burning gas, indicating the formation of carbonic oxide, the slip is withdrawn by means of tackling, placed in a large iron case or cooler, covered with a closely fitting lid, and allowed to remain until all the fire is extinguished, which takes about 4 hours; the charcoal is then emptied into smaller coolers, and sent to store. The charcoal is carefully picked over by hand, to ascertain that it all is properly and evenly burnt, and that no rivets from the slips have broken off. It is then kept from ten days to a fortnight in store before being ground, to obviate the danger from spontaneous combustion (caused by absorption of oxygen from the air) to which charcoal is liable when ground directly after burning.

The smaller the cylinders used, the more uniform is the composition of the charcoal produced, since so high a temperature is not needed to carry the heat to the centre of the charge; in the English powder mills, the tendency has been to use small cylinders, some of which hold only 77 lbs. of wood. The use of small cylinders, however, raises the cost of production (Désortiaux).

Violette states that, for the same temperature, a slow carbonisation gives a much higher yield of charcoal than a quick carbonisation; the percentage of carbon being also a little higher in the former case.

Instead of fixed carbonising cylinders, movable cylinders are now used in most black-powder factories. No 'slip' is used, but two cylinders are provided for each furnace, one being charged while a carbonisation is proceeding in the other. The charged cylinders are run into the furnace on rails, which support them over the fire. An elaborate arrangement for the regular distribution of the gases and products of distillation of the wood is used, by means of which they can at will be directed into any one of the furnaces or allowed partially to escape by the chimney.

The principal advantages claimed for this system are homogeneity of the charcoal, the ready regulation of the combustion of the gases by means of the distribution apparatus, and the cooling down of the charcoal out of contact with the air, which does away with the possibility of the charcoal taking fire.

In some English factories, vertical movable cylinders are used, the advantages being that a larger number can be fired at the same time, and the moving of the cylinders into the cooling room is greatly facilitated.

Böckmann mentions that some years ago the use of rotating cylinders was introduced in Sweden; the cylinders being turned 90° about their horizontal axes every half-hour during carbonisation. It is stated that a more uniform carbonisation is obtained, and fuel saved.

Violette, in 1848, introduced the carbonisation of wood by means of superheated steam. The steam was used at a pressure of $\frac{1}{2}$ to 1 atmosphere, and was raised to the required temperature by being passed through a worm of

wrought-iron heated by a fire. For the production (from dogwood) of charcoal *roux* containing 70 p.c. carbon, the temperature of the steam had to be about 280°; by using steam heated to about 350°, charcoal containing 77 p.c. carbon was produced, and by heating both cylinder and steam to a temperature not exceeding 450°, charcoal of 89 p.c. carbon was obtained. The charcoal produced by means of superheated steam is remarkably uniform in composition. The method, however, was abandoned, because it gave a larger yield of charcoal *roux*, but not of black charcoal, than the ordinary method of carbonisation in cylinders; and the lightly-burnt charcoal was then only required for sporting powder. Also, the cost of production of the charcoal by the superheated steam apparatus was greater.

Güttler, in 1887, invented a process for carbonising wood, especially cuttings and pulp, straw, peat, &c., in heated CO₂. Carbon dioxide is stated to be preferable to superheated steam, on account of the moist state of the charcoal when cooled in the steam. Gases of combustion, as free as possible from oxygen, are actually used. A producer-furnace is arranged by the side of the charring furnace, in which the CO₂ is produced by blowing air through burning coke by means of a fan. The carbonic acid gas is then blown through a tube into the carbonising cylinder during the carbonising of the wood, &c., and the flow of CO₂ is maintained during the cooling, which in consequence of the presence of the gas may be very rapid.

Composition, &c., of the charcoal.—Carbonising the wood raises the percentage of carbon, diminishing the percentages of hydrogen and oxygen.

Désortiaux states that woods recently cut have almost the same percentage composition; the mean composition of the dried wood being 49.37 p.c. C, 6.14 p.c. H, 43.42 p.c. O and N, 1.07 p.c. ash.

Heintz gives the composition of alder wood *minus* ash, as 48.63 p.c. C, 5.94 p.c. H, 44.75 p.c. O, 0.68 p.c. N. Peterson and Schödler give alder wood *minus* ash as 49.20 p.c. C, 6.22 p.c. H, 44.58 p.c. O and N.

On heating, water, carbon monoxide, carbon dioxide, hydrogen, acetic acid, methyl alcohol, and tar are produced.

Violette found that dogwood was converted into slack-baked charcoal (*charbon roux*) at a temperature of 280°–300°; at 300° the yield (on the small scale) was about 34 p.c. and the composition of the charcoal was 73.24 p.c. C, 4.25 p.c. H, 21.94 p.c. O and N, 0.57 p.c. ash. Between 350° and 400°, black charcoals are produced, the yield being from 31 p.c. to 28 p.c., the composition ranging from about 77 p.c. to 81 p.c. C. Between 1000° and 1250°, the charcoal obtained was very black and hard, the yield was about 18 p.c., and the composition of the charcoal 82.0 p.c. C, 2.30 p.c. H, 14.10 p.c. O and N, 1.60 p.c. ash, at the lower temperature, and 88.14 p.c. C, 1.42 p.c. H, 9.24 p.c. O and N, 1.20 p.c. ash, at the higher temperature.

Experiments made at the Chemical Department of the War Department showed no great difference in the specific gravity of charcoals prepared from willow and alder at 394°–558°;

their specific gravity at 15·6° was 1·41 to 1·44. Willow charred at the maximum temperature of 394° for 9½ hours had the composition of 79·22 p.c. C, 4·02 p.c. H, 15·32 p.c. O and N, 1·44 p.c. ash, and specific gravity (at 15·6°) 1·414.

The higher the temperature of carbonisation, the less is the inflammability of the charcoal in air, and the greater the thermal conductivity. Violette states that the charcoals prepared from any kind of wood at 300° take fire when heated in the air to 360°–380°; the charcoals from light and porous woods burning more easily than those from hard and close woods. For the same wood he makes the following statement as to the relation between temperature of charring and that of inflammation in air:—

Temperature of charring	Temperature of inflammation
260°–280°	340°–360°
290°–350°	360°–370°
432°	about 400°
1000°–1500°	600°–800°

The lightly-burnt charcoals are much more absorbent of water than those charred at a high temperature.

The charcoals used for the various kinds of Service black gunpowder range in composition from about 75 p.c. C to 86 p.c. C, according to the nature of the powder. All other conditions being the same (viz. proportion of KNO_3 , S, and charcoal, size of powder, density, and moisture), the charcoal burnt at lower temperatures (having lower percentage of carbon) gives higher muzzle-velocities and pressures than charcoal burnt at higher temperatures and having higher percentage of carbon; that is, for gunpowder of the composition 75 p.c. nitre, 10 p.c. sulphur, and 15 p.c. charcoal. The greater inflammability of the lighter-burnt charcoal makes the gunpowder, of which it forms part, quicker-burning.

The wood is charred to expel moisture, which would lower the temperature of the explosion products of gunpowder, and to obtain a charcoal of suitable inflammability. Charcoal for large-grained powders should be jet-black in colour; for small-grained powders a more slackly burnt charcoal of brown-black colour is used. Before use the charcoal is hand-picked to remove any impurities and any portions insufficiently 'burned.'

Appended is a table of the percentage composition of some charcoals from gunpowders of Waltham Abbey make, and of a sporting powder, which will serve as types of the charcoal used in the different kinds of black gunpowder:—

	W. A. Pebble	W. A. Rifle Large Grain	W. A. Rifle Fine Grain	W. A. Fine Grain	Curtis & Harvey Sporting.
C . . .	85·26	80·32	75·72	77·88	77·36
H . . .	2·98	3·08	3·70	3·37	3·77
O (and N)	10·16	14·75	18·84	17·60	16·62
Ash . .	1·60	1·85	1·74	1·15	2·25

(Noble and Abel, Phil. Trans. 1880, 171, 218).

Pulverising, mixing, and incorporating the ingredients.—At Waltham Abbey, the refined nitre is used for gunpowder without being previously dried or ground, but the moisture is estimated and allowed for. The charcoal is ground in a mill; the grinding is done by a cone working in a cylinder, both being suitably toothed. The ground charcoal is made to pass through a spout into a revolving reel of 32-mesh copper-wire gauze, 8½ feet long and 3 feet in diameter, inclined at an angle of about 4° to the horizontal, and making 38 revolutions per minute. The charcoal which passes through the gauze is fit for use, and is collected in a closed reel case; the charcoal too coarse to pass through the gauze falls through the further end of the reel into a vessel, and is reground. The sulphur is ground under a pair of iron edge runners, a smaller-sized incorporating mill, and is sifted through a reel similar to that used for the charcoal. Precautions are taken to connect the sulphur mill to earth, in order to allow the electricity generated by the rubbing of the sulphur to escape, and the machinery is not run rapidly. In some works the sulphur is mixed with a little nitre before grinding to prevent electrification. Besides the danger of ignition by a spark, the electrical charge causes the sulphur to ball together and interferes with the grinding.

The ground ingredients are carefully weighed out in their proper proportions; the largest charge worked in the incorporating mill is 80 lbs. The charge receives a preliminary mixing in the mixing machine, a cylindrical drum of gunmetal or copper, about 2 feet 9 inches in diameter and 1 foot 6 inches wide. An axle bearing 8 rows of gunmetal 'flyers' or fork-shaped arms passes through the centre of the drum; the drum and arms are made to revolve in opposite directions, the former making about 40 revolutions per minute, the latter 120. The mixing occupies five minutes, the mixture being then hand-sifted through an 8-mesh copper-wire sieve over a hopper, to remove foreign substances, which otherwise are liable to cause an ignition in the incorporating mill; the 'green charge' is then tied up in a bag ready for the incorporating mill.

The incorporating mill consists of a circular iron bed, about 7 feet in diameter, very firmly fixed in the floor of the building, on which two iron cylindrical edge runners revolve. The iron runners are 6½ feet in diameter, 15 inches wide, and weigh about four tons. They have a common axle resting in a solid cross-head attached to a vertical shaft, which passes through a bearing in the centre of the bed, and is in gear with the machinery.

The bed has a sloping outside rim. The runners are at an unequal distance from the axis, the eccentricity being equal to half the thickness of a runner; they thus work the charge in the inner and the outer part of the bed, their paths overlapping. The runners are followed by two 'ploughs' of wood, covered with leather, attached to the cross-head by arms; one plough works near the vertical shaft, the other near the rim of the bed, throwing the composition under the runners.

The green charge is spread evenly on the bed of the mill by means of a wooden rake; it is

damp with the moisture of the nitre, but an additional quantity of distilled water (2 to 7 pints) is added from time to time, according to the state of the atmosphere; the moisture assists the incorporation, and the charge is kept not too dry or it would slip away from the runners or cling to them.

The iron runners make 8 revolutions per minute, the green charge is worked under them for 4 hours for R.F.G. powder, for 7 to 8 hours for R.F.G² powder, and for 3 hours for R.L.G² and R.L.G⁴. Dust and reworked charges are worked for 40 minutes.

A drenching apparatus is placed over the bed of each mill, by means of which, in case of an explosion, a tank of water is overturned and the charge drowned. This is done by the action of the explosion gases on a flat wooden lever arrangement, pivoted, and attached to the tank. By means of a horizontal shaft connecting all the levers of a group of mills, an explosion in one mill drowns all the others.

The short radius of the circular path traversed by the runners causes them to take a twisting as well as a rolling motion, and gives them a combined crushing and grinding action very favourable to the thorough trituration and incorporation of the ingredients.

The 'mill-cake,' as the worked charge is called, should have a uniform appearance, and should contain 1 p.c. to 3 p.c. moisture for small-arm powders, 3 p.c. to 6 p.c. for the larger-grained powders. Any 'mill-cake' left firmly caked on the bed is removed by wooden tools after thoroughly moistening. Many accidents have been caused through the use of metal tools.

Breaking down the mill-cake and pressing.

—The mill-cake is next reduced to meal, for convenience in charging the press-box, and in order that the powder may be uniformly pressed. The mill-cake is broken down by means of two pairs of gun-metal rollers, the upper pair being grooved and placed directly above the other pair, which are smooth. The rollers revolve towards each other, dangerous friction from the accidental presence of any hard substance being prevented by one roller of each pair working in sliding bearings connected with a weighted lever causing a pressure of about 56 lbs., so that the rollers would open at any greater pressure. The rollers are fed with mill-cake from a hopper (placed at one end of the machine, below the level of the upper pair of rollers), by means of an endless band of canvas 2½ feet wide, with cross strips of leather sewn on at intervals of about 4 inches. The band passes over a roller at the bottom of the hopper, and over another placed above the upper pair of rollers; on being set in motion it carries the cake from the hopper to a point from which it falls on to the first pair of rollers; the crushed cake then falls on to the second pair, by which it is reduced to meal. It falls into wooden boxes, and is transferred to a magazine ready for pressing.

The meal is pressed into cake by a hydraulic press, fed from an accumulator, the head and bed-plate of which are made of cast iron or cast steel. The powder is pressed between plates about 1 foot 8 inches by 2 feet 4 inches and about

¾ inch thick. Formerly brass plates were used, but now ebonite plates are usually preferred, because they are not so easily bent out of shape, and also because they have sufficient elasticity to transmit the pressure evenly all over the layer of powder, even if they should get out of the horizontal. They have the disadvantage of becoming easily electrified; in fact, alternate layers of ebonite and powder really form an electric pile. To obviate any danger from the possible accumulation of electricity, the presses are provided with an earth connection.

In charging the press, a plate is first put on to the carriage, and round this is placed a wooden frame, deeper than the thickness of the plate. This frame is filled with powder, and the surface smoothed by means of a flat lath, and a second plate placed on the top. The frame is then lifted to the level of the second plate, and the process repeated until the whole charge is made up. A pressure of between 375 and 450 lbs. per square inch is applied, according to the fineness of the powder, the amount of moisture it contains, the state of the atmosphere, and the density required. The pressure is slowly applied, eased off and reapplied several times in order to obtain great density without using excessive pressures: the compression usually lasts from 30 to 40 minutes. A pressure of 375 lbs. per square inch applied for from 1½ to 2 hours produces a cake with an average density of 1.7 to 1.8. The centre of the cake has, however, a greater density than the edges; the edges of the cake are on that account cut away to the extent of about an inch. The amount cut away need not exceed 10 p.c. The centre layers of the pile are slightly less compressed than the top and bottom layers, but these differences in density are partly removed by the subsequent operations. The layers of pressed cake are broken into pieces with a wooden mallet and put into barrels.

Granulating or Corning.—The press-cake is converted into grain by means of a machine consisting of three or four horizontal pairs of gun-metal rollers in a gun-metal frame. The pairs of rollers are placed one above the other, on an axial line inclined at about 35° to the horizontal, the vertical distance between the pairs of rollers being about 2½ feet. For fine-grain powders, the highest pair of rollers has teeth ½ inch apart, the next pair has ¼ inch teeth, and the two bottom pairs have no teeth. Like those of the breaking-down machine, the rollers work in sliding counter-weighted bearings; they make about 25 revolutions per minute. The machine is fed with press-cake from a hopper by means of a moving endless band. Short screens, covered with copper-wire gauze (10-mesh for small-arm powders), are placed under each pair of rollers except the bottom pair, so that the powder too large to pass through the gauze passes on from one pair of rollers to the next. Beneath the short screens are placed two long screens in an inclined position, the upper one of 10-mesh, and the lower one of 20-mesh copper gauze fixed in a frame. A rapid, longitudinal, vibratory motion is imparted to all the screens while the machine is working, to assist the sifting and the flow of the powder. The grain that passes through the short screens will fall through the 10-mesh long screen. That which

is retained on the 20-mesh screen is R.F.G. or R.F.G.² powder; it falls into boxes made to move forward as they are filled. The grains too large to pass through the short screens fall into separate boxes, and are transferred to the hopper to be passed again through the rollers; while the fine powder which passes through the 20-mesh sieve falls on to the wooden bottom of the frame and is collected separately, to be sent back to the incorporating mill for a short reworking.

For granulating R.L.G.² and R.L.G.⁴ powders, three pairs of rollers are usually employed, the two upper pairs with larger teeth, the bottom pair smooth. The grain from the granulating machine is called 'foul grain.' By granulating a gunpowder there is no danger, as there would be with a dust, of segregation of the ingredients during transport according to their densities, the powder is less hygroscopic, there is less danger of escape from storing vessels, and the inflammability and rate of burning of the powder is increased, since the flame can penetrate more quickly through the charge.

Dusting and glazing.—R.F.G. and R.F.G.² powders are freed from dust after granulation by being passed through a dusting-reel. This is a cylindrical frame about 8 feet long and 1½ feet in diameter, covered with 20-mesh copper-wire gauze, and set at a very small angle with the horizontal. The reel is enclosed in a case to catch the dust, but is open at both ends; it is fed continuously at the upper end with powder from a hopper, while the reel makes about 40 revolutions per minute. The powder falls from the lower end of the reel into barrels.

The polish given to the powder grains by glazing is of advantage in diminishing the tendency of the powder to absorb moisture, by breaking off any sharp angles and points, and stopping up the outer pores of the grain, and in enabling it to bear transport without going to dust. Glazing also increases the density of the powder: a powder with a density of, for example, 0.810 before glazing, having its density progressively increased to 0.893 after 42 hours' glazing. The small-arm powders, R.F.G. and R.F.G.², are glazed in large drums—cylinders 2 feet wide and 6 feet in diameter (a pair of drums on one axle) making about 12 revolutions per minute. The drums each take about 900 lbs. of powder; they are run 5½ hours for R.F.G., and 10 hours for R.F.G.². No graphite is used for these powders; the friction and heat caused by the motion suffice to produce a brilliant glaze. The glazed powder receives another dusting in a reel covered with 20-mesh wire-gauze, and is then sifted through an 11-mesh sieve into barrels. R.L.G.² powder is run for 1½ hours in drums as above, with about one ounce of graphite per 100 lbs. powder. R.L.G.⁴ is glazed for 3 hours in the old pattern glazing barrels, the same proportion of graphite as for R.L.G.² being added after the barrels have run for 2 hours. Each barrel takes about 400 lbs. of powder; they are 5 feet long by 2½ feet diameter of ends, and make 34 revolutions per minute. The graphite increases the gloss of the powder, and the powder is also rendered less hygroscopic through the increased density of the surface layer.

Stoving or drying, finishing, blending.—The

next operation is drying, which is carried out in a drying-room heated by steam pipes. The gunpowder is placed in wooden frames about 3 feet × 1½ feet × 2½ inches with canvas bottoms, each holding about 12 lbs. of powder, and placed on open framework shelves with which the room is fitted, seven or eight tiers of shelves rising one above another, the steam pipes running under them. The moist air of the room is constantly changed by means of ventilators. At Waltham Abbey, about 50 cwts. of gunpowder are dried at one time. The time and temperature of drying vary with the kind of powder and the amount of moisture in it, the length of time and the temperature increasing with the size of the grain. Thus, R.F.G. requires 1 hour, and R.F.G.² 2 hours at 38°, R.L.G.² 2 hours at 43°, and R.L.G.⁴ 6 hours at 46°. Another system of drying is to drive a current of cold air over steam-heated coils into the drying-room or stove by means of fans. In some factories, a current of cold air is used, after being freed from its moisture by means of calcium chloride, caustic lime, or strong sulphuric acid; and drying at ordinary temperatures *in vacuo* has also been tried. The drying should be done evenly and not too rapidly, so that the pores of the powder are not opened too quickly.

Rapid drying, too, has a tendency to cause the larger-grained powders to crack, and sometimes causes an efflorescence of nitre on the surface of the grains.

The dried powder is *finished* by being rotated in a horizontal reel—a long cylindrical wooden frame covered with canvas, making 45 revolutions per minute—the fine-grain being reeled longer than the large-grain powders. Finishing frees the powder grains from the small amount of dust produced in the process of drying, and gives them (and especially to small-arm powders) a final glaze.

Before drying, and again after finishing, a uniform blend or mixture is made of a large number of barrels of gunpowder. Advantage is taken of every opportunity, in the processes of the manufacture of gunpowder, to mix or 'blend' the grain together so as to obtain more uniform results at proof. This is done by means of a wooden hopper divided into four equal compartments, each able to hold a barrel of gunpowder; the compartments can be emptied simultaneously into a central shoot by means of openings with sliding shutters in the bottom of each. This method of blending, especially with the smaller sizes of grain, is found to give batches of powder with very uniform firing results.

Pebble and prismatic powder. These cut and moulded powders are no longer manufactured, as smokeless powder is now used even for guns of the largest calibre, but a short account of them is given, owing to their great historical interest. The use of pebble powder in this country dated from about the year 1865. Rodman had previously shown that in the gun the pressure diminished as the size of the grains of gunpowder increased, and that the velocity of the projectile could at the same time be maintained by an increased weight of charge.

Pebble powders (P, cubes of ⅝-inch; and P², 1½-inch cubes) were used for larger guns than

were the rifle large-grain powders. Up to the formation of the press-cake, the processes of manufacture were, with some variations, the same as for the finer-grained powders.

The *P* powder was cut from the press-cake, which was pressed into slabs of about 15 inches by 30 inches, and of the required thickness. The cutting machine consisted of two pairs of phosphor-bronze rollers, having longitudinal knife-edges with spaces between them corresponding to the required size of the powder. The first pair of rollers cut the press-cake into strips, which were fed on endless bands to the second pair of rollers, set at right angles to the first, which cut the strips into cubes. These cubes were allowed to fall into a dusting reel, with copper-wire meshes but little smaller than the cubes.

P² powder was cut by hand from the press-cake by means of lever-knives of gun-metal—knives hinged at one end, with a handle at the other. The press-cake was first cut into strips and then across into cubes.

Both *P* and *P²* powders were run in the glazing barrels, by which treatment the edges and corners of the cubes were rubbed down, and a harder surface produced. The powders were then dried at 54°, which required a very much longer time than for the smaller-grained powders; a finishing process followed, the powders being run in wooden barrels with ribs wide enough apart to combine sifting with the finishing glazing. A small quantity of graphite was introduced into the barrels towards the end of the finishing process.

Prismatic powder. This may be regarded as a modification of the perforated cake powder devised by Rodman in 1860. The latter powder consisted of cakes of powder compressed by the hydraulic press, of the diameter of the bore of the gun, and pierced longitudinally with holes of about $\frac{1}{4}$ inch diameter, the cakes being packed in the cartridge so that the holes should correspond. Rodman was led to introduce this form of powder by the consideration that, with solid grains of gunpowder, the surface undergoing combustion in the gun diminishes as the combustion proceeds, and that consequently the strain on the gun is greatest in the earlier stages of the combustion. In the case of the perforated cake gunpowder, as the combustion progressed in the longitudinal holes, the surface undergoing combustion increased. Rodman's theoretical views were confirmed by experiment, but the liability of the perforated cake powder to break up by carriage or when handled, led to its replacement by much smaller hexagonal prisms with one central cylindrical hole; the prisms used in this country were about 1 inch high, the distance between opposite sides of the hexagon about 1·37 inches, the central hole about 0·4 inch in diameter. They were used for heavy breech-loading guns, and were packed so as to form rigid cartridges.

The prisms were pressed from a moderately large-grained powder granulated from press-cake freed from dust in the ordinary way, but not glazed, and finally dried and blended. The increased density of the powder due to the compression delayed the burning and reduced the initial pressure in the gun.

Brown or cocoa gunpowder. The intro-

duction of this powder was a great innovation in powder making, as it greatly improved the shooting of big guns and allowed the use of guns of still larger calibre than even the black prismatic powder. It was composed of 79 p.c. nitre, 3 p.c. sulphur, and 18 p.c. charcoal per 100 of dry powder, and contained ordinarily about 2 p.c. moisture. The 'charcoal' also was a very lightly baked material, the percentage of carbon contained in it being but little higher than that in the (dry) wood or straw from which it was made.

This powder was used for heavy breech-loading guns in the form of hexagonal prisms, having the same dimensions as the black prismatic powder. The rate of ignition and of combustion of the brown prismatic powder was slower than that of the black, and for equal muzzle velocities of the projectile it produced less pressure in the powder-chamber of the gun than black powder, and gave a thinner smoke than the latter. This was due to the fact that the brown charcoals flowed under the high manufacturing pressure and bound the ingredients into a non-porous mass; black prismatic powder was comparatively porous.

Brown or cocoa powder gives on explosion a greater quantity of heat and a smaller volume of permanent gases than does an equal weight of black gunpowder; but the larger amount of water vapour in the products of explosion of brown powder have an important influence in lowering temperature. The products of explosion of brown powder undergo considerable dissociation at first, thus lowering the initial pressure in the gun, and subsequent recombination, and so giving sustained pressures as the projectile moves along the bore. The more gradual development of the pressure and the reduction of the maximum pressure increased the life of the gun and rendered the use of lighter guns possible.

Sporting powder. Considerable quantities of black gunpowder are still used for sporting purposes. The proportions of the ingredients vary slightly from those used for military powders, in order to produce the desirable qualities of quick ignition and combustion. The ease of ignition of a black powder does not vary much with the composition, but an excess of charcoal quickens, whilst an excess of nitre slackens, the rate of combustion. To increase the rapidity of combustion, a slack-burnt or red charcoal is usually used instead of black. The composition of the sporting powder of several countries is given in the following table:—

Composition of Black Powder used for Sporting Purposes.

	Potassium nitrate	Sulphur	Charcoal
England . .	75·0	10·0	15·0
France . .	78·0	10·0	12·0
Germany . .	78·0	10·0	12·0
Austria-Hungary	76·0	9·5	14·5
Switzerland .	78·0	9·0	13·0

The powders are of high grade and carefully made by processes practically identical with

those used in the manufacture of military powders. Occasionally there are modifications, such, for instance, as the use of drums instead of mills for powdering and mixing the ingredients, because the charge can be less moist and the mixing more rapid, so that better incorporation results in a given time, with resultant greater regularity in shooting.

Mining and blasting powder. The chief requirements of blasting powder are that it should be cheap, slow burning, and develop as large as possible a quantity of gas at a high temperature. The usual composition of blasting powders in various countries is:—

Composition of Black Powder used for Mining and Blasting Purposes.

	Potassium nitrate	Sulphur	Charcoal
England . . .	75.0	10.0	15.0
France . . .	72.0	13.0	15.0
Germany . . .	70.0	14.0	16.0
Austria-Hungary . . .	60.0	18.5	21.5
Italy . . .	70.0	18.0	12.0
Russia . . .	66.6	16.7	16.7

These proportions are by no means rigidly adhered to. Thus, in England, blasting powders varying from the above proportions to—potassium nitrate 65, sulphur 20, charcoal 15,—are made, the proportion of nitre being diminished to make the mixture slower burning, an effect otherwise obtained by increasing the size of the grains or compressing to a higher density. Other compositions especially made for use in fiery mines will be mentioned later under 'Black powder safety explosives.'

Blasting powder is a large-grained powder, sometimes coated with graphite, compressed into cartridges by means of a hydraulic press. As will be mentioned further on, while the mining powder with low nitre and high sulphur gives on explosion a larger volume of permanent gases, it gives a much smaller quantity of heat than black gunpowder.

Fuse powder. A gunpowder of special quality and constant composition is now manufactured for use in 'safety' and other fuses. Formerly, siftings from mining powder were frequently used, but this caused unevenness in burning and was frequently the cause of accidents through 'hang-fires.' It is a mealed powder; that is, of very fine granulation, but free from dust.

Suitable mixtures, determined by trial, of slower and quicker burning powders are made to give the correct time of burning in the time-rings of shell fuzes.

Bickford's safety-fuse (Eng. Pat. 6159, 1831) is a time-fuse in the form of a flexible cord or cable which fits into the metal cases of the detonators for initiating the explosion of cartridges or other masses of high explosive. It consists of a continuous and uniform train of specially prepared fine-grained powder enclosed in a covering of jute fibre, this core being contained in a tube of waterproof composition and tape, or sometimes, for use under water, in a metal tube. The rate of burning per unit length varies and is stated with the supply, and it is also liable to alter slightly on storage.

Properties and products of explosion.—The

'density' (as determined by Bianchi's densimeter) of the different kinds of gunpowder mentioned ranges from about 1.67 in the case of R.L.G.² to about 1.87 in the case of brown prismatic powder. Increase of density of a gunpowder causes its slower combustion, and (under comparable circumstances) diminishes the muzzle velocity of the projectile and the pressure in the gun.

Increase of the amount of moisture in a gunpowder causes diminished temperature of the products of explosion, and lessens the muzzle velocity of the projectile and the pressure in the gun.

Black gunpowder can be ignited by a blow or by an increase of temperature: it explodes at about 300°. The exploding temperature was taken by heating small grains of the gunpowder buried in the sand of a small deep sand-bath, in which the bulb of a Geissler pressure mercurial thermometer was immersed. Black prismatic gunpowder inflamed at about 290°, brown prismatic at 304°. At a temperature slightly above 100° the sulphur can be completely volatilised out of the powder without inflammation taking place. Violette determined the ignition-point by projecting the powder on to molten tin kept at different temperatures. He found that all classes of gunpowder after powdering fired at from 265° to 270°, and that the firing-point depends but little on the composition, but that the size and shape of the grain and the perfection of the incorporation affected the results; thus, blasting powder in grains fired at 270° and extra fine sporting powder at 320°.

The ignition of gunpowder is more difficult and the rate of combustion diminishes with diminished atmospheric pressure. In an atmosphere maintained at a pressure of about 0.5 inch mercury, gunpowder is not exploded by contact with a platinum wire heated to redness by an electric current; the grains in contact with the wire fuse, and, if the passage of the current be maintained, burn slowly without causing the explosion of the remainder. Under the high pressures produced in a gun when fired, the velocity of combustion of gunpowder very rapidly increases.

The products of the combustion of gunpowder have been examined by several chemists, of whom Gay-Lussac (1823), Chevreul (1825), Bunsen and Schischkoff (1857), Karolyi (1863), Federow (1868), Noble and Abel (1875-80), may be more particularly mentioned.

The investigation of the subject by Noble and Abel is much more complete than the others, and some of their results will be briefly mentioned.

The quantity of heat evolved by the explosion of gunpowder was determined by firing 10 to 26 grams of gunpowder in strong steel explosion vessels of 32 and 119 c.c. capacity respectively, the explosion vessels being surrounded by water in a calorimeter of the usual kind.

The volume of permanent gases produced was determined by exploding in closed steel vessels, having an internal capacity of about one litre, quantities of gunpowder varying in weight from about 100 to 800 grams. The vessels retained the whole of the products of explosion, and were provided with an arrangement by which the gases could be allowed to

escape, and could be collected or measured. The pressure in the vessels was measured by means of the usual crusher-gauge (piston acting on, and compressing, a small copper cylinder) contained in a plug screwed into the vessel.

The pressures in the explosion vessels varied with the density of charge $\left(\frac{\text{volume of powder}}{\text{capacity of vessel}} \right)$

With a density of charge of 0.3, the pressure observed was about 5 tons per square inch; with 0.7 density, the pressure was about 20 tons; with density 1, the pressure was about 42 tons; and with density 1.2, the pressure was about 56 tons.

The powders experimented with had the following percentage composition; the first three were of Waltham Abbey make:—

Nature of powder	Potassium nitrate	Potassium sulphate	Potassium chloride	Sulphur	Carbon	Hydrogen	Oxygen	Ash	Water
Pebble powder	74.67	0.09	—	10.07	12.12	0.42	1.45	0.23	0.95
Rifled large-grain R.L.G.	74.43	0.13	—	10.09	12.40	0.40	1.27	0.22	1.06
Fine-grain	73.55	0.36	—	10.02	11.36	0.49	2.57	0.17	1.48
Sporting powder	74.40	0.29	trace	10.37	10.66	0.52	2.29	0.31	1.17
Mining powder	61.66	0.12	0.14	15.06	17.93	0.66	2.23	0.59	1.61
Spanish spherical powder	75.30	0.27	0.02	12.42	8.65	0.38	1.68	0.63	0.65
Cocoa powder	78.83	—	—	2.04	Charcoal 17.80				1.33

The composition of the solid and gaseous products of the explosion of these gunpowders is given in the following table; the numbers given for the first three powders are the means

of 9 experiments with density of charge from 0.1 to 0.9; the sporting and mining powders had density of charge 0.3, the Spanish spherical, 0.7:—

PERCENTAGE COMPOSITION BY VOLUME OF THE DRY PERMANENT GASES.

—	Pebble	R.L.G.	Fine-grain	Sporting	Mining	Spanish spherical	Cocoa
Carbon dioxide	48.95	49.29	50.62	50.22	32.15	53.34	51.30
„ monoxide	13.63	12.47	10.47	7.52	33.75	4.62	3.42
Nitrogen	32.16	32.91	33.20	34.46	19.03	37.80	41.71
Hydrogen sulphide	2.60	2.65	2.48	2.08	7.10	2.74	—
Methane	0.31	0.43	0.19	2.46	2.73	—	0.31
Hydrogen	2.35	2.19	2.96	3.26	5.24	1.29	3.26
Oxygen	—	0.06	0.08	—	—	0.21	—

PERCENTAGE COMPOSITION BY WEIGHT OF THE DRY SOLID RESIDUE.

—	Pebble	R.L.G.	Fine-grain	Sporting	Mining	Spanish spherical	Cocoa
Potassium carbonate	59.26	61.05	51.88	59.10	41.36	35.66	KHCO ₃ 13.55
„ sulphate	12.93	15.10	22.71	21.65	0.59	48.55	K ₂ CO ₃ 64.12
„ monosulphide	18.98	14.46	18.16	12.42	37.10	7.72	22.33
Sulphur ¹	8.08	8.74	6.90	6.45	14.11	7.04	none
Potassium thiocyanate	0.25	0.22	0.13	—	2.95	0.04	—
„ nitrate	0.24	0.27	0.17	0.29	0.09	0.95	trace

Charcoal	0.16	0.08	—	—	2.02	—	—

The cocoa powder gives a completely oxidised saline residue, and the proportion of incompletely oxidised gases is smaller with this powder than with the others.

The quantity of heat (in gram-degree units), and the volume (at 0° and 760 mm.) of the permanent gases, per 1 gram of dry powder, were found by Noble and Abel to be:—

¹ Present in the residue as higher sulphide of potassium.

—	Units of heat	Cubic centimetres Permanent gases
Cocoa	837.0	198.0
Spanish spherical	767.3	234.2
Sporting	764.4	241.0
Fine-grain	738.3	263.1
R.L.G.	725.7	274.2
Pebble	721.4	278.3
Mining	516.8	360.3

It will be seen that the order of decrease of units of heat is that of increase of volume of permanent gases; and Noble and Abel observed that the products of heat-units by gas volume do not differ greatly from a constant value, that this points to the conclusion that the pressures at any given density of charge, and the power of doing work of the various powders, are not very materially different,—a conclusion verified by experiment for the three Waltham Abbey powders, and in a less degree also for the other powders. The total potential energy of gunpowder they estimated at about 340,000 kilogram-metres per 1 kgm. of powder, or a little under 500 foot-tons per 1 lb. This calculation supposes the infinite expansion of the products of combustion, but they estimated the actual energy of gunpowder realised by modern guns as varying from about one-tenth to one-fifth of the total theoretical effect.

The temperature produced by the explosion of gunpowder they estimated at about 2,100° in the case of the pebble or R.L.G. powder, at about 2,200° in that of the Spanish pellet powder (Noble and Abel, *Trans. Roy. Soc.* 1875, 1880; Nobel, *Heat-Action of Explosives: a Lecture to Inst. Civil Eng.* 1884).

Debus, in 1882, first showed that potassium disulphide is a product of the combustion of black powder. He considered that the combustion takes place in two stages, at first on oxidation, with the formation of potassium sulphate and carbonate, carbonic acid gas, free nitrogen, and, perhaps, carbonic oxide; and, secondly, a reduction in which free carbon and sulphur reduced the potassium sulphate and carbonate.

Debus also showed that from the percentage composition of the powders fired and the products of combustion, the combustion of the powder, as an end result, could be represented in the form of an ordinary equation, from which the theoretical work obtainable from the powder can be calculated (Debus, *Annalen*, vols. 212, 213, 265, and 268).

Examination of gunpowder.—The powder, examined by the eye, should have a perfectly uniform colour, depending on its composition and a proper amount of glaze. Small white specks on the surface of the grains indicate that the nitre has effloresced during drying. The grains must be compact, not flat, in shape; and their size must be uniform, as tested by sifting; and free from dust, as shown by the powder leaving no mark on running it over a sheet of paper. The grains must be hard and crisp, as judged by crushing in the hand. The thoroughness of the incorporation is tested by 'flashing' a small measured quantity of the powder on a porcelain tile by means of a hot wire. The 'flash' should show but few sparks, and there should be no residual solid matter.

By the density, or real density, of a powder is understood the specific gravity of the grains or prisms, including the air contained in their pores. It is usually determined by the Bianchi densimeter. 100 grams of the sample, crushed, if necessary, but free from dust, are weighed out and transferred to the globe of the densimeter. This removable glass globe is fitted with stopcocks above and below, the upper is attached to an air pump, the lower connected by means of a tube with a vessel of mercury, the density of

which is known, at the temperature, usually 60°F. or 70°F., to which it is adjusted. The lower stopcock is closed, the globe exhausted, the stopcock opened, and the mercury then allowed to rise to the height which the atmosphere will support, the lower stopcock closed again, and the upper part of the apparatus opened to the air by means of the air-pump gauge stopcock. The operations are repeated, the mercury surrounding the powder grains being thus subjected to two atmospheres pressure. The globe is then closed, unscrewed, and weighed. Then if S = density of mercury at temperature of determination, W = weight of globe filled with mercury, and W_1 = weight of globe filled with powder and mercury; density of sample

$$\frac{S \times 10}{(W - W_1) + 100}$$

Hygrometric test.—All kinds of black powder are liable to absorb more or less moisture from the air, depending on the quality of their charcoal and saltpetre. The tendency any powder has to absorb moisture is determined by exposing it for a given time—24 hours for the smaller powders—in a specially insulated box at a recorded temperature, to air saturated with moisture, from a saturated solution of saltpetre. The increase in the weight of the powder, added to its previous moisture content, is taken as a measure of its 'hygrometric quality.' The results are, however, not very reliable.

Analysis.—*Moisture* is determined by loss, on the coarsely powdered sample, after 1 hour at 70°, or preferably by exposure over sulphuric acid until of constant weight.

The nitre is determined by extraction with warm water, filtering, and evaporating the solution in a platinum dish. The final washings should be kept separate, as the charcoal has a tendency to come through the filter, evaporated to dryness and again extracted, when the filtrate is clear and is added to the bulk. The nitre is dried at 280°, cooled and weighed.

The sulphur is estimated by heating 1 gram of powder in a beaker with strong nitric acid until the action moderates, cooling a little, adding a little potassium chlorate to complete the oxidation, and evaporating to dryness. The residue is treated with strong hydrochloric acid, and again evaporated to dryness. The residue is taken up with water (any insoluble matter, grit and graphite, being filtered off and weighed), and the solution precipitated with barium chloride, &c., as usual.

The charcoal.—The nitre is removed from the gunpowder by treatment with water, the charcoal and sulphur filtered off, dried, powdered, and treated with carbon disulphide to remove sulphur. The dried charcoal still retains a small quantity of sulphur, which is estimated by the method given above, after the charcoal has been dried in hydrogen in the same manner as for a combustion. The weight of sulphur is, of course, deducted from the weight of charcoal used for the combustion. About 0.5 gram of charcoal is taken for combustion; it is dried (in the boat in which it is to be burnt) by heating for 15 minutes to 170°, in the case of a black charcoal, in a current of hydrogen. The charcoal is allowed to cool in the current of hydrogen, and is transferred to an air-pump

receiver, which is then exhausted. The boat with the charcoal is weighed in a closed tube. The combustion is made in oxygen, a length of granulated copper oxide, maintained at a red heat, being in front of the boat; and in front of the oxide of copper is a shorter length of lead chromate, heated to very low redness to absorb SO_2 or SO_3 ; in other respects, the combustion is made as usual.

Other Potassium Nitrate Mixtures.

Sulphurless gunpowder of various compositions has frequently been tried for special purposes, but without much success. Sulphur renders a powder easy of ignition and increases its rate of burning, and its inclusion is practically essential. Sulphurless powder, moreover, has a tendency to crumble to dust on storage or handling.

Antimony sulphide has been proposed as a substitute for sulphur in black powder, but it is only in certain detonating compositions that it is actually used.

Many combustible substances, amongst others coal, coke, peat, sawdust, bark, bran, tan, sugar, starch, dextrin, gum, hydrocarbons such as paraffin and naphthalene, ferro- and ferricyanides of potassium, tartaric acid, Rochelle salt, sodium acetate, &c., have been proposed and patented as substitutes for all or part of the charcoal in nitrate mixtures. Many of these substances are substituted in order to reduce the amount of smoke. They almost invariably reduce the inflammability of the powder, slacken its combustion, and leave a large amount of residue, but frequently give off larger quantities of gas. These mixtures were suggested principally as blasting explosives, and many were authorised for manufacture in this country, but at the present time their use is practically confined to the Continent.

A few of these explosives will suffice:

Fortis was a mixture of nitre, tan, and sulphur, with small quantities of iron sulphate and glycerol, and it was claimed that nitroglycerin was produced during explosion in a blast hole, with consequent increase of power.

Carbonite, as introduced by Hellhoff of Berlin, was a mixture of nitrobenzene, potassium nitrate, sulphur, and kieselguhr; said to be plastic enough to fill a bore hole, to be non-explosive by blows, when inflamed to burn away quietly without explosion, and when detonated to have the same explosive force as kieselguhr dynamite. It has been used in coal-mines in Germany, but modern carbonites contain nitroglycerin, and are mentioned under 'Dynamites.'

Carboazotine was a mixture of nitre, lamp-black, sawdust, and sulphur, with a little iron sulphate. This explosive required compression into cartridges before it would explode.

Petrolite, as manufactured in Hungary, is a mixture of nitre, wood pulp, coke-dust, and sulphur.

Jahnite, as made in Austria, is a mixture of nitre, lignite coal, and sulphur, with very small quantities of picric acid, potassium chlorate, and calcined soda.

Amidogène, a similar mixture to the last, contained nitre, charcoal, bran, or starch, and sulphur, with a little magnesium sulphate. This

powder had a very slow rate of combustion, but developed large quantities of gas. It was used on a large scale for blasting operations at the Iron Gates on the Danube, and in coal-mines.

Black Powder Safety Explosives.

Ordinary black gunpowder is unsuitable as a blasting agent for use in fiery mines, and its use is everywhere prohibited for this purpose. Many modifications of gunpowder have been tried, and several mixtures have been manufactured which were able to pass the official tests. A few of these mixtures are:—

Argus powder, which contained 81 p.c. potassium nitrate, 18.5 p.c. charcoal, containing 30 p.c. of volatile matter, and 0.5 p.c. sulphur.

Earthquake powder, which contained 79 p.c. nitre, and 21 p.c. charcoal, containing 56 p.c. volatile matter.

Elephant-brand powders, which had the composition of ordinary gunpowder, but No. 1 was fired with 6 inches of ammonium oxalate, and No. 2 with 6 inches of sodium bicarbonate, in front of the cartridge.

Oxalate blasting powder, which was composed of 71 p.c. nitre, 14 p.c. charcoal, and 15 p.c. ammonium oxalate.

All these explosives were subsequently removed from the 'permitted' list.

Bobbinite, manufactured by Curtis and Harvey, is still on the 'permitted' list, and was the most extensively used of all safety explosives in this country in 1913. It is really a high-grade gunpowder, containing but little sulphur, with added ingredients to increase the safety. As originally made, it consisted of 64 p.c. nitre, 2 p.c. sulphur, and 19 p.c. charcoal, with 15 p.c. of a mixture of ammonium sulphate and copper sulphate. In a later composition the mixture of ammonium and copper sulphates was replaced by 8 p.c. of starch and 3 p.c. of paraffin wax, the other ingredients being correspondingly increased. The mixture is compressed into pellets, which are coated with paraffin wax.

Bobbinite is safe to handle, and is fired without detonators; it is slow burning, and does not break up the coal so much as most safety explosives. A Home Office Committee was appointed in 1906 to investigate the alleged danger of 'bobbinite' in fiery mines, but it concluded that these fears were groundless, and the manufacture and use of the explosive was still permitted. The committee also concluded that the damage with 'bobbinite,' as with other explosives, was greater when the shots were not efficiently stemmed. It was the only powder of this class to pass the Woolwich test for 'Permitted Explosives,' but it afterwards failed in the more severe Rotherham test, and in 1914 its use was restricted to mines that were not fiery.

Sodium Nitrate Mixtures.

Sodium nitrate has a higher percentage of available oxygen than potassium nitrate, and is also cheaper, but its hygroscopicity is a great drawback to its use in powders intended for keeping a long time. In dry climates the sodium nitrate powders, made as required for consumption, have been used, as they effect a saving, and are more powerful than the corresponding nitre mixtures. A sodium nitrate mining powder was

used, for instance, on a large scale and with considerable economy in the Suez Canal works; but such mixtures are not in very general use.

The replacement of the potassium nitrate of black gunpowder by an equivalent quantity of sodium nitrate would give, according to Berthelot's calculation, if the chemical reactions were exactly the same in the two cases, a slightly greater quantity of heat and a larger volume of gases.

Mixtures containing sodium nitrate do not ignite so readily, and burn more slowly than those containing the potassium salt.

The hygroscopic properties of sodium nitrate are chiefly due to traces of nitrates and chlorides of calcium and magnesium, which it is impossible to eliminate on a commercial scale; chemically pure sodium nitrate being only slightly deliquescent. In recent years, it has been proposed to add a small quantity of oil, or liquid, or molten solid hydrocarbon, to sodium nitrate explosives, in order to coat the particles of nitrate, and so prevent the absorption of moisture.

Sodium nitrate has been used, or proposed, in mining powders, either alone or in partial substitution of the potassium nitrate, with practically all the numerous combustible substances given under 'other potassium nitrate mixtures.' For example, one of the early forms of 'carbonite,' made by Schmidt and Bichel of Schleichbusch, consisted of 9-10 parts of sodium nitrate, 1 part of sulphuretted tar oil, and 0.5 part of nitro-cumene.

Considerable quantities of sodium nitrate black blasting powder are used in the United States, an average composition being: 73 to 74 p.c. sodium nitrate, 16 p.c. charcoal, and 10 to 11 p.c. sulphur, and a mild explosive known as *sprengsalpeter*, which has the composition 75 p.c. sodium nitrate, 15 p.c. brown coal, and 10 p.c. sulphur, is largely used in the Stassfurth mines. Another German explosive of this class is called *Petroklastit* or *Holoklastit*. It is a compressed mixture of 69 p.c. sodium nitrate, 5 p.c. potassium nitrate, 15 p.c. coal-tar pitch, 10 p.c. sulphur, and 1 p.c. potassium bichromate. It is more powerful, but less sensitive to blow, than ordinary gunpowder.

Barium Nitrate Mixtures.

Barium nitrate contains a smaller percentage of available oxygen than potassium nitrate, but, owing to its higher specific gravity, it contains more oxygen, bulk for bulk, than the latter salt, and from this point of view should be more valuable in disruptive explosives. It also has the advantage that it is the least hygroscopic of all the nitrates used in explosives, but its higher price is against its use. Explosives containing it have a higher ignition-point and are slower burning than those containing potassium nitrate.

Barium nitrate, mixed with gunpowder, was used at one time in Prussia for heavy guns, and a black powder containing barium nitrate, sulphur, and charcoal was also used. Wynants, in Belgium, introduced a gunpowder for military purposes, in which nitre was practically or wholly replaced by barium nitrate, the grains being dusted over with gunpowder to increase the inflammability. It was found to be unsuitable for small arms on account of its slow combus-

tion, and for cannon because of its 'fouling,' and was only used as a blasting powder.

Barium nitrate is chiefly used as a constituent in some modern military and sporting smokeless powders, but is occasionally suggested as the oxidising agent in blasting powders, for example, Easton (Eng. Pat. 18551, 1909) proposed a mixture of barium nitrate, trinitrotoluene, and aluminium powder for this purpose; and Burrows (U.S. Pat. 968919, 1910) specifies a mixture of 32 parts barium nitrate, 10 parts of toluene, and 8 parts of aluminium, with or without the addition of charcoal and paraffin wax. An English 'authorised' explosive named *Brookite* is a mixture of barium nitrate and aluminium powder.

Barium nitrate, however, is more usually found as a secondary oxidising constituent in explosive mixtures containing larger proportions of other oxygen salts. These are classified under the principal, or most characteristic, oxygen salt.

Ammonium Nitrate Mixtures.

In 1867 in Sweden, Ohlsson and Norrbm patented the use of ammonium nitrate alone as an explosive, and also of its mixtures with combustibles, such as charcoal, sawdust, naphthalene, nitrobenzene and picric acid, in proportions to give complete combustion. These mixtures were used to a limited extent for some time, but, owing to the hygroscopicity of the mixtures and the difficulty in ensuring their explosion, their use was dropped on the invention of blasting gelatine by Nobel.

Sprengel, in 1873, showed that a mixture of ammonium nitrate and lampblack or charcoal, mixed with ordinary sporting powder, when fired in a rifle, caused a considerable increase in the initial velocity of the bullet, as compared with the velocity imparted by the same weight of sporting powder (Chem. Soc. Proc. 1873, 805). Ammonium nitrate, although containing 60 p.c. oxygen, having a combustible base, has only 20 p.c. oxygen available for the oxidation of other substances: $\text{NH}_4\text{NO}_3 = \text{N}_2 + 2\text{H}_2\text{O} + \text{O}$; whilst potassium nitrate has 39.6 p.c. available oxygen, supposing K_2O to be formed. Ammonium nitrate melts at about 100° , and begins to decompose at 200° , undergoing what is practically an internal combustion. If heated suddenly to a high temperature, as by projecting it on a red-hot surface, it deflagrates violently, and De Bruyn, in 1891, showed that it can be detonated by the use of a sufficiently powerful detonator. The great drawback to the use of ammonium nitrate in explosive mixtures is that it is extremely hygroscopic.

An explosive powder for use in guns and for blasting purposes, patented by Gaens in 1885, and termed *amide powder*, is a mixture of ammonium and potassium nitrates with charcoal. The constituents were used in such proportions as to give, on ignition, potassium KH_2N , in accordance with the equation:

$$\text{KN}_3 + \text{NH}_4\text{NO}_3 + 3\text{C} = \text{KH}_2\text{N} + \text{H}_2\text{O} + \text{CO} + 2\text{CO}_2 + 2\text{N}_2$$

according to which the powder should be composed of 101 parts by weight potassium nitrate, 80 parts ammonium nitrate, and 40 parts charcoal. The potassium amide is stated to be volatile at high temperatures, increasing the useful effect

of the explosive, and burning without residue. It is claimed further for the *amide powder* that when burned it leaves very little residue, and gives much less smoke than ordinary gunpowder.

A so-called smokeless powder, known as '*Hebber powder*,' was at one time manufactured in Switzerland, and consisted of a mixture of nitre, ammonium nitrate, sulphur, and charcoal. It was practically non-hygroscopic.

Not only does ammonium nitrate leave no solid residue on combustion, but its use in explosives has been found to greatly reduce the temperature of explosion, and this has caused it to be very largely employed in modern so-called 'safety explosives' for use in fiery mines. There are also a considerable number of ammonium nitrate explosives now in use for general blasting work, and the very large demand for shell high explosives during the last few years has led to the general use of ammonium nitrate mixtures with nitrohydrocarbons, especially with trinitrotoluene, for this purpose (*see* under Trinitrotoluene). The increasing manufacture of nitric acid and ammonia by synthetic methods will probably lead to the use of this class of explosives being still further considerably extended. As above stated ammonium nitrate alone under sufficient impulse is an explosive, but it has been found that the addition of some combustible substance, not necessarily explosive in itself, is necessary to form an efficient blasting agent or military high explosive.

These explosives are used with thoroughly water-proofed wrappers, treated with paraffin, ceresin, and resin, crude vaseline, petroleum products, &c., or with wrappers of thin metal foil, and the particles of nitrate are frequently coated with similar substances, or with the other constituents of the mixture, from solution or by fusion, so as to render them non-hygroscopic. The addition to ammonium nitrate mixtures of several substances, such as semi-solids made of glue, dextrin, &c., aniline metallic compounds, such as aniline copper sulphate, kieselguhr, &c., has been patented to counteract the action of atmospheric moisture, by absorbing any moisture originally present, or subsequently taken up on storage, and so leaving the explosive constituents in a dry state.

In manufacture, the ammonium nitrate is roughly crushed if necessary, then thoroughly dried and powdered in a steam-jacketed edge-runner mill and sieved. The sieved nitrate is then intimately mixed in the same mill, or in a steam-jacketed pan with gunmetal stirrers, with the other ground and sieved ingredients. If a nitro-body of low melting point is a constituent of the mixture, it is usually added in the molten form, so as to coat and waterproof the grains of nitrate as far as possible. Finally the mixture is allowed to cool down to a certain extent, and then made up into cartridges and waterproofed, or packed for transport in metal-lined hermetically sealed packages. Ammonium nitrate undergoes a change of crystalline form at 32° with increase in volume, and its mixtures should not be made up into cartridges or packed at a higher temperature than this, or the cartridges exposed to the direct rays of the sun, as, especially in the presence of a little moisture, they may set very hard and become extremely insensitive to detonation. In an atmosphere of

less than a certain humidity ammonium nitrate is not hygroscopic, and wet ammonium nitrate will lose moisture and become quite dry again under these conditions, though deterioration of the explosive may have taken place whilst it was wet.

The ammonium nitrate mixtures are non-sensitive to shock, and require a strong detonator to ensure there is not a 'miss-fire,' and to detonate them completely and so develop their full force. Although the power of these mixtures is increased by compression, the difficulty of detonation also increases. Where increase in power is necessary, but the use of a more powerful detonator is undesirable, the difficulty of detonation may be overcome by using a small quantity of an intermediary 'priming' explosive, which frequently may be the original explosive itself in a loose form. The Soc. Universelle d'Explosifs (Fr. Pat. 451754, 1912) claims that the ease of detonation of ammonium nitrate explosives is improved by adding an aqueous solution of gum with gunpowder in suspension to the granulated explosive. Many of these mixtures are extremely difficult to ignite, and almost impossible to keep burning. Le Chatelier has proposed to crystallise a little potassium chlorate with the ammonium nitrate to render the mixtures more sensitive. Mere addition of the chlorate is inadmissible, because of the great danger in mixing, and the action of the mixtures is also somewhat irregular; the salts being isomorphous, they may be crystallised together in any proportions, and these difficulties overcome.

The following are some of the more important ammonium nitrate explosives, containing simple combustible substances:—

Cologne Rottweil contains 93 p.c. ammonium nitrate, 4.9 p.c. vegetable oil, 1.2 p.c. sulphur, and 0.9 p.c. barium nitrate. This explosive is manufactured in this country under the name of *Pembrite*.

Dahmenite at one time consisted of a mixture of the nitrates of potassium and ammonium with naphthalene. *Dahmenite A*, the modern variation, is composed of 91.3 p.c. ammonium nitrate, 6.5 p.c. naphthalene, and 2.2 p.c. potassium dichromate. The naphthalene is melted with the nitrate, so as to coat and waterproof it.

Two Austrian safety explosives are *Dynamon*, containing 87–88 p.c. ammonium nitrate and 12–13 p.c. charcoal, and *wetter-dynamon*, which contains 94 p.c. ammonium nitrate, 2 p.c. potassium nitrate, and 4 p.c. charcoal.

Electronite, a 'permitted' safety explosive made by Curtis and Harvey at Tonbridge, is a mixture of 75 p.c. ammonium nitrate, and 5 p.c. barium nitrate with wood meal and starch. The products of detonation are chiefly water, nitrogen, and a little carbon dioxide, and the flame is of too low a temperature to fire explosive gas mixtures.

Electronite No. 2 consists of 95 p.c. of ammonium nitrate and 5 p.c. of wood meal and starch.

Fractorite contains 90 p.c. ammonium nitrate, 4 p.c. resin, 4 p.c. dextrin, and 2 p.c. potassium dichromate.

Progressite contains 89.1 p.c. ammonium nitrate, 4.7 p.c. aniline hydrochloride, 6 p.c.

ammonium sulphate, and 0.2 p.c. colouring matter.

Romite, a Swedish explosive invented by Sjöberg (Stockholm, Eng. Pat. 11658, 1887), was a mixture of ammonium nitrate mixed with a solid melted hydrocarbon (naphthalene, paraffin, and the like) gelatinised with a liquid hydrocarbon (such as paraffin oil), and contains pure or similarly gelatinised potassium chlorate. It was found to be unsafe, owing to the interaction between the nitrate and chlorate.

Westfalite is made by the Westphälisch-Anhaltische Sprengstoff-Actien-Gesellschaft. No. 1 contains 95 p.c. ammonium nitrate and 5 p.c. of resin or gum-lac. In No. 2, 4 p.c. of the ammonium nitrate is replaced by nitre; and in *Westfalite improved*, 3 p.c. of ammonium nitrate is replaced by potassium dichromate. The ingredients are ground together with alcohol or other solvent of the resin, and then heated to drive out the solvent, ground further, and compressed into cartridges by a special shaking machine.

The nitro derivatives of the aromatic hydrocarbons, which, as a rule, are not in themselves explosive, form powerful explosives when mixed with ammonium nitrate.

Abelite is an English 'permitted' explosive of this class. Several varieties have been made. No. 1 contains ammonium nitrate, dinitrobenzene, and trinitrotoluene with sodium chloride as a moderant. No. 4 contains ammonium nitrate, trinitrotoluene, and starch, with sodium chloride.

The *Ammonites* are a class of explosives containing the nitronaphthalenes, manufactured by the Miners' Safety Explosives Co. As originally permitted it contained 88 p.c. ammonium nitrate and 12 p.c. dinitronaphthalene, but this was rendered safer by the addition of sodium chloride, the modified composition being 75 p.c. ammonium nitrate, 5 p.c. dinitronaphthalene, 20 p.c. sodium chloride, and up to 1 p.c. moisture. The charge is contained in a lead-tin alloy case, waterproofed with paraffin wax; limit charge 18 oz., pendulum swing 2.44 ins. No. 5 contained tri- instead of di-nitronaphthalene, and No. 4 had part of the ammonium nitrate replaced by sodium nitrate. The limit charge of No. 5 is 26 oz., and the pendulum swing 2.41 ins.

Amvis is a mixture of 90 p.c. ammonium nitrate, 5 p.c. wood meal, and 5 p.c. of chlorodinitrobenzene, or of a mixture of dinitrobenzene and chlorinated naphthalene.

Bellite, invented by Lamb, of Stockholm, is a mixture of ammonium nitrate with metadinitrobenzene. No. 1 contains 16.5 p.c., and No. 3, 7.5 p.c. of the nitrohydrocarbon.

The mixture is heated to a temperature of between 50° and 100°, in order to coat the particles of the nitrate with the fused nitro compound, and compressed into cartridges before the mixture is cold. In earlier mixtures, other nitrates were used, and the specification mentions other nitrohydrocarbons. *Bellite* is difficult to ignite, and ceases to burn if the source of heat is removed. It is claimed to be a very powerful and safe explosive for use in fiery mines, and can only be fired by a fulminate detonator.

As manufactured by the Lancashire Explosives Co., *Bellite* No. 1 contains 62-65 p.c. ammonium nitrate, 14-16 p.c. trinitrotoluene, 15.5-17.5 p.c. sodium chloride, 3.5-5.5 p.c.

starch, and up to 2 p.c. moisture; limit charge 20 oz., pendulum swing 2.74 ins. Later varieties containing dinitrobenzene, which have passed the Rotherham test, are No. 2, containing 61 p.c. ammonium nitrate, 12 p.c. dinitrobenzene, and 27 p.c. sodium chloride; limit charge 32 oz., pendulum swing 2.42 ins.; and No. 4, containing 66 p.c. ammonium nitrate, 14 p.c. dinitrobenzene, and 20 p.c. sodium chloride; limit charge 18 oz., pendulum swing 2.92 ins.

Black Bellite contains 61 p.c. ammonium nitrate, 12 p.c. trinitrotoluene, 24 p.c. sodium chloride, and 3 p.c. plumbago; limit charge 30 oz., pendulum swing 2.48 ins.

The *Densites* are mining explosives of this class which have passed the Belgian tests for safety explosives. No. 3 contains 74 p.c. ammonium nitrate, 22 p.c. sodium nitrate, and 4 p.c. trinitrotoluene; limit charge 700 gms.; and No. 4 18 p.c. ammonium nitrate, 45.5 p.c. potassium nitrate, 19 p.c. trinitrotoluene, and 17.5 p.c. ammonium chloride; limit charge 850 gms.

Dorfit is a German explosive containing ammonium nitrate with 5 p.c. of potassium nitrate, the combustibles being trinitrotoluene and 4 p.c. flour, and some 15 to 20 p.c.; sodium chloride being added as restrainer.

Dreadnought powder on the English authorised list contains 73-77 p.c. ammonium nitrate, 14-17 p.c. sodium nitrate, 4-6 p.c. ammonium chloride, 3-5 p.c. trinitrotoluene, with up to 1 p.c. of moisture, and coloured with a trace of 'red oil'; limit charge 32 oz., pendulum swing 2.05 ins.; requires a No. 7 or more powerful detonator.

Faversham powder is a 'permitted' explosive, manufactured by the Cotton Powder Co. It consisted at one time of 85 p.c. ammonium nitrate, 11 p.c. dinitrobenzene, 1.5 p.c. ammonium chloride, and 2.5 p.c. sodium chloride; but more recent compositions are: No. 1, 84-86 p.c. ammonium nitrate, 10-12 p.c. trinitrotoluene, 1-2 p.c. ammonium chloride, 1-3 p.c. sodium chloride, and 0-2½ p.c. moisture; and No. 2, 87-93 p.c. ammonium nitrate, 9-11 p.c. dinitrobenzene, and 0-1 p.c. moisture. The explosive is contained in a metal case and fired by a No. 6 detonator. A later variety, compounded to meet the Rotherham test, contains 47.5 p.c. ammonium nitrate, 24 p.c. potassium nitrate, 10 p.c. trinitrotoluene, and 18.5 p.c. ammonium chloride; limit charge 24 oz., pendulum swing 2.61 ins.

Favier's explosive, the pioneer explosive of this class, first patented in 1883 by Favier of Paris, was a mixture of ammonium nitrate, mono-, di-, or trinitronaphthalene, and a little ammonium chloride, mixed and compressed whilst warm into metal cartridges, and coated with a solution of lac or resin. It was manufactured in England under the name of *Ammonite*, and by the French Government under the name of '*Explosifs N*' or '*Grisounites*.' Two explosives which have passed the Belgian tests are *Favier 2 bis*, containing 77.6 p.c. ammonium nitrate, 2.4 p.c. dinitronaphthalene, and 20 p.c. ammonium chloride; limit charge 500 gms.; and *Favier 3 bis*, containing 60 p.c. ammonium nitrate, 11 p.c. potassium nitrate, 8.5 p.c. trinitrotoluene, 6 p.c. flour, 5 p.c. alum, 5 p.c. barium carbonate, 4 p.c. ammonium

chloride, and 0.5 p.c. potassium permanganate; limit charge 750 gms.

Fractorite B is an explosive on the Belgian permitted list. It contains 75 p.c. ammonium nitrate, 2.8 p.c. dinitronaphthalene, 2.2 p.c. ammonium oxalate, and 20 p.c. ammonium chloride; limit charge 450 gms.

Glückauf is a German ammonium nitrate safety explosive with wood meal as the principal combustible, but also contains 1 p.c. dinitrobenzene and 5 p.c. copper oxalate.

The *Grisounites* are French explosives founded on Favier's patent. *Grisou-naphtalite-couche N1a* contains 95 p.c. ammonium nitrate and 5 p.c. trinitronaphthalene, and *N4* is of similar composition, except that 5 p.c. of the ammonium nitrate is replaced by potassium nitrate. These two explosives, which have a theoretical temperature of explosion of not greater than 1500° are used for coal getting; they are dyed green. *Grisou-naphtalite-roche N1b*, used for rock blasting, contains 91.5 p.c. ammonium nitrate and 8.5 p.c. dinitronaphthalene; it has a theoretical temperature of explosion of not greater than 1900°, and is dyed red. A variety, *N1c*, used in non-dangerous coal mines, contains 87.4 p.c. ammonium nitrate and 12.6 p.c. dinitronaphthalene, and is dyed yellow. *Grisou-tetrylite-couche* contains 88 p.c. ammonium nitrate, 5 p.c. potassium nitrate, and 7 p.c. 'tetryl.'

Kentite is an English permitted explosive containing 32-35 p.c. ammonium nitrate, 32-35 p.c. potassium nitrate, 16-18 p.c. ammonium chloride, 14-16 p.c. trinitrotoluene; and up to 2 p.c. moisture; limit charge 18 oz., pendulum swing 2.64 ins.

Minolite Antigrisouteuse is on the Belgian 'permitted' list. It contains 72 p.c. ammonium nitrate, 23 p.c. sodium nitrate, 3 p.c. trinitrotoluene, and 2 p.c. trinitronaphthalene; limit charge 400 gms.

Negro powder, as authorised for manufacture in this country, is a mixture of 86-90 p.c. ammonium nitrate, 9-11 p.c. trinitrotoluene, 1-3 p.c. graphite, 0-1 p.c. moisture, and a little colouring matter. The cartridges are wrapped in paraffined paper, and are fired by a No. 6 detonator.

Negro powder No. 2, which has passed the Rotherham test, contains 57 p.c. ammonium nitrate, 15 p.c. trinitrotoluene, 27.5 p.c. sodium chloride, and 0.5 p.c. graphite; limit charge 24 oz., pendulum swing 2.21 ins.

Neuwesfabit, a variety of Westfalit, containing nitrohydrocarbon, is on the German authorised list. It contains 70 p.c. ammonium nitrate, 11 p.c. dinitrotoluene, 2 p.c. flour, and 17 p.c. sodium chloride; limit charge 540 gms.

Nitroferriite contains 93 p.c. ammonium nitrate, 2 p.c. trinitronaphthalene, 2 p.c. potassium ferriyanide, and 3 p.c. of crystallised sugar.

Roburite, patented by Roth of Charlottenburg, in 1887 (Eng. Pat. 267a, 1887), had as a new feature the use of a chlorinated nitrohydrocarbon, chlorinated dinitrobenzene, said to render the explosive more sensitive, and also increase the dynamic effect, but all samples do not now contain this substance. Large quantities are manufactured in England near Wigan. *No. 1* contains 87.5 p.c. ammonium nitrate, 7 p.c.

dinitrobenzene, 5 p.c. ammonium sulphate, and 0.5 p.c. potassium permanganate, and *No. 3* 87 p.c. ammonium nitrate, 11 p.c. dinitrobenzene, and 2 p.c. chloronaphthalene. In later samples, trinitrotoluene is used in place of dinitrobenzene, with wood meal and potassium permanganate. *No. 4*, which has passed the Rotherham test, contains 61 p.c. ammonium nitrate, 16 p.c. trinitrotoluene, and 23 p.c. sodium chloride; limit charge 18 oz., pendulum swing 2.86 ins.

Two German compositions that have passed the tests for safety explosives are *Roburit II. 2*, containing 71.5 p.c. ammonium nitrate, 5 p.c. potassium nitrate, 12 p.c. trinitrotoluene, 6 p.c. flour, 5 p.c. sodium chloride, and 0.5 p.c. potassium permanganate, and *Roburit II.*, containing 55 p.c. ammonium nitrate, 9.5 p.c. potassium nitrate, 12 p.c. trinitrotoluene, 6 p.c. flour, 7 p.c. sodium chloride, 5 p.c. ammonium chloride, 5 p.c. magnesite, and 0.5 p.c. potassium permanganate. The limit charge of the former is 350 gms., and of the latter 650 gms.

The dried nitrate is incorporated with the molten nitro compound and compressed into cartridges as usual. *Roburite* has a brownish-yellow colour. It burns readily, but does not explode on burning. It is not sensitive to shock, friction, or pressure; it is practically flameless, and safe in fiery mines. It is more powerful than gunpowder, and its effect is not shattering.

Securite, a safety explosive invented by Schöneweg, in 1886, consists of 74-85 p.c. ammonium nitrate, and 15-26 p.c. metadinitrobenzene. Later varieties, called *Flameless securite*, also contain ammonium oxalate, and sometimes trinitrobenzene and trinitronaphthalene are used. The explosive is made by dissolving the salt in water, evaporating, drying at 80°, and adding the nitrohydrocarbon. The mixtures are coated with nitrated resin.

Stamford powder, a permitted explosive, contains 68-72 p.c. ammonium nitrate, 21-23 p.c. sodium nitrate, 3-4 p.c. trinitrotoluene, 3.5-4.5 p.c. ammonium chloride, and up to 1 p.c. moisture; limit charge 12 oz., pendulum swing 2.12 ins.

Thunderite contains 92 p.c. ammonium nitrate, 4 p.c. trinitrotoluene, and 4 p.c. flour.

Titanite No. 1 is a mixture of 85-88 p.c. ammonium nitrate, 6-8 p.c. trinitrotoluene, 4.5-6.5 p.c. charcoal dried at 100°, and 0-1 p.c. moisture.

Uplees powder contains 62-65 p.c. ammonium nitrate, 12.5-14.5 p.c. sodium nitrate, 4-6 p.c. trinitrotoluene, 13.5 p.c. ammonium chloride, 2-4 p.c. starch and up to 1.5 p.c. moisture; limit charge 16 oz., pendulum swing 2.64 ins.

Verstärktes chromammonit, reinforced chromammonite, is a modern German safety explosive containing 70 p.c. ammonium nitrate, 10 p.c. potassium nitrate, 12.5 p.c. trinitrotoluene, 7 p.c. chrome ammonium alum, and 6.5 p.c. vaseline.

Steele, in 1906 (Eng. Pat. 4115), proposed a mixture of 85 p.c. ammonium nitrate with 15 p.c. of nitrated resin, or a nitrated mixture of resin and starch; the latter is added in three successive portions, each portion being treated with atomised methylated spirit. The resin in this way is caused to coat the particles of nitrate and render them non-hygroscopic. In some cases 1-5 p.c. powdered aluminium may be added. A variety of this explosive called

Steeleite A, containing 2 p.c. castor oil, has been authorised in England.

Westfalite No. 3 contains 58-61 p.c. ammonium nitrate, 13-15 p.c. potassium nitrate, 4-6 p.c. trinitrotoluene, 20-22 p.c. ammonium chloride, and water up to 1 p.c.; limit charge 12 oz., pendulum swing 2.55 ins.

Withnell powder is a mixture of 88-92 p.c. ammonium nitrate, 4-6 p.c. trinitrotoluene, 4-6 p.c. dried flour, and 0-1.5 p.c. moisture. The explosive is contained in a water-proofed linen-paper wrapper, and fired by a No. 7 detonator.

Ammonium nitrate mixtures with organic basic substances and their nitrates, such as aniline, guanidine nitrate, and urea nitrate, have been proposed. Kùbin (Eng. Pat. 11502, 1894) patented a mixture of 75-95 p.c. ammonium nitrate and 5-25 p.c. aniline or toluidine nitrate, The Carbonite Syndicate, Ltd., in the same year, proposed a mixture of 94 p.c. ammonium nitrate and 6 p.c. aniline hydrochloride, under the name of *Progressite*. Girard (Fr. Pat. 350371, 1904) claims that a powerful explosive is formed by fusing together 80 parts ammonium nitrate and 88 parts guanidine nitrate.

A class of ammonium nitrate safety explosives has come into use, in which a little nitroglycerin, sometimes gelatinised with soluble nitrocellulose, is added to overcome the insensitiveness of the mixture, but not containing enough of this constituent to place them amongst the dynamites. Explosives of this type are:

Ammon-carbonit is composed of 80.3 p.c. ammonium nitrate, 5 p.c. potassium nitrate, 6 p.c. coal dust, 4.5 p.c. powdered starch, 4 p.c. nitroglycerin, and 0.2 collodion cotton.

Donarit, which contains 80 p.c. ammonium nitrate, 12 p.c. trinitrotoluene, 4 p.c. flour, 3.8 p.c. nitroglycerin, and 0.2 p.c. collodion cotton.

Melling powder contains 51-55 p.c. ammonium nitrate, 11-13 p.c. sodium nitrate, 5-7 p.c. trinitrotoluene, 3-5 p.c. wood meal, 4-6 p.c. nitroglycerin, 18-20 p.c. ammonium oxalate, and up to 2 p.c. moisture; limit charge 12 oz., pendulum swing 2.62 ins.

Super-Excellite consists of 73.5-77 p.c. ammonium nitrate, 6.5-8 p.c. potassium nitrate, 2-4 p.c. wood meal, 3.5-5 p.c. nitroglycerin, 9-11 p.c. ammonium oxalate, and up to 1.5 p.c. moisture; limit charge 10 oz., pendulum swing 2.74 ins.

Superite contains 80-84 p.c. ammonium nitrate, 9-11 p.c. potassium nitrate, 2-5 p.c. starch, 3.5-4.5 p.c. nitroglycerin, and up to 2 p.c. moisture; limit charge 10 oz., pendulum swing 2.53 ins.

Some ammonium nitrate mixtures are sensitised with nitrocellulose instead of with nitroglycerin or nitroglycerin jelly. For example, the German Explosive *Fulmenit* contains 86.5 p.c. ammonium nitrate, 5.5 p.c. trinitrotoluene, 2.5 p.c. paraffin oil, 1.5 p.c. charcoal, and 4 p.c. gunccotton. *Weiter Fulmenit* is of similar composition, except that 10 p.c. of the ammonium nitrate is replaced by sodium chloride, in order to reduce the temperature of explosion.

Monachit contains 12 p.c. trinitroxylen and 1 p.c. charcoal as combustibles, reinforced by 1 p.c. of collodion cotton.

Escapes, of Munich, in 1899, first proposed the

use of aluminium in an explosive, which was manufactured under the name of *Wenghoffer* (Eng. Pat. 24377), whilst in 1900 von Dahmen (Eng. Pat. 16277) claimed the use of aluminium, magnesium, or other light metal mixed with an oxidising agent, a suitable mixture suggested consisting of ammonium nitrate, aluminium, and charcoal in the proportions $4\text{NH}_4\text{NO}_3 + 2\text{Al} + \text{C}$. Subsequently, the charcoal was omitted, and an explosive suggested on the basis of the equation:

That is, a mixture of ammonium nitrate and aluminium in proportions for the complete combustion of the latter would contain 81.6 p.c. ammonium nitrate and 18.4 p.c. aluminium. This mixture would yield 1578 calories per gram and evolve 682 c.c. of gas. The charcoal is added to facilitate the detonation. Von Dahmen's explosive is now on the market under the name of *Ammonal*, and has given very good results, both as a mining explosive and as a high explosive for shells, the proportion of aluminium being varied according to the effect desired. The 'ammonal' permitted in this country as a mining explosive has the composition 93-97 p.c. ammonium nitrate, 4-6 p.c. aluminium, and 0-1 p.c. moisture, the explosive being contained in a thoroughly water-proofed case.

Ammonal B has the composition 94-96 p.c. ammonium nitrate, 2.5-3.5 p.c. aluminium, 2-3 p.c. wood charcoal, and 0-1 p.c. moisture. This explosive passed the Woolwich test. For ordinary blasting purposes a more powerful mixture is used, containing 72 p.c. ammonium nitrate, 25 p.c. aluminium, and 3 p.c. charcoal. These explosives are manufactured by the Roburite and Ammonal Co.

Ammonal is very insensitive, and burns with difficulty. It is said to be one of the safest explosives known. It is stable under dry conditions, but is hygroscopic under the conditions of humidity in which ammonium nitrate itself absorbs moisture. It is fired with the usual detonator, and the products of combustion are said to be harmless; they, however, contain a considerable proportion of carbon monoxide.

For an ammonal containing 72 p.c. ammonium nitrate, 23.5 p.c. aluminium, and 4.5 p.c. charcoal compressed to a density of 0.9, Bichel found the velocity of detonation to be 3450 m. per sec. The heat of explosion was 1600 calories, and the calculated explosion pressure was 9425 kg. per sq. cm. (Zeitsch. angew. Chem. 1905, 1889).

Ammonal has been used in this country for military purposes in bombs and grenades. In Austria four grades are manufactured containing 80-90 p.c. ammonium nitrate, 4-18 p.c. aluminium, and 2-6 p.c. charcoal, and it is a service explosive in that country.

Since the introduction of 'ammonal,' aluminium has been added as an ingredient in many other explosives, chiefly in mixtures of the ammonium nitrate class with nitrohydrocarbons. The aluminium is usually used in the form of powder, which is made by first pouring the molten metal into water, and then pounding the small irregular fragments so produced, after drying, under stamp-mills until a sufficiently fine powder is obtained. The use of aluminium

and other easily oxidisable metals in the form of 'metal wool,' has been patented, the fineness of division being said to exert a considerable influence on the force of the explosive.

The oxidation of the aluminium sets free a large amount of heat, and it is claimed that the mechanical effect of the explosives is considerably increased. Bichel, however (*l.c.*), contends that the results showing this increase have been obtained in the lead block test, and are fallacious, and that actual use in mines has demonstrated that the increase in efficiency due to the addition of aluminium, is extremely slight. He affirms that aluminium can only be added economically to those explosives which have a low temperature of explosion; as with others, although there is some increase in the temperature of the explosion, it is more than counterbalanced by the decreased volume of gas produced. It has been found that the addition of a few per cents. of aluminium increases the rate of detonation of the explosives.

Macnab and the Ammonal Explosives Co., Ltd. (Eng. Pat. 16514, 1904) propose the addition of potassium dichromate to explosives of the 'ammonal' type. It is claimed that in this way more aluminium may be used, giving greater explosive power, without diminishing the safety of the explosive.

Ripping ammonal contains 84-87 p.c. ammonium nitrate, 7-9 p.c. aluminium, 2-3 p.c. charcoal, 3-4 p.c. potassium bichromate, and 0-1 p.c. moisture, and *St. Helen's powder* contains 92-95 p.c. ammonium nitrate, 2-3 p.c. aluminium powder, 3-5 p.c. trinitrotoluene and 0-1 p.c. moisture. Both these explosives passed the Woolwich tests. A more powerful variety for ordinary blasting purposes contains 47 p.c. ammonium nitrate, 22 p.c. aluminium, 30 p.c. trinitrotoluene and 1 p.c. charcoal. *Gesteins-Westfalit B* and *C* are German ammonals containing dinitrobenzene and dinitrotoluene respectively.

Besides aluminium and magnesium, many other metals and similar substances which yield oxides reducible with difficulty, including copper, zinc, iron, silicon, ferro-silicon, silicon carbide, various alloys, calcium, boron, and such rare metals as those of the cerium group, have been proposed and patented for addition to explosive mixtures.

Sabulite is an ammonium nitrate explosive containing calcium silicide, with trinitrotoluene to help the detonation. It has been used in England for filling bombs and grenades, a usual formula being 78 p.c. ammonium nitrate, 14 p.c. calcium silicide and 8 p.c. trinitrotoluene. When loose this explosive has a density of about 0.8 and is compressed in cartridges to a density of 1.0 to 1.15 with consequent increase of efficiency, but if compressed beyond this it cannot be detonated satisfactorily. Segay (Eng. Pat. 113083, 1917) proposes to considerably increase the proportion of silicide, so that on explosion the products are not those of complete combustion, and states that the most powerful results are obtained when the proportions are such that the carbon is turned to carbon monoxide, and only half the hydrogen is turned to water. Suggested proportions are 66 p.c. ammonium nitrate, 27 p.c. calcium silicide and 7 p.c. trinitrotoluene. He claims that with this mixture

the power is increased by 10 p.c. when loose, that the explosive can readily be detonated even when compressed to a density of 1.45, that it is less hygroscopic, and that it is more easily handled. The trinitrotoluene may be replaced by tetryl, tetranitraniline, hexanitrodiphenylamine, or nitroglycerin.

The metals may be mixed with other oxidising agents than ammonium nitrate, for instance, barium nitrate has been proposed in recent mixtures with aluminium. Adinau (U.S. Pat. 1056389) proposes a mixture of 69 p.c. barium nitrate, 29 p.c. trinitrotoluene and 2 p.c. lead chromate.

Lead nitrate has been proposed as the oxidising agent in explosive mixtures, together with the usual nitrohydrocarbons, or other explosive or semi-explosive compounds, for example, de Macar (Eng. Pat. 10456, 1900) proposes mixtures containing lead nitrate mixed with 17 p.c. dinitroxylylene, 10 p.c. aminoazobenzene, or 45 p.c. dinitrocellulose. Ermel (Fr. Pat. 377509, 1907) claims that the addition of lead nitrate to ammonium nitrate explosives ensures certainty of detonation, the increased sensitiveness being counteracted by the addition of a small proportion of glycerol or liquid hydrocarbon.

Chlorate Mixtures.

The chlorates contain a large store of available oxygen, with which they part at a comparatively low temperature, and with combustible substances yield extremely brusque and violent explosives. Chlorates contain approximately the same percentage of available oxygen as the corresponding nitrates, but they form more sensitive and violent mixtures, owing to the fact that they are endothermic: the nitrates, with the exception of ammonium nitrate, are not. Berthelot (Mem. des Poudres et Salpêtre, 1900-1910) has shown that potassium chlorate alone can be made to detonate, by allowing a small drop of the fused salt to fall on a red-hot surface. Chlorate mixtures are readily exploded by friction or percussion, rendering their manufacture highly dangerous, and they are all liable to spontaneous ignition, if the ingredients contain, or are liable to generate, traces of acid. Mixtures with sulphur or a metallic sulphide are very sensitive, and are liable to become unstable. Traces of sulphurous and sulphuric acid present in the sulphur, or formed by oxidation on storage, liberate chloric acid which accelerates the oxidation and may ultimately lead to spontaneous ignition of the mixture. A further drawback to their use is that their sensitiveness to percussion and friction frequently increases on keeping and exposure alternately to moist and dry conditions,—a phenomenon that has been partly attributed to fine crystals of chlorate crystallising out on the surface of the mixture. The chlorates alone are liable to explode when suddenly heated to a high temperature: explosions have occurred when large quantities of potassium chlorate have been involved in fires.

Potassium chlorate mixtures. Berthelot, who discovered potassium chlorate in 1788, proposed its use as a substitute for nitre in explosive mixtures, but early experiments led to several serious accidents and temporary abandonment

of its use. Since that time innumerable mixtures have been patented, usually with some attempt to counteract the extreme sensitiveness of the mixtures, by the addition of some deadening agent, such as an oil, vaseline or paraffin wax, to coat the grains of chlorate, or some special mechanical expedient, such as only mixing the chlorate and combustible immediately before use.

The usual combustible substances, sulphur, charcoal, peat, tan, sawdust, bran, starch, gum, sugar, and frequently potassium ferrocyanide and realgar, have been proposed, together with such deadeners as tar, pitch, paraffin, ozokerite, soap, glycerol, a syrup of grape sugar, boiled linseed oil, and indiarubber solution. The mixtures were frequently proposed to be used in a moist pasty condition.

Very few need be cited as examples. *White gunpowder* was a mixture of approximately two parts of potassium chlorate and one part each of potassium ferrocyanide and sugar. *Kinetite* was an explosive proposed by Petry, Fallenstein, and Lisch (Eng. Pat. 10986, 1884), consisting of potassium chlorate incorporated with nitrobenzene, thickened and gelatinised with a little collodion cotton and sulphur, as precipitated antimony sulphide. A modified 'kinetite' was made by omitting the antimony pentasulphide. It required a high temperature for ignition, and did not explode on heating. It was, however, very sensitive to friction and percussion, and so chemically unstable that its manufacture in this country was not authorised. Among foreign attempts may be mentioned *Petrofracture*, favourably reported on by an Austrian military committee, consisting of 67 p.c. potassium chlorate, 20 p.c. potassium nitrate, 10 p.c. nitrobenzene, and 3 p.c. antimony sulphide; and Turpin's explosive, *Duplexite*, a mixture of 70 p.c. potassium chlorate, 10 p.c. charcoal, 10 p.c. dinitrobenzene, and 10 p.c. coal tar (Fr. Pat. 189426, 1888). In England, Kitchen (Eng. Pat. 11102, 1889) submitted a sample of explosive to the Home Office authorities, containing 3 parts potassium chlorate, 7 parts potassium nitrate, 7 parts sugar, and 1 part coal-dust and paraffin oil, that was favourably reported on, but was never put on the market; and practically the only chlorate mixture that was ever used, until some ten years ago, was *Asphalite* (Eng. Pat. 2488, 1881), which consisted of 54 p.c. potassium chlorate, 42 p.c. bran, and 4 p.c. nitre and potassium sulphate. The mixture was deadened with paraffin, ozokerite, or soap, and coloured pink with fuchsine. This explosive was manufactured at Llangollen, but it was not a practical success, owing to its bulky nature, and the licence for manufacture was subsequently withdrawn.

For many years no explosive containing potassium chlorate was licensed, and invention was turned in other directions, owing to the high cost of chlorate explosives, and the greater explosive power of such explosives as dynamite and guncotton. On the introduction of electrolytic potassium chlorate, the price was greatly reduced, and efforts were again made to obtain a practical chlorate explosive. The first electrolytic chlorate factory was started at Villers-sur-Hermès, in Switzerland, in 1889. It has not been found possible to make a satisfactory propellant with a chlorate mixture, as they are

all too violent and uncontrollable, and explosives of this class that have had extended use are all detonating or blasting explosives.

Street, in 1897, invented *Cheddite* (Eng. Pat. 9970, 1897), the name being derived from Chedd in Switzerland, where it was first made. This explosive satisfied all tests, and is now very largely used as a blasting explosive. The composition of cheddite is constantly undergoing change in detail, but it is essentially a mixture of potassium chlorate with one or more nitrohydrocarbons and castor oil. Some examples are: *Type 41*, 80 p.c. potassium chlorate, 12 p.c. mononitronaphthalene, and 8 p.c. castor oil. *Type 60*, 80 p.c. potassium chlorate, 12 p.c. mononitronaphthalene, 6 p.c. castor oil, and 2 p.c. picric acid. *Type 60 bis*, 80 p.c. potassium chlorate, 13 p.c. mononitronaphthalene, 5 p.c. castor oil, and 2 p.c. dinitrotoluene. *Type 60 bis M*, 79 p.c. potassium chlorate, 15 p.c. dinitrotoluene, 5 p.c. castor oil, and 1 p.c. mononitronaphthalene. The cheddites of *Type 60* are more violent than *Type 41*.

Colliery cheddite, as permitted for use in this country, has the composition 76.5-79.5 p.c. potassium chlorate, 14.5-15.5 p.c. mononitronaphthalene, 1.5-2.5 p.c. dinitrotoluene, 4.5-5.5 p.c. castor oil, and 0-1 p.c. moisture.

The method of manufacture of 'cheddites' is to heat the castor oil by steam, in a jacketed enamelled iron pan, to a temperature of 70°. The nitrohydrocarbon, or nitrohydrocarbons, are then added, and when the mass is molten and homogeneous, it is allowed to cool to 55°, when the warm and dry powdered chlorate is mixed in by means of a wooden spatula, and stirred until all white particles have disappeared. 25 kilos. of material can be made in about 7 minutes. Finally, the mixture is poured on to a wooden bench, allowed to cool to about 30°-35°, the mass being still somewhat plastic, and then crushed by rolling it with a wooden roller. The rolling process is repeated when the mass is cold. The finished explosive is in the form of brownish-white or yellow grains, but is sometimes artificially coloured.

The stability of 'cheddites' is said to be increased on prolonged storage. They are insensitive to shock and friction at ordinary and at very low temperatures, and burn more or less rapidly, without any tendency to explode even when fired in large masses. Keeping for a long period at 120° causes no decomposition. At 200° the oil decomposes, the nitro-compounds volatilise, and the mass dries and blackens; and they do not deflagrate until heated to the temperature of decomposition of the chlorate. 'Type 60' is said to be about as powerful in blast-holes as 'dynamite No. 1,' although it only produces about half the effect of the dynamite in the lead-block test.

Deering, in 1905, found that a 'cheddite,' having the composition 73 p.c. potassium chlorate, 16 p.c. dinitrotoluene, 6 p.c. starch, and 5 p.c. castor oil, gave an explosive effect in a lead block=0.75, guncotton being unity, and that a thin layer between hardened steel surfaces required a blow of 120 foot-lbs. per sq. inch to cause slight charring in one part, whilst, with a blow of 160 foot-lbs. per sq. inch, the explosive practically all fired.

If incorrectly proportioned the 'cheddites'

are liable to exude oil on storage. They are readily compressible and their sensitiveness to detonation diminishes with increased density; care is, therefore, necessary to avoid over-ramming in use. The velocity of detonation increases with compression up to a certain point, but beyond this it rapidly diminishes.

Many explosives of the Street type have been introduced since 'cheddite,' various nitrohydrocarbons being combined with the chlorate. Improvements have been directed towards minimising the chance of exudation in hot climates. Street himself (Eng. Pat. 12760, 1898) proposed to use a sulphurated oil, fat, or fatty acid, made by heating the oils or fats with sulphur at 180° until they thicken, instead of ordinary oil. Girard (Eng. Pat. 214, 1900) thickened the oil with 10-15 p.c. hard or soft soap, and Bonnet (Zeitsch. angew. Chem. 1901, [44] 1120) displaced part or the whole of the oil by the free fatty acids. The French 'Explosif O4' is a mixture of 90 p.c. potassium chlorate and 10 p.c. paraffin wax; it has been used for military purposes. In O6 or 'minelite' the combustibles are a mineral oil residue and paraffin wax, and in 'Sébonite' they are tallow and nitrotoluene or dinitrobenzene.

Pyrodialite, introduced by Turpin in 1899, is prepared in two forms. First, Nos. 0 and I., explosives with flame, containing respectively 88 and 80 p.c. potassium chlorate, 5 and 6 p.c. vegetable charcoal, 10 and 18 p.c. neutral gas tar, and 3 and 4 p.c. sodium or ammonium dicarbonate. Second, Nos. II. and III., explosives without flame, in which about half the chlorate is replaced by sodium or potassium acetate, the other ingredients being approximately in the above proportions. Later, Turpin proposed the addition of 10-50 p.c. nitroglycerin to render these explosives more sensitive to detonation, and prepared similar explosives with ammonium perchlorate.

Ammonia nitrate powder is an explosive composed of 80 p.c. ammonium nitrate, 5 p.c. potassium chlorate, 10 p.c. nitroglucose, and 5 p.c. coal tar.

In 1908 a chlorate mixture called *Colliery Steelite*, consisting of 74 p.c. potassium chlorate, 25 p.c. so-called nitrated resin, and 1 p.c. castor oil, was licensed as a safety explosive. Steele (Eng. Pat. 22095, 1909) has proposed a safety explosive containing 85-97.5 p.c. potassium chlorate, 2.5-15 p.c. liquid vaseline of sp.gr. 0.885-0.89. *Kohlensilezia 4A* is a German safety explosive containing 80 p.c. potassium chlorate, 16 p.c. resin, and 4 p.c. nitrated resin; a considerable proportion of sodium chloride is present in the 'safety' variety of this explosive.

The use with chlorate of explosive compounds like nitroglycerin and guncotton has also been patented. The nitrophenols form very sensitive mixtures with potassium chlorate, and ammonium salts should never be used in chlorate mixtures, owing to the possibility of the formation of ammonium chlorate on storage. Potassium chlorate is a constituent of nearly all detonating compositions, used as initial detonating agents for other explosives.

Other potassium chlorate explosives are mentioned under 'Sprengel Explosives.'

Other chlorates. Sodium chlorate is frequently substituted for the potassium salt in the various

mixtures mentioned. For example, 'cheddites' are manufactured of the compositions *Type 41N*, 80 p.c. sodium chlorate, 12 p.c. nitronaphthalene, and 8 p.c. castor oil; *Type 60N*, 80 p.c. sodium chlorate, 13 p.c. nitronaphthalene, 2 p.c. dinitrotoluene, and 5 p.c. castor oil; and *Type O5*, 79 p.c. sodium chlorate, 16 p.c. dinitrotoluene, and 5 p.c. castor oil. These mixtures have very similar properties to those containing potassium chlorate: they are, however, liable to absorb moisture and the cartridges are consequently dipped in paraffin wax. They should not contain more than 1 p.c. moisture.

Barium chlorate has been proposed in a few mixtures, but its application is practically limited to pyrotechnic compositions.

Lead chlorate. Martin (Fr. Pat. 478351, 1915) suggests explosives made from basic lead chlorate by interaction with glycerin, sugar, dextrose, mannitol or tannin. Crystalline products are obtained which are used either alone or mixed with combustible materials.

Ammonium chlorate yields extremely powerful explosive mixtures, but on account of its instability, it has no practical value. It decomposes even at ordinary temperatures, and mixtures containing it are liable to spontaneous explosion. According to Gelhaur (Zeitsch. ges. Schiess u. Sprengstoffw. 1916, 166) a thin layer of the dried salt lost 80 p.c. of its weight in seven weeks, its nitrogen being partly oxidised to nitric acid, and violent decomposition took place after 11 hours at 40°, 45 minutes at 70°, or about 3 minutes at 100°. He also found that the dry salt was detonated by a weight of 2 kilos. falling through a distance of 15 cm.

Perchlorate Mixtures.

Perchlorates contain a larger percentage of oxygen, and decompose at higher temperatures than the chlorates. Mixtures containing them are not only more powerful, but also much less sensitive to ignition, percussion, and friction, and consequently are safer to store and use than the corresponding chlorate mixtures. As with chlorates, the electrolytic production of these compounds, cheaply and in a pure state, has led to their largely increased use in recent years.

Potassium and sodium perchlorate mixtures. Formerly, potassium, and occasionally sodium, perchlorate was mainly used, combined with the usual combustible or explosive ingredients, but their use has now been almost entirely superseded by the ammonium salt. However, Trench (Eng. Pat. 8358, 1908) proposed the addition of 5-20 parts of potassium perchlorate to 100 parts of gunpowder to increase the strength and regularity of the explosive, and in the same year, Harris (Eng. Pat. 28012, 1908) suggests mining explosives, consisting of mixtures of potassium perchlorate and carbon with naphthalene and benzene, and other nitro derivatives in various proportions. Small proportions of paraffin oil and castor oil are also added.

M.B., or Modified Black, Powder, No. 1, is a black gunpowder, used for blasting purposes, in which part of the potassium nitrate is replaced by potassium perchlorate. The potassium nitrate may be replaced by sodium or barium nitrate.

Chilworth Powders, No. 4 and No. 5, contain mixtures of potassium nitrate and perchlorate as oxidising agents, the combustibles being sulphur and charcoal, with the addition of a little flour in the former or paraffin wax in the latter.

A class of explosives called *Permonites* is made in Germany according to several formulæ, but all containing roughly equal parts of potassium perchlorate and ammonium nitrate as oxidising salts. The combustible constituents are trinitrotoluene, flour or starch, and wood meal; a little nitroglycerin, or nitroglycerin gelatinised with soluble nitrocellulose, is sometimes added to render the explosive more susceptible to detonation; and a mild form of the explosive contains a considerable proportion of sodium chloride.

Some varieties are: *Permonite I*, or *Gesteins-Permonit*, 30 p.c. potassium perchlorate, 40 p.c. ammonium nitrate, 7 p.c. sodium nitrate, 15 p.c. trinitrotoluene, 4 p.c. flour, 3 p.c. wood meal and 1 p.c. of a jelly of gelatine in glycerine; *Permonite S.G.P.*, on the Belgian permitted list, 24.5 p.c. potassium perchlorate, 29 p.c. ammonium nitrate, 6 p.c. nitroglycerin, 7 p.c. trinitrotoluene, 4 p.c. flour, 3 p.c. wood meal, 1 p.c. of a jelly of gelatine in glycerine, and 25 p.c. sodium chloride; *Permonite*, as placed on the British authorised list, 31-34 p.c. potassium perchlorate, 39-43 p.c. ammonium nitrate, 3-4 p.c. nitroglycerin, 0.5-1 p.c. soluble nitrocellulose, 11-13 p.c. trinitrotoluene, 5-9 p.c. starch, 1.5-3.5 p.c. wood meal and 0-2.5 p.c. moisture. *Permonite I* is more powerful, but also more sensitive to blow, than the *S.G.P.* variety.

Several explosives containing potassium perchlorate have passed the latest tests and have been placed on the British list of authorised explosives, but as these also contain a considerable proportion of gelatinised nitroglycerin they have been classified amongst the 'dynamites.'

Ammonium perchlorate mixtures. In 1898 Alvisi (Rev. prod. chim. 2, [6] 83, and Eng. Pat. 25838, 1898) proposed the use of ammonium perchlorate, then made from the sodium salt by double decomposition with ammonium nitrate, in explosive mixtures. He claimed that it increased the explosive and propulsive force of the mixture, as well as the ratio of the former to the latter. The ammonium perchlorate was substituted for the other oxidising salts in the proportion of their available oxygen, and sulphur or a metallic sulphide was added to counteract the insensitiveness to ignition or detonation, and he pointed out that the maximum effect of the mixtures is preferably obtained by the use of detonators themselves containing ammonium perchlorate. Ammonium perchlorate is stable at ordinary temperatures, but decomposes slowly at 145° according to the equation $\text{NH}_4\text{ClO}_4 = 2\text{H}_2\text{O} + \text{N} + \text{Cl} + \text{O}_2$.

Besides having a large percentage of available oxygen, ammonium perchlorate evolves a large amount of gas and heat on decomposition. It is endothermic, and has the advantage over the perchlorates of the fixed bases that its products of decomposition are entirely gaseous, but owing to the internal combustion of its hydrogen, it has less available oxygen. The decomposition is rapid and the velocity of the explosion wave is great. It can be detonated alone but only with great difficulty, and a very powerful de-

tonator is necessary to give complete detonation. Its limit of sensitiveness to impact is represented by a weight of 5 kg. falling 50 cm.

It is non-hygroscopic and insensitive when pure; but the insensitiveness of the salt is greatly diminished if it contains even small quantities of ammonium chlorate. Admixture of ammonium perchlorate explosives with potassium or sodium chlorate in quantity is dangerous owing to the liability to the formation of unstable ammonium chlorate on storage, but the Aktiebolaget Carlit, Stockholm, has suggested (Eng. Pat. 112417, 1917) the presence of 0.005 to 1 p.c. of a chlorate other than ammonium chlorate to render ammonium perchlorate explosives more sensitive and increase their violence. Alvisi, later (Gazz. chim. ital. 31, i. 221), confirmed experimentally, by testing various mixtures with combustible and explosive substances, the theoretical advantages of ammonium perchlorate over all other oxidising salts, except ammonium chlorate; and Carbonelli (L'Ind. chim. 1910, 209) obtained equally favourable results.

Explosives containing ammonium perchlorate have the disadvantage of generating hydrochloric acid, and occasionally chlorine in the mine. This drawback is usually overcome by the addition of potassium or sodium nitrate, but manganese or its compounds, oxides, silicic, boride, manganate, or permanganate, have also been suggested for the same purpose.

Ammonium perchlorate is used in combination with the various combustible and explosive substances mentioned under the other oxidising salts. These mixtures are now established as powerful and safe explosives, and are largely used in England, the United States and on the Continent.

The ammonium perchlorate is manufactured from the electrolytically produced sodium salt, either by double decomposition with ammonium chloride or sulphate, or by the combined action of carbonic acid gas and ammonia on the solution. In the former process the sodium sulphate can be deposited in an anhydrous condition and free from perchlorate by evaporation of the mixed solutions under reduced pressure at from 60° to 85°C. (Aktiebolaget Carlit, Stockholm, Eng. Pat. 110544, 1917); the latter process has been patented by Given and the Atlas Powder Co. of U.S.A. (U.S. Pat. 1273477, 1918).

Yonck (Eng. Pat. 24511, 1903) suggested a series of safety mining explosives containing ammonium perchlorate, amongst which are: (1) 21.2 p.c. ammonium perchlorate, 37.3 p.c. sodium nitrate, and 11.5 p.c. naphthalene; (2) 37.4 p.c. ammonium perchlorate, 27.17 p.c. sodium nitrate, 8.34 p.c. ammonium nitrate, and 27.09 p.c. trinitronaphthalene; and (3) 48.4 p.c. ammonium perchlorate, 33.8 p.c. calcium oxalate, and 17.8 p.c. trinitrotoluene. Webster (Eng. Pat. 18622, 1909) proposed a mixture of 35 p.c. ammonium perchlorate, 45 p.c. sodium nitrate, 10 p.c. dinitrobenzene, and 10 p.c. sawdust, or the same mixture with 2 p.c. of the sawdust replaced by vaseline. Trench (Eng. Pat. 8358, 1908) proposed to increase the strength and regularity of gunpowder by the addition of from 5 to 20 p.c. of ammonium perchlorate.

Some 'cheddites,' containing ammonium

perchlorate are: 'Type B,' 82 p.c. ammonium perchlorate, 13 p.c. dinitrotoluene, and 5 p.c. castor oil; and 'Type C,' 50 p.c. ammonium perchlorate, 30 p.c. sodium nitrate, 15 p.c. dinitrotoluene, and 5 p.c. castor oil.

Amasite is an English 'authorised' explosive, consisting essentially of ammonium perchlorate and myrabolans, usually with some sodium or potassium nitrate and a small quantity of agar-agar.

Blastine, manufactured by Marpal, Ltd., Cornwall, an English 'authorised' explosive that has been used in large quantities both for industrial and for military purposes. A usual composition is 60 p.c. ammonium perchlorate, 22 p.c. sodium nitrate, 11 p.c. dinitrotoluene, and 7 p.c. paraffin wax. In some varieties a little aluminium powder or alternately charcoal is used. It is in the form of soft yellow grains, which are readily compressed.

M.B. Powder, No. 2 is a mixture of ammonium perchlorate and sodium, potassium, or barium nitrate, with charcoal and sulphur as combustibles.

P.S.E. No. 15 is a mixture of ammonium perchlorate and rosin, and *shellite* is a mixture of ammonium perchlorate and paraffin wax.

The *Yonckites* are Belgian explosives of this class. *No. 10 bis*, on the Belgian authorised list, contains 25 p.c. ammonium perchlorate, 30 p.c. ammonium nitrate, 15 p.c. sodium nitrate, 10 p.c. trinitrotoluene, and 20 p.c. sodium chloride, the limit charge being 900 gms.; *No. 13*, a more violent mixture, contains 20 p.c. ammonium perchlorate, 27 p.c. ammonium nitrate, 27 p.c. sodium nitrate, 6 p.c. barium nitrate, and 20 p.c. trinitrotoluene.

Metals are used in mixtures suggested by Bowen (Eng. Pat. 21481, 1903) as a shell powder, 75 p.c. ammonium perchlorate, 12 p.c. aluminium, and 13 p.c. paraffin, and as a blasting powder, 72 p.c. ammonium perchlorate, 11 p.c. aluminium, and 17 p.c. nitronaphthalene; and by Palmer (Fr. Pat. 394833, 1908), in a mining powder, claimed to be non-hygroscopic, stable, powerful, and rapid, consisting of 50 p.c. ammonium perchlorate, 14 p.c. dinitrotoluene, 31 p.c. sodium or potassium nitrate, 5 p.c. aluminium powder, and 5 p.c. paraffin wax.

The Belgian explosive *Megadyne* is a mixture of ammonium perchlorate with aluminium powder and paraffin wax, and similar compositions, with or without the addition of wood meal, have been used for military purposes in this country. These explosives are cheap, easy to manufacture, safe to handle, permanent, and readily compressed; they do not explode, but only burn, when ignited, require a powerful detonator to detonate them, but are extremely powerful when their full power is brought out, and the rate of detonation is high for an explosive mixture (of the order of 4000 m. per sec.), so that they are locally violent. They must not, however, be too strongly compressed in use, or the rate of detonation, like that of the chlorate 'cheddites' is lowered again.

Zinc powder has been suggested by Palmer and the Perchlorate Powder Co., Canada (Fr. Pat. 477678, 1915), in ammonium perchlorate explosives, which are stated to detonate readily and completely, and to have great stability. The specified composition consists of 82 p.c.

ammonium perchlorate, part of which may be substituted by the potassium salt, 10 p.c. zinc powder, 5 p.c. combustible carbon compounds, such as mineral jelly, and 3 p.c. of an asphaltic pitch or petroleum residue. If the last ingredient does not contain sulphur, this may be added up to 5 p.c. The ingredients are incorporated with alcohol and benzene, which are afterwards dried off. An explosive mixture of similar composition has been used for military purposes in England for bomb filling under the name of *Permite*.

Johnson and the Perchlorate Safety Explosive Co. (Eng. Pat. 14866, 1915, and 1480, 1916) claim mixtures of ammonium perchlorate, part of which may be replaced by the potassium salt, with 4 to 8, and 16 p.c. of rosin in different grades of the explosive. Other varieties contain zinc or aluminium, and mineral oil or wax may also be added. The explosive *Rexol* is of this type.

The use of silicon or a silicide, usually ferro-silicon, instead of a metal, as temperature raiser in this type of explosive has been suggested by the Stockholm Superfosfat Fabriks Aktiebolag, Sweden (Eng. Pat. 17583, 1915). The main combustible is either nitrated or un-nitrated naphthenes (rockoil residue of over 250°C. b.p.), or this together with the mixture of nitro-toluenes commercially known as 'liquid trinitrotoluene,' gelatinised by the addition of a little nitrocellulose, a little wood meal being also added to increase the speed of detonation. Two formulæ given are: (1) 74 p.c. ammonium perchlorate, 6 p.c. ferro-silicon, 18 p.c. rock oil residue, and 2 p.c. wood meal; (2) 74 p.c. ammonium perchlorate, 5 p.c. ferro-silicon, 10 p.c. gelatinised liquid trinitrotoluene, 9 p.c. nitrated rock oil residue, and 2 p.c. wood meal. The ferro-silicon is supposed to bind at least part of the chlorine in the residue; aluminium silicide is also suggested.

Mixtures of ammonium perchlorate with explosive compounds have also been proposed; for example, explosives compounded of ammonium perchlorate and nitroglycerin, with or without the addition of collodion cotton, and a detonating mixture with mercury fulminate, were suggested by Alvisi (Eng. Pat. 25838, 1898); and Luciani suggests the addition of guncotton to ammonium perchlorate mixtures, more especially with metals (Fr. Pat. 326037, 1902).

OTHER OXIDISING AGENTS.

The permanganates of potassium and sodium, the dichromates of potassium and ammonium, and the peroxides of lead and manganese are all good oxidising substances, and are used to some extent in explosive mixtures, but usually in combination with the other salts, and need no separate mention. Potassium permanganate mixtures are frequently very sensitive. The utilisation of the expansive force of liquid air as an explosive has been described by Wood (Eng. Pat. 25025, 1902), and, more recently, liquid air and liquid oxygen have been suggested as the oxygen vehicle in explosives of the Sprengel type.

Sprengel Explosives.

Sprengel (Eng. Pat. 921 and 2642, 1871; Chem. Soc. Trans. 1873, 796) suggested the use,

for blasting purposes, of a new class of explosives consisting of mixtures, made immediately before use, of an oxidising agent and combustible substance, in themselves non-explosive.

Some of these explosives are very powerful when detonated by means of mercury fulminate, and they have the advantage of being perfectly safe during storage and transport; but, seeing that they are really manufactured when the mixing takes place, their use in most countries would be forbidden, as this manufacture can only be authorised in a duly licensed factory. Further, they are difficult for a miner to manipulate with cleanliness and safety. In some modern Russian Sprengel explosives, the liquid combustible is contained in a vessel divided into separate compartments, so that separate portions of the cartridge are uniformly impregnated with separate portions of the liquid, with the result that the explosive action is more uniform.

Sprengel proposed mixtures of nitric acid of about 1.5 sp.gr. with nitrobenzene, naphthalene, nitronaphthalene, and picric acid, and of porous cakes of potassium chlorate with such combustible liquids as carbon disulphide, nitrobenzene, petroleum, and benzene, the mixtures being made in the proportions required for complete combustion.

Care has to be taken that the nitric acid does not get accidental access to the fulminate detonator, or premature explosion will occur.

By adopting the Sprengel principle, the use of chlorate explosives may be made reasonably safe, and considerable quantities have been used in the United States and on the continent. One objection to them is that, unless great care is taken in the dipping, variable quantities of liquid are absorbed and uneven effects and possibly partial detonation only may result. They are sometimes primed with gunpowder, and when this is the case precaution is necessary to avoid admixture of the gunpowder and chlorate.

Rackarock, as used in the United States in 1885 for blasting the Hellgate rocks at the entrance of New York Harbour, was a mixture of 79 p.c. powdered potassium chlorate, and 21 p.c. nitrobenzene, the chlorate contained in cotton cases being suspended in a wire cage from a spring balance and dipped in the liquid until the requisite weight was absorbed. These proportions were found by Abbot to give the maximum effect under water, the intensity of action being 108 p.c. of that of dynamite No. 1. '*Rackarock Special*' contains, in addition, from 12 to 16 p.c. of picric acid. Sometimes 'dead oil,' or a mixture of this, with nitrobenzene was used.

Rackarock has also been used in other important engineering work, in blasting the headings of the Vosburg Tunnel in Pennsylvania, and in works connected with the first Chinese railways.

Explosif O₃, or *Prométhée* is a French Sprengel explosive in which the liquid combustible is a mixture of nitrobenzene, turpentine, and naphthalene in various proportions, but with the nitrobenzene as chief constituent, and the absorbent oxygen magazine is a mixture of potassium chlorate with a little manganese dioxide.

Wain (U.S. Pat. 1240272, 1917) suggests a Sprengel explosive of the chlorate type, the

combustible liquid being a mixture of equal volumes of castor and raw linseed oils, with eight times their combined volume of petroleum, that has been submitted to a nitrating treatment with nitric acid. This liquid has a sp.gr. of 0.816, and is stated to be twice as readily absorbed in the chlorate as nitrobenzene.

Hellhoffite, introduced by Hellhoff of Berlin, was a mixture of dinitrobenzene and nitric acid. It was tried in shells; the two substances mixing during their flight or on impact. Suitably detonated, the mixture is a powerful explosive, more so than gun-cotton or ordinary dynamite.

Pandastite.—Turpin, under this name (Eng. Pat. 4544, 1881; and 1461, 1882), proposed the use of liquid nitrogen peroxide, a mixture of equal parts of carbon disulphide and nitrogen tetroxide, that is, $3CS_2 + 5NO_2$, being recommended as giving the maximum effect. The advantages of nitrogen tetroxide over nitric acid are its higher percentage of available oxygen, lower heat of formation, and absence of water, but the disadvantages in its use are obvious.

Oxonite, invented by Punshon (Eng. Pat. 2428, 1883), was a mixture of 46 p.c. picric acid and 54 p.c. nitric acid, sp.gr. 1.5, the acid being contained in the cartridge in a glass tube, which was broken just previously to use.

Donar is a Sprengel explosive invented by Fiedler (Eng. Pat. 8101 and 23284, 1901). The cartridge contains a compressed dry powdered mixture of potassium chlorate and potassium permanganate, with or without potassium dichromate, and a vessel containing a mixture of turpentine with nitrobenzene or phenol; the dry powder being saturated with the fluid shortly before use.

The Soc. Franç. des Poudres de Sûreté (Fr. Pat. 351289, 1905) proposes three combustible mixtures: (1) 27 p.c. orthonitrotoluene, 9 p.c. mononitronaphthalene, and 64 p.c. dinitronaphthalene; (2) 35 p.c. paraffin wax, 50 p.c. orthonitrotoluene, and 15 p.c. trinitrotoluene; (3) 23 p.c. paraffin wax, 13 p.c. nitrotoluene, 13 p.c. trinitrotoluene, and 51 p.c. iron filings. These combustible mixtures are liquefied by warming to about 65°, and mixed with the oxygen yielding constituents, when required for use. A mixture of nitrates of ammonium, potassium, and aniline is used with (1), potassium chlorate with (2) and (3). Winand (Eng. Pat. 26261, 1907) has patented a mixture of tetranitromethane $C(NO_2)_4$, a liquid boiling at 126°, with petroleum and other carbonaceous matter. Tetranitromethane is a stable substance and only feebly explosive, but somewhat readily exploded by percussion. It dissolves paraffin and other hydrocarbons, forming a pasty mass. It contains 65 p.c. of available oxygen, and is exothermic.

Liquid air and liquid oxygen explosives.—Sprengel himself called attention to the possibilities of liquid oxygen, and pointed out that the beau idéal of a detonating explosive is a mixture of 8 parts, 88.9 p.c., of liquid oxygen, and 1 part, 11.1 p.c., of liquid hydrogen. The chemical affinities of oxygen in the liquid state are still strong, and a mixture of liquid oxygen with combustible matter, when initiated by a suitable detonator, forms powerful explosives.

Linde, in 1896, made practical use of the

idea, and first used explosives in which liquid air was absorbed in cotton wool, wood charcoal, and other combustibles. These mixtures were found not to detonate very readily, and subsequently kieselguhr, petroleum charcoal, and cork charcoal were used as absorbents, sometimes with the addition of liquid petroleum; liquid oxygen was also tried. This improved the detonation, but the explosives were found to be unduly sensitive to blow. The porous case containing the absorbent was dipped in a vessel of liquid air for some time, and the cartridge was fired in the usual way by means of an electric detonator or Bickford fuse.

These explosives were patented under the name of *Oxyliquit*, and a full description of them is given by Sieder in the *Zeitsch. ges. Schiess- u. Sprengstoffwesen*, 1906, 87. They were given an exhaustive trial by an Austrian Commission in 1899, and were largely used in blasting the Simplon Tunnel. Their cost is comparatively small, there is no danger in their manufacture, and they are powerful, but the practical difficulties in their use are great. The plant for producing the liquid air has to be close to the blasting operations, the liquid being transported in open cans, with consequent loss, the cartridges have to be fired within 5 to 15 minutes after preparation, according to their size, and the effect varies with the time of standing.

Schulz (Glückauf, 1898, 341) experimented with coal dust soaked in liquid air. He found that when the cartridges were dipped in liquid air of normal composition, containing 23.2 p.c. oxygen by weight, they were less powerful than ordinary dynamite, but were more powerful than dynamite if liquid air that had partly evaporated and contained 50 to 60 p.c. oxygen was used.

Fürstenhoff (Fr. Pat. 377103, 1907) suggested an absorbent of powdered metal, such as aluminium or magnesium, the rapidity of explosion being increased by mixing the metals with hydroxides of calcium and sodium. The principle of keeping the liquid oxygen definitely apart from the combustible until the moment of use was introduced by Nodon (Fr. Pat. 448732, 1911). A thin brass cylinder containing the liquid oxygen was introduced into another double-walled brass cylinder with non-conducting material between the walls, surrounded by kieselguhr, saturated with a liquid carbon compound, such as alcohol, glycerin, benzene, or pitch, the cylinder of liquid oxygen being punctured immediately before the cartridge was fired. The Soc. L'air Liquide (Fr. Pats. 450750 and 451265, 1912) proposed an absorbing porous cylinder closed at one end, made of a mixture of kieselguhr with aluminium, or a metallic silicide or hydride, bound together by a little sodium silicate. The liquid oxygen being poured into the cylinder immediately before use, and in a later modification (Fr. Pat. 451265, 1912) substituted the aluminium by coal or a hydrocarbon.

Owing to the excessive military requirements of high explosives of a permanent character during the last few years, liquid air explosives have been largely used for industrial blasting work on the Continent. No new principles in their use have been enunciated, but the details have been the subject of several patents. Weber

in Germany has suggested, for example, an absorbent of cotton, sawdust, powdered cork, or other combustible material, capable of absorbing more than its own weight of liquid air, the cartridge being reinforced by aluminium powder, or a mixture of this with magnesium, antimony, silicon, etc., in a separate container. For obtaining disruptive effects of a lower order, inert material, such as iron-ore dust, is substituted for part or all of the metal.

EXPLOSIVE COMPOUNDS.

In explosive compounds the combustibles, carbon and hydrogen, exist in infinitely close contact with oxygen in the same molecule. The most important compounds contain nitrogen in loose combination with all or part of the oxygen, so that the chemical equilibrium is more or less unstable. With the requisite exciting force the molecule undergoes more or less complete internal combustion, with almost instantaneous evolution of highly heated gaseous products. Explosive compounds are consequently, as a class, more sudden and violent in their action than the explosive mixtures, and it is evident that the nature of their explosion cannot be graded, as in these mixtures, by varying the ratio of combustible to oxygen.

The most important explosive compounds are produced by the nitration of organic compounds. They may be subdivided chemically into two main groups, the nitro derivatives and the true nitric esters, although technically they are all termed nitro explosives. Besides these two main groups, there are other classes of explosive compounds, such as the fulminates, amino, nitroamino, azo derivatives, azides, etc.

NITRO DERIVATIVES.

The nitro derivatives are, as a class, more stable and less energetic than the nitric esters. They are, unlike the nitric esters, not liable to spontaneous decomposition if slightly impure, and are stable even in the presence of relatively large quantities of acid. The difference in the explosive characteristics of the two classes is due to a lower percentage of oxygen, and consequent less complete combustion, and a more stable internal structure of the molecule in the nitro derivatives.

They are extremely difficult to explode by simple heating, although Berthelot has shown that even nitrobenzene may be exploded if a small quantity be dropped on to a highly heated surface, but they can all be exploded by the use of a sufficiently powerful detonator. Some of the higher derivatives, such as trinitrotoluene and trinitrophenol, are amongst the most powerful and important 'high' explosives known, but the lower derivatives are not explosives in themselves except under initiatory impulses impossible in practice, and are mostly used as constituents of explosive mixtures, principally with ammonium nitrate, potassium chlorate, or ammonium perchlorate, the nitrohydrocarbons being usually fused before mixing with the oxidising ingredient. Mixtures of nitro compounds are frequently used as explosives for specific purposes. The sensitiveness of trinitrotoluene may be increased, for example, by mixing with picric acid, and that of picric acid reduced by mixing with dinitrophenol.

Another advantage obtained by using such mixtures is that the mixtures melt and can be poured at a considerably lower temperature than the constituents. The eutectic mixture of picric acid and trinitrotoluene, containing about 34 p.c. of the former, melts at 55°.

Nitrohydrocarbons.

The hydrocarbons are nitrated in the usual manner by mixtures of nitric and sulphuric acids, the degree of nitration being controlled by the composition of the mixed acid, its proportion relative to the hydrocarbon, and the temperature of nitration. For the higher nitrations, 'oleum' or Nordhausen sulphuric acid is used for bringing up the concentration of the mixed acids, and when the nitration takes place in stages the spent acid from the higher nitration stage is frequently used, after adjustment of its composition for the first stage of the process. Economy of working is effected by the use of solid sodium nitrate instead of nitric acid in some cases.

The aromatic hydrocarbons used for the manufacture of nitro explosives are usually obtained by the fractionation of coal-tar, but some naturally occurring petroleum contain a considerable proportion of benzenoid hydrocarbons, and processes have been patented in the United States and in Germany for their production from petroleum and paraffin hydrocarbons by a process of 'cracking' and fractional distillation. The American Aetna Explosives Co. spent large sums in developing the U.S. Bureau of Mines' vapour phase cracking process, but the cracked oil contained only about 3 p.c. benzene and 2½ p.c. toluene, and the best benzene and toluene obtained by fractionation contained about 10 p.c. of paraffins of the same boiling point. In the nitration of the toluene so obtained, for example, the mononitrotoluene first formed may be separated from the paraffins by solution in sulphuric acid before further nitration (Flürscheim, U.S. Pat. 1225321, 1917).

The *nitrobenzenes* are not used as explosives alone, although they can be exploded with difficulty, but the mono- and di-derivatives are used, in combination with oxidising salts or with more explosive compounds, in many modern explosives mostly used for blasting purposes. Numerous instances of these are given. Dinitrobenzene is also used to some extent in some sporting semi-smokeless powders, and is added as a constituent in some dynamites to lower the freezing-point of the nitroglycerin and prevent freezing. Tri- and tetra-nitrobenzenes, obtained by the drastic treatment of benzene with mixed acids, are both more easily exploded than the di-derivatives, but little use has been made of them up to the present, owing to the difficulty in their manufacture and the poor yields obtained, although trinitrobenzene has been proposed as a substitute for picric acid as a high explosive by the Chemische Fabrik Griesheim (Ger. Pat. 79477, 1893). Trinitrobenzene is more powerful than trinitrotoluene. According to Dautriche (Mém. P. et Saltp. 1911-1912, 27) trinitrobenzene when compressed into pellets at pressures from 275 to 4125 kilos. per sq. cm. has a density of from 1.343 to 1.662. When loose its velocity of detonation is 3900 metres per sec., and in pellets at a density of

about 1.3 a velocity of detonation of 6,700 metres per sec. 10 gms. exploded in a lead block gave an expansion of 241 c.c., that of trinitrotoluene being 216 c.c., and of picric acid 228 c.c.

Mono- and dinitro- benzene are active poisons, and care is necessary in handling bare explosives containing them as ingredients.

Nitrotoluenes.

The mono-, di-, and tri-nitrotoluenes are all, but principally the two latter, used as constituents of explosive mixtures, but the trinitro derivative has also become of importance as a high explosive for military purposes. Trinitrotoluene is obtained by the nitration of toluene in stages, so that it is unnecessary to make separate mention of the manufacture of dinitrotoluene.

The lower nitrotoluenes have toxic properties, and usually cause a very irritant dermatitis, although some persons are more or less immune from the latter. The poisonous character and irritant properties of crude trinitrotoluene are probably largely due to the lower nitro impurities, especially dinitrotoluene, but fatal cases of poisoning have been attributed to the presence of tetranitromethane.

Trinitrotoluene in the explosives industries of this country is usually known as 'T.N.T.', and this was at one time the service name, but it is now called 'Trotyl.' It is also known in different countries under the names 'tolite,' 'trilit,' 'trinol,' 'tritolo,' and 'triton.'

Manufacture.—It is manufactured by the nitration in stages of the carefully purified hydrocarbon, about 99 p.c. pure and of about 0.866 sp.gr. The nitration is carried out usually in either two or three stages, in cast-iron vessels, sometimes enamelled. The nitrating pans are jacketed so that the temperature may be controlled by the circulation of either cold or warm water, and are provided with a suitable stirring apparatus, such as paddles and baffle plates, and usually with a cover through which pass a fume pipe, the acid supply pipe, a pipe for the hydrocarbon and a thermometer. The toluene is nitrated first of all to mononitrotoluene, or directly to dinitrotoluene in the two-stage method. In the first stage the waste acid from a previous tri-nitration is used after being brought up to the requisite strength by the addition of nitric acid, this being run into the toluene in some factories, in others the hydrocarbon is run into the mixed acid. A suitable acid mixture for mononitration is 170 parts of mixed acid, containing 2 parts of nitric acid of sp.gr. 1.42 and 3 parts of sulphuric acid of sp.gr. 1.84 per 100 parts by weight of toluene. The acid or hydrocarbon is run gradually and with constant agitation into the hydrocarbon or acid, the temperature not being allowed to rise above about 30°. When the admixture is complete and there is no tendency to further rise of temperature, the reaction is allowed to continue for about 30 minutes, the mixture allowed to separate, and the spent acid is drawn off. The crude mononitrotoluene is then converted into dinitrotoluene by treating 100 parts of the former with 215 parts of mixed acid, containing 1 part of nitric acid sp.gr. 1.5 and 2 parts of sulphuric acid of sp.gr. 1.84, the temperature during their slow admixture being about 60°

to 70° and then raised gradually, with constant agitation of the mixture, to 90° to 100° and kept at this temperature for 30 minutes. The stirring is then stopped, the mixture allowed to settle, and the spent acid drawn off. The trinitration is effected by heating 100 parts of the crude dinitro product with 225 parts of oleum, containing 20 p.c. SO_3 , and 65 parts of nitric acid of sp.gr. 1.5, first for 1 hour at 95° and then for 1½ hours at 120°C. After standing for some time, the spent acid is drawn off and the trinitrotoluene washed with water. A yield of some 80 to 85 p.c. of the theoretical is obtained.

It is advisable to carry out the nitration of the dinitro into the trinitro product as a separate operation, otherwise a very large volume of strong mixed acids at a high temperature is required, and this leads to a low yield owing both to the solubility of the product in the mixed acid, and to its partial oxidation. The manufacture of trinitrotoluene by one continuous process has, however, been considerably improved and is now frequently used. Will (Ber. 1914, 707) states that trinitrobenzoic acid and tetranitromethane may occur among the products of nitration, the latter, if present, being readily recognisable by its powerful and characteristic odour, and Capisaw (Chem. News, 1915, 247) states that the oxidising action of the nitrating acids is increased by the presence of metallic salts, sodium nitrate, and especially ammonium nitrate. Phenolic compounds are liable to be formed by the action of hydrogen liberated by the action of acid on the metal nitrating vessels, and sulphonic acids may occur if there is any deficiency of nitric acid in the mixed acids.

The waste acids of the early nitrations contain trinitrotoluene and other nitro products, which may be separated by dilution with water, or removed by agitation with solvents, before the acid is denitrated and concentrated. Leitch (Eng. Pat. 15455, 1915) uses toluene or mononitrotoluene for the extraction, under suitable conditions of temperature and concentration, the product being again submitted to the nitration processes, and Johnson (U.S. Pat. 1271578, 1918) submits the spent acid to reduced pressure, the liberated gas bubbles float the trinitrotoluene to the surface and the spent acid is drawn off from below.

Purification.—The crude trinitrotoluene, which melts at about 70°, is washed free from acid by melting and repeated agitation with hot water, sometimes made alkaline in the early washes with a little caustic or carbonate of soda. Purification by washing with alkali is inadvisable, however, for Will has shown (Ber. 1914, 711) that dinitrocresylates are formed from the β and γ trinitrotoluenes present as impurities by the action of alkalies, which like the nitrophenates are sensitive salts. After drying the product forms commercial *crude trinitrotoluene*, and is used of this purity for most commercial explosive mixtures and for many military purposes. It consists essentially of symmetrical α , or 2,4,6 trinitrotoluene, with small quantities of the β or 2,3,4, and γ or 2,4,5 trinitrotoluenes with some dinitrotoluene and possibly mononitrotoluene. In addition, besides traces of the impurities mentioned above, free acid and sometimes alkali, may be present.

For some purposes the crude trinitrotoluene is further purified either by soaking the powder in a solvent such as cold alcohol or benzene, in which the impurities are more soluble, or by recrystallisation from the same solvents, or preferably a mixture of the two is used containing 10 p.c. benzene, or from light petroleum or toluene. Recrystallisation from mononitrotoluene has been patented by Roberts and Stuart (Eng. Pat. 7047, 1915), the solution of impurities being used for further manufacture of trinitrotoluene, but freeing the product from mononitrotoluene must be difficult, and in France recrystallisation from strong sulphuric acid is sometimes used, with subsequent washing with water. In recrystallisation from alcohol, or alcohol and benzene, the crude trinitrotoluene is dissolved in a steam-jacketed vessel fitted with a condenser, the solution sucked through a filter cloth by a vacuum, and the trinitrotoluene allowed to crystallise out. A second recrystallisation may be used where a product of the highest degree of purity is required. The crystals are freed from residual solvent first by whizzing in a centrifugal and then by exposing on trays in drying ovens heated by hot air, or sometimes the product is dried more quickly in the molten condition in vacuum driers, and afterwards cast and powdered.

Specifications.—The following specifications for the two grades of trinitrotoluene issued by the U.S. Navy Department are typical:—

Grade A. Refined.—The trinitrotoluol must be a high-grade material, made from a suitable quality of raw materials. It must be thoroughly purified by recrystallisation from an approved solvent, so that the finished product shall have the following characteristics. The material must be in the form of a slightly yellow, fine, and uniform crystalline powder. At least 99 p.c. must pass through a sieve of 12 mesh to the linear inch. No odour of any by-product or crystallising agent may be present. It shall have a m.p. of at least 79°. It shall be free from acidity, and shall not show more than traces of metallic salts or residual solvents. The average moisture of a lot shall not be greater than 0.1 p.c. The average ash of a lot shall not be greater than 0.1 p.c. It shall not contain more than 0.15 p.c. material insoluble in alcohol. It shall contain no free toluol, or impurity giving a nitric acid reaction with a sulphuric acid solution of diphenylamine. It shall contain not less than 18.20 p.c. nitrogen as determined by Dumas' combustion method. It shall give a heat test of at least 30 minutes at 65.5° with potassium iodide—starch paper.

Grade B. Crude.—The trinitrotoluene must be a high-grade material made from a suitable quality of raw materials. It shall be a yellowish, uniform, crystalline powder of such fineness that at least 90 p.c. will pass a sieve of 10 meshes per linear inch. It shall have a m.p. of at least 75.5°. It shall be free from acidity. It shall show not more than traces of metallic salts. The conditions as to ash, moisture, insoluble in alcohol, content of free toluol, and products giving a reaction with diphenylamine are the same as for the refined product. It shall contain not less than 18 p.c. nitrogen as determined by Dumas' combustion method.

One objection to the use of crude trotyl as

a shell charge is that the lower melting impurities tend to exude as an oil during storage at a high temperature, and if this exuding oil penetrates to the priming or detonating charge this may be so deadened that failure to detonate results.

Liquid trinitrotoluene. The nitrated products recovered from the solvent used in the recrystallisation of crude trinitrotoluene, a thick brown syrup consisting essentially of a mixture of β and γ trinitrotoluenes, dinitrotoluene and a little mononitrotoluene is used in certain plastic explosive mixtures under the name of 'liquid trinitrotoluene.' A liquid product obtained by the direct nitration of crude trinitrotoluene is also used by this name, it is of similar composition except that it contains more α -trinitrotoluene and some un-nitrated hydrocarbons.

Properties.—Trinitrotoluene crystallises from alcohol in sulphur-yellow needles, but when petroleum or toluene is used the crystals are darker and of a light buff colour. Its colour is darkened by exposure to light; when freshly sublimed in the dark it is quite colourless. When pure, it is without odour and practically insoluble in cold water. It melts at 81.5° . It is soluble to a slight extent in hot water, and dissolves readily in alcohol, light petroleum, benzene, and other organic solvents. It dissolves in concentrated sulphuric acid at 90° – 100° , and separates unchanged on cooling.

Crystals of trinitrotoluene have a density of 1.5, that of the solidified mass after fusion being 1.6.

Trinitrotoluene is chemically very stable, but undergoes very slight decomposition with evolution of gas at 180° . On application of a flame, trinitrotoluene burns with a hot but very smoky flame. It ignites more readily than picric acid, its ignition point being about 250° . It cannot be exploded by flame in the open and alone, and only quite locally by very strong percussion, but can be readily detonated by means of mercury fulminate. As much as 1000 kilos. have burned away quite quietly in a conflagration, and a rifle bullet may be fired through a solid mass without causing explosion; but disastrous explosions have occurred when very large quantities have been involved in a fire. It may be detonated in the powdered or finely crystalline form by means of a No. 3 detonator containing 0.54 gram fulminate composition, but when fused, it requires priming either with some of the loose powder, or other explosive such as 'tetryl.' Its velocity of detonation depends on its density, or degree of compression, but is about 7000 m. per sec. It is quite safe to handle, and is stable under very varying atmospheric conditions.

Trinitrotoluene is the most important of shell high explosives. Over picric acid it has the distinct advantages that it does not combine with metals, and, generally, has no acid properties. When pure its dust and vapour are not irritating or injurious to those working with it, and it has a considerably lower melting-point and is not so sensitive. It is slightly less powerful than picric acid in the ratio of about 91 : 100, and owing to its lower velocity of detonation has less shattering effect; but this is an advantage, since in the fragmentation of a shell the pieces

are sufficiently large to have considerable destructive effect. The lower bursting effect of trinitrotoluene, as compared with picric acid, is attributed by Kast to its lower density and lower rate of detonation (6700 metres per second against 7100 metres per second). It is a less powerful explosive than wet gun cotton, but its effect at a distance is greater, and it has replaced gun cotton in most countries as a charge for torpedo war-heads and for submarine mines. It was first used in Germany in 1904.

Trinitrotoluene fulfils in a high degree the requirements of a military high explosive. The desirable properties are that it should be very powerful, but that its effects should not be too shattering or local, that it should be safe to handle, transport, and store under normal conditions of use, including those of a ship's magazine in a hot climate, that it should be chemically stable under all storage conditions, that it should be capable of certain and complete detonation, both in small and in large shell, under suitable impulse, but that it should be sufficiently insensitive to withstand the shock of discharge when fired in a big shell at full range.

Trinitrotoluene is deficient by 65.9 p.c. in oxygen for the complete combustion of its carbon and hydrogen, and by 22 p.c. when its carbon is burned to monoxide, and when detonated even completely free carbon is liberated in the form of thick black smoke.

According to Dautriche (Mem. Poud. et Saltp. 1911–1912, 27) when crystals are compressed into pellets at pressures varying from 275 to 4125 kilos. per sq. cm., trinitrotoluene has a density varying from 1.320 to 1.610, picric acid varying from 1.315 to 1.740, the velocity of detonation of the loose powder being 4100 metres per sec., picric acid being 5100, and of pellets at a density of 1.3 being 6200 m. per sec. for trinitrotoluene, and 6300 m. per sec. for picric acid. When 10 grams were fired in a standard lead block the expansion with trinitrotoluene was 216 c.c., that of picric acid being 228 c.c.

Shells are usually filled with trinitrotoluene, as with picric acid, by melting the compound and allowing it to solidify in the shells. Bichel (Fr. Pat. 357925, 1905) proposes to use compressed trinitrotoluene, which he had previously shown to have a higher velocity of detonation than in the loose condition, as an explosive for shells, mines, and torpedoes, by cementing together blocks of the compressed material by means of the fused compound, and, in a later patent (Fr. Pat. 369371, 1906), proposes to obtain a higher density than by simple casting, with trinitrotoluene as well as with other fusible nitro-explosives, by casting in a closed vessel, first placed under evacuation, to remove all air bubbles, and then submitting the molten mass, whilst rapidly cooled by means of a water-jacket, to compressed air or carbonic acid gas. A density as high as 1.69 has been obtained in this way.

Nobel (Ger. Pat. 212169, 1907) has patented a method of increasing the density of trinitrotoluene, and other suitable nitrohydrocarbons, by first cooling the shell to 0° before pouring in the liquid. Rudeloff, by compression under 3000 atmospheres, has obtained a mass with a density of 1.7, that can be cut and worked like wet gun cotton. The detonation of the densified

solid is facilitated by using some of the loose trinitrotoluene as a primer.

Trinitrotoluene is also used in considerable quantities for detonators. It is employed either alone, with a priming of mercury fulminate, or as an ingredient in cap and detonating compositions. It is, for example, stated that in a No. 7 detonator the 1.5 grams of fulminate can be advantageously replaced by a mixture of 0.7 gram of trinitrotoluene and 0.5 gram of fulminate.

Trinitrotoluene has been suggested in various mixtures as a high explosive for shells and torpedoes. Bichel (Fr. Pat. 369661, 1906) makes a plastic explosive called '*plastrotyl*,' by mixing it with a solid or liquid resin, such as copaiba balsam, or larch turpentine, with or without the addition of dinitrotoluene and collodion cotton. Rudeloff and Allendorff (Ger. Pat. 201306, 1906) make '*triplastit*,' with a density as high as 2.5 by mixing with a jelly prepared from dinitrotoluene and soluble dinitrocellulose, heating slowly to about 80°, and incorporating, as an oxygen carrier, a mixture of potassium chlorate and lead nitrate.

Trinitrotoluene is a constituent of many modern ammonium nitrate safety explosives, in which it has replaced the dinitrobenzene, which was more common in earlier mixtures, as it is not only more powerful but also less toxic.

Mixtures of ammonium nitrate with trinitrotoluene have been generally and largely used as a military high explosive for shells, bombs, grenades and mines. Sometimes a little wood meal and nitroglycerin are added to assist in the detonation, as in the German '*Astralite*.'

Amatol. In this country the mixtures of ammonium nitrate and '*trotyl*' are known as '*Amatol*.' The mixtures are used in various proportions designated by a fraction of which the percentage of ammonium nitrate is the numerator, for example, 90/10, 80/20, 50/50, and 40/60. The proportions for complete combustion of the trinitrotoluene are 78.7 p.c. ammonium nitrate and 21.3 p.c. *trotyl*, so that '*Amatol* 80/20' approximately fulfils this condition. Sometimes the mixtures are milled cold and 'stemmed' or rammed into the receptacles, sometimes, when the proportion of *trotyl* is high, this is melted and the plastic mixture is poured directly, or compressed into slabs and packed, into shells. These mixtures form powerful high explosives, somewhat more powerful than *trotyl* alone, owing to the more complete combustion, but the shattering effect is less than with *trotyl* alone, owing to the lower velocity of detonation which is of the order of 5000 to 6000 metres per sec., according to the proportions. The lower shattering effect is not necessarily a drawback. The mixtures are difficult to detonate, the difficulty increasing with the proportion of ammonium nitrate and with the degree of compression, and it is necessary to prime them with another explosive, when the use of a powerful fulminate detonator is inadmissible. They are hygroscopic, and precautions have to be taken to protect them from atmospheric moisture, and when efficiently detonated they are practically smokeless, giving only a slight grey or white cloud. Crude trinitrotoluene can be used for these mixtures,

especially in those containing a large proportion of ammonium nitrate, as there is no danger of the impurities exuding as an oil on storage at high temperatures.

Other nitrohydrocarbons. Nitroxylenes. The mixed tri-, di- and mono- nitrohydrocarbons obtained by the nitration of the fraction of coal-tar distillate containing the three isomeric xylenes are used in some explosives. '*Monachit*' is an ammonium nitrate explosive containing nitroxylenes, essentially the trinitro product. The nitrohydrocarbons, largely di- and trinitro derivatives of mesitylene and pseudocumene, obtained by nitrating solvent naphtha, have been proposed by Schulz and Gehre (Eng. Pat. 5687, 1905, and 19565, 1907) for use in explosive mixtures of the usual type, known as '*Vigorite*' and '*Bavarite*.'

The nitronaphthalenes, usually dinitronaphthalene, are occasionally used, principally associated with ammonium nitrate in safety explosive mixtures. Mononitronaphthalene occurs in the '*cheddites*,' di- and tri- nitronaphthalenes in the '*Grisounit*' and '*Ammonite*' class of explosives.

The nitrohydrocarbons of the fatty series have so far met with only a limited use. The Soc. anonyme d'Explosifs et de Prod. Chim. (Fr. Pat. 394992, 1907) claim the use in particular of mononitromethane, a liquid boiling at about 99°-100°, in smokeless powders with nitrocellulose, or nitrocellulose and nitroglycerin, and the use of tetranitromethane by Winand has already been mentioned under '*Sprengel Explosives*.'

Nitrophenols.

The potassium salt of mononitrophenol can be detonated by percussion, and it has been proposed in America (U.S. Pat. 792716, 1905, and 940580, 1909) to use dinitrophenol mixed with picric acid, to lower the melting-point of the latter, and as an ingredient in explosive mixtures, but the only nitro derivative of ordinary phenol used to any extent is picric acid, symmetrical trinitrophenol, which is largely used by itself as a high explosive, and to a limited extent in explosive mixtures, usually of the detonating class.

Dinitrophenol is used occasionally in mixtures of nitro bodies used as explosives, but is usually an intermediate product in the manufacture of picric acid from benzene. The benzene is first chlorinated, the chlorobenzene nitrated, and the resulting dinitrochlorobenzene heated with caustic alkali. The dinitrophenate is finally decomposed with hydrochloric acid, and the dinitrophenol washed and purified as usual. When pure it is a yellow crystalline substance, melting at 113.1°. Ellis and Wells (U.S. Pat. 1220078, 1917) nitrate the chlorobenzene by heating with sodium nitrate and sulphuric acid.

Picric acid. Manufacture.—Direct nitration of phenol with strong nitric acid gives picric acid, but the action is very violent, and there is considerable loss by oxidation, and it is preferable, therefore, to sulphonate the phenol before nitration. The reactions are:

In the old method of manufacture of picric acid, which is still largely used, very simple

apparatus is used, little or no care is taken in temperature control of the process, and considerable waste of sulphuric and nitric acids occurs, clouds of nitrous fumes from the nitrating pots being allowed to disperse over the surrounding country. A pure quality of phenol is taken, obtained either by careful fractionation of the coal-tar product or the synthetic material, and melted in its drums in a steam-heated chamber. The hot molten phenol is poured into about five times its weight of concentrated 98 p.c. sulphuric acid, from which the lead sulphate has been allowed to settle, contained in iron or enamelled-iron vessels, frequently ordinary household baths, arranged round a shed. The mixture is stirred occasionally with wooden or iron paddles for about two days, until the product is in the form of a solid white paste, without phenolic odour and completely soluble in water. A charge of the sulphionate and excess of sulphuric acid, sufficient to require a whole carboy of strong nitric acid for its nitration, is weighed out into the nitration pot, a little water is added and the mixture stirred occasionally during the day. The earthenware nitration pots, arranged in rows down a long shed open at the sides, are embedded in a non-conducting mass of ashes or similar material. A carboy of nitric acid is placed at the side of, and above the level of, the nitrating pot, and a narrow glass siphon arranged so that the nitric acid passes in a thin stream into the midst of the mixture during the night. The mixture is not stirred and the pots are unattended during this time. The mixture sets solid, but is stirred occasionally during the next day to complete the nitration, after the orange to red coloured crusts of low melting-point material have been removed, for sale as second-grade material after washing. The preliminary washing of the product is carried out in wooden boxes, with inclined bottoms perforated at the lower end, by pouring a few buckets of water over it. For the final washing the contents of several boxes are emptied into baths similar to those used in the sulphonation stage, water is run in from a tap and the contents of the bath stirred by hand with wooden paddles, the wash water, like that from the preliminary washing, being run away down a drain or gully to a small pond, by opening the plug of the bath. Three or four such washings are found to efficiently remove the mineral acidity. The completion of a batch of picric acid by this process takes about a week.

In more modern practice, the sulphonation is carried out in large iron lead-lined tanks or 'kettles,' fitted with a steam jacket and paddle agitators. As the mixture is kept hot and agitated a smaller proportion of sulphuric acid is required, $3\frac{1}{2}$ to 4 parts being used. The nitration is sometimes carried out in earthenware pots, as above, but fitted with covers and fume pipes leading to a stack; but the most modern method is to have the nitration pots of enamelled iron and jacketed, and nitration is temperature controlled by the circulation of hot or cold water. The temperature of the hot sulphionate is allowed to fall to about 20° , and whilst rapidly agitated, the nitric acid is gradually run in, the quantity used being about four-thirds that theoretically required. The temperature is allowed to rise gradually during the

addition to the nitric acid of about 70° – 80° , and the nitration completed by further agitation for about 2 hours. The nitrous fumes evolved are condensed and reconverted into nitric acid. The product is run off into wooden or enamelled vessels, diluted with about an equal volume of water, and allowed to cool. The crystals of picric acid are filtered off, often with use of a vacuum, and washed by a spray of water in a centrifuge, until practically free from sulphuric acid. The crystals, owing to the agitation, are small and free from aggregations, are pure and readily washed.

A further quantity of picric acid is obtained in the early part of the concentration of the spent sulphuric acid. The final washing is sometimes done with alcohol: this gives a purer product as the alcohol dissolves resinous impurities, and also facilitates the drying of the picric acid, the alcohol being recovered.

Large quantities of picric acid are now produced, especially on the Continent, by the direct action of sulphuric acid and sodium nitrate on phenol; the difficulty in freeing the picric acid from sodium sulphate is one objection to this process.

Drying, grinding and sifting. The preliminary drying of the picric acid, sometimes filled into large canvas bags, is effected in the centrifugals. For the final drying, the picric acid is spread out, in stoves or sheds, on broad glass shelves, the glass being strengthened by wire-netting insertion. In some stoves the shelves are of enamelled iron or of aluminium, but wet picric acid has a slight action on aluminium. The stoves are heated by steam pipes below the shelves, and the acid is turned over occasionally with wooden rakes until dry. The dry acid is fed by means of a hopper through a sieve worked mechanically into a closed chamber, from which the material is packed. Lumps and aggregations of crystals left on the sieve are ground in an edge-runner mill and re-sieved. The drying and grinding of picric acid are dangerous operations, and whenever possible are not performed in the picric acid works, the product as it leaves the centrifugals being transported in the damp condition to the explosives factory. With this precaution and care to avoid contact between the damp picric acid and metals, except aluminium and tin, the manufacture of picric acid is practically free from danger.

To obtain more perfect purification from the last traces of mineral acids, picric acid may be converted into its sodium salt by dissolving in hot solution of sodium carbonate. On cooling, almost chemically pure sodium picrate crystallises out; this is centrifugated, washed with cold water, dissolved again in hot water, and the acid precipitated by adding an excess of hydrochloric acid. This is finally purified by washing and centrifugation, and the last traces of acid are volatilised on drying.

Gutensohn (Eng. Pat. 16628, 1900) proposes to add the phenol, dissolved in paraffin or similar oil, directly to the nitric acid, covered with a layer of the same oil, in order to moderate the nitration reaction without sulphonation.

Wenghöffer (Ger. Pat. 125096, 1900) suggests aniline as the primary material instead of phenol, as being less subject to variation in

market price. It is converted, through sulph-anilic acid, into diazobenzene sulphonic acid, which readily yields picric acid on nitration, a yield of 90 p.c. of the theoretical being claimed.

Hepp (Annalen, 1882, 344) suggested the preparation of picric acid from benzene by first converting this into trinitrobenzene, and then oxidising the product with a mild oxidising agent such as an alkaline solution of potassium ferricyanide. He claimed a good yield, and successful commercial manufacture based on this suggestion is said to have taken place, but the difficulty in the trinitration of benzene would seem to throw doubt on this.

Properties.—Picric acid crystallises in bright pale-yellow plates or prisms. When recently sublimed in the dark it is quite colourless, and the colourless tautomeride is also the stable form in contact with strong acids. It is sparingly soluble in cold, but more soluble in hot water. It has an exceedingly bitter taste, and its taste and colour are imparted to very dilute aqueous solutions. It is readily soluble in alcohol, acetone, ether, and benzene. It melts at 121.6° to a yellow liquid, and by careful heating may be sublimed without decomposition, the vapours being very bitter and irritating. Picric acid ignites at about 260°. Suddenly heated, it deflagrates sharply, with a bright-red sooty flame, and Berthelot has shown that a small quantity dropped on a red-hot surface decomposes with explosive violence.

Large masses of picric acid can be heated in a confined space without explosion, but Berthelot is of the opinion that the explosion of a small quantity by a heated surface may, under certain conditions, cause detonation of a large mass of picric acid. Some big explosions following fires at picric acid works are to be explained in this way.

It is difficult to explode picric acid by direct percussion, but it can be readily detonated by mercury fulminate; 1.5 grams of fulminate act well for the dry powder; even wet picric acid, containing as much as 15 p.c. of water, can be so detonated if a priming of the dry acid is used.

The heat of formation of picric acid is 49.1 cals., and the heat of total combustion in oxygen 618.4 cals. (Berthelot).

Picric acid does not contain sufficient oxygen for complete combustion, and it is 3.49 p.c. deficient for the formation of carbon monoxide, and 45.41 p.c. deficient for the formation of carbon dioxide. Nevertheless, when efficiently detonated, it is one of the most powerful explosives known, exceeding dynamite and compressed guncotton in power, especially when densified by fusion and solidification. Complete detonation is accompanied by a black smoke. The density after casting is 1.6–1.7, and it can be obtained with a still higher density by Bichel's method of casting under pressure.

Picric acid was first suggested for use as a semi-explosive ingredient in propellant explosives. Sprengel (Chem. Soc. Trans. 1873, 803) was the first to call attention to the explosive possibilities of picric acid in itself, but it was not till 1886 that Turpin made a practical high explosive of it, by suggesting the use of compressed or molten picric acid as a charge for shells. The value of picric acid as a high explosive lies in the fact, as Turpin pointed out,

that in this class of explosives the maximum effect does not coincide with complete combustion, but occurs where the carbon is burnt to carbonic oxide, the greater gas evolution more than counterbalancing the smaller heat of combustion. Turpin's first '*Melinite*,' adopted in France as a high explosive for shells, was picric acid made into a colloidal state and densified by the addition of a solution of 3–5 p.c. collodion cotton in alcohol and ether, but very soon this was abandoned in favour of the fused picric acid alone, as Turpin showed this to be still more powerful, and so insensitive that it could only be detonated under strong confinement. Picric acid was adopted for use as a high explosive in Germany in 1888. The English '*Lyddite*' is simply fused picric acid, melted in large cans of copper tinned, of aluminium, or enamelled iron, in a carefully regulated hot-air stove, at 130°–140°, and filled directly into the shells, a central cavity being left for the exploder. Picric acid has been used for similar purposes, also for mines and torpedoes, by most other countries under various names, such as '*Ecrasite*,' '*Shimose*,' '*Portite*,' '*Picirnit*,' &c.; in some cases additions of other substances, such as nitronaphthalene, di- and trinitrotoluene, trinitrocresol, being made in order to reduce the melting-point. As the melting-point of picric acid is so high, and its sensibility to percussion increases with the temperature, its fusion on the large scale is to some extent dangerous. Girard (Eng. Pat. 6045, 1905) gives a long list of the melting-points of equimolecular mixtures of picric acid with other nitro derivatives; in all cases the melting-point of the mixture is well below that of the constituent of lower melting-point.

The cast picric acid, when unconfined, is much more difficult of detonation by mercury fulminate than the loose acid; 3 grams of fulminate fired in the mass will not explode it. It may be detonated by using a priming of the loose acid or of guncotton, but much more perfectly by a primer of '*picric powder*,' or trinitrotoluene.

On the assumption that the explosion of '*lyddite*' is represented by the equation:

de la Roque (Rev. de Chim. Industrielle, 11, 5) has calculated the following constants:—

Heat evolved at constant pressure per kgm.	853.4	kgm.-cals.
Heat evolved at constant volume per kgm.	876.0	” ”
'Potential' (i.e. maximum work by unit weight, assuming complete gasification and adiabatic expansion)	272,280	kgm.-metres
Volume of gas from 1 kgm.	683,453	c.c. at N.P.T.
Temperature of explosion	2832°	
Pressure developed by the explosion of 1 gram in unit volume	8086	kgms. per sq. cm.

Actual analysis has shown that, when explosion takes place, the decomposition is more complicated than this, the products being: carbon monoxide, carbon dioxide, nitrogen, nitric oxide, water, hydrocyanic acid, and residual carbon.

Picric acid is safe to manufacture and transport. The advantages of cast picric acid as a high explosive are many, its physical and chemical stability are very great, and it can be kept for an indefinite period under varying atmospheric conditions; it is difficult to ignite, and it is very insensitive to percussion; is quite safe from the danger of being fired by the shock of the discharge of guns of large calibre, yet when perfectly detonated it is extremely powerful in its bursting effects. On the other hand, there are such disadvantages as its high melting-point, the objectionable nature of its vapours, which not only dye the hair, skin, and clothing of those working with it, but are also extremely irritating, if not harmful. It is difficult to detonate completely, and incomplete detonation yields very deleterious gases. The most serious objection of all, however, is its acidic character, which leads to the formation, in contact with metals and some of their compounds, of picrates, many of which are highly sensitive, the picrates of lead particularly so. Serious accidents have resulted in the use of picric acid, which have been attributed to the formation of these compounds, and for this reason the interiors of the shells are varnished, and lead compounds are carefully guarded against in the lutings used on the screw threads on the shell plugs, and in all paints and varnishes connected with picric acid shells. Trinitrotoluene is free from most of these objectionable features, and it has consequently more or less replaced picric acid in its many uses.

Emmensite (Eng. Pat. 370, 1888), the invention of Emmens of the United States, is produced as crystals, said to be different from picric acid, by the action of fuming nitric acid of sp. gr. 1.52 on picric acid. The explosive was favourably reported upon by the U.S. War Dept., and is said to be satisfactory, both as a propellant and as a high explosive.

Picrates. The picrates, formed by the action of the acid on the metals, their oxides, hydrides, or carbonates, are well-defined, crystalline compounds, which are quite stable under ordinary conditions, but they are all more sensitive to heat, friction, and percussion than the acid itself, particularly when free from water of crystallisation. This is true, to some extent, even of the alkaline salts, whilst the picrates, normal and basic, of some of the heavy metals, especially lead, are extremely sensitive and violent. Anhydrous ferrous picrate is very sensitive. The order of sensitiveness to percussion of some of the picrates most likely to occur is: lead, iron, cobalt, nickel, barium, copper, manganese, zinc, calcium, and sodium. They detonate with violence, and their detonation is sufficient to prime an indefinite amount of picric acid, and even wet picric acid may be involved. Ammonium picrate is the most insensitive. It has been proposed as a substitute for picric acid for use in shells, as it has no tendency to form dangerous picrates. The temperatures of ignition of picrates are given by Silberrad and Phillips (Chem. Soc. Trans. 1908, 474), and their relative sensitiveness by Kast (Zeitsch. f. d. Ges. Scheiss- u. Strenstoffw. 1911, 7, &c.). A very serious explosion of picric acid, near Manchester, in 1887, was caused by melted picric acid flowing on to

litharge, detonating with it, and thereby acting as a primer, causing the detonation of all the picric acid present. In connection with this explosion, Deering showed that very rough mixtures of picric acid with litharge, red lead, lead nitrate, strontium nitrate, lime, &c., detonated violently, and were sufficient to prime a large mass of picric acid. Mixtures of picric acid with certain peroxides will fire spontaneously.

Explosive mixtures containing picric acid and picrates. Many years before picric acid was used as a high explosive, attempts were made to use it and the picrates in explosive mixtures. It was recognised that picric acid is deficient in oxygen, and, consequently, picric acid and the picrates were proposed to be used mixed with various oxidising agents. However, the insensibility of picric acid is largely due to its deficiency in oxygen, and for this reason the mixtures with oxidising agents are all much more sensitive to heat, percussion, and friction than the acid itself. Mixtures containing picric acid, with either nitrates, chlorates, chromates, or permanganates, are extremely unstable, and liable to undergo spontaneous explosion, owing to the slow displacement of the highly oxidising acids by the picric acid, in the presence of even traces of moisture, and many serious accidents have been caused by such mixtures. Attempts have been made to increase the stability of picric acid mixtures by coating the particles of the acid with an insensitive and protective film; for instance, Roth (Eng. Pat. 173550, 1886) proposed a mixture of picric acid and ammonium nitrate with a fatty drying oil, and Turpin patented various mixtures of picric acid with gum, oils, fats, collodion jelly, &c.; but the picrates are far preferable to the free acid in explosive mixtures.

The picrates of ammonium, potassium, or sodium are those most frequently used in explosive mixtures. In 1869 Designolle made mixtures of potassium picrate and charcoal with nitre, in proportions varying according to their use, for small-arm and cannon powders, and mixtures of potassium picrate and nitre for filling torpedoes and shells. These mixtures were made in much the same way as ordinary gunpowder; they gave very good results, and were in use for some time in the French Navy. 60 grams of the propellant powders were said to give the same result as 350 grams of ordinary gunpowder, and the intensity of action of the disruptive powder was nearly 70 p.c. of that of dynamite No. 1. In the same year, Brugère and Abel, independently, recommended mixtures of ammonium picrate and nitre. Brugère's powder was composed of 54 p.c. of ammonium picrate and 46 p.c. of nitre. It was insensitive to friction or shock, slow burning, nearly smokeless, in small arms quite as powerful as gunpowder, and non-erosive. Abel's mixture, 3 parts of nitre and 2 parts of ammonium picrate, was at first proposed for use in shells, but afterwards adopted in the Service, under the name of *Picric powder*, as an exploder for priming lyddite shells. It is very stable, burns only locally with slight deflagration on application of flame, and requires strong confinement to develop its force, when it is very powerful. At one time it was manufactured and granulated like

Designolle's mixtures, but a mixture of 57 p.c. of nitre and 43 p.c. ammonium picrate, dry mixed, was subsequently adopted. It is easier and safer to make in this way, and the product is also more stable, for the wetting in the old method of manufacture caused the formation of a little hygroscopic ammonium nitrate by double decomposition. Its theoretical decomposition is :

Ammonium picrate, and more rarely, potassium picrate, mixed with the nitrates of barium, potassium, and ammonium, and other ingredients combustible and explosive, have been the subject of innumerable patents for so-called smokeless and safety powders, usually in America, Austria, or France. Detonating mixtures containing picrates and chlorate of potash have been proposed, and picrate of lead has been suggested for the same purpose. The picrate mixtures generally, however, are shunned in this country, owing to their chemical instability and the extreme danger in their storage and use.

Trinitroanisole, the methyl ester of picric acid, $C_6H_2OCH_3(NO_2)_3$, has been used to some slight extent as a high explosive in bombs by the Germans. Its manufacture is not easy, as the nitrating acids tend to attack the side chain. A method of preparation stated to give a 85 p.c. yield is described by Broadbent and Sparre (8th Int. Cong. App. Chem. 1912). 30 parts of anisole are added drop by drop to a mixture of 130 parts of nitric acid of sp.gr. 1.52, and 220 parts of sulphuric acid of sp.gr. 1.84, cooled to $-5^\circ C.$, the temperature being kept below 0° during the addition. The temperature is then allowed to rise slowly to $65^\circ-70^\circ C.$, and kept at this temperature for 20 minutes. The acids and mixture are kept constantly agitated during the addition and nitration. After cooling, the crystals of trinitroanisole are separated and washed, first with a 2 p.c. solution of sodium carbonate, and finally with water. The product was in the form of lemon-yellow crystals, melting at $64^\circ-65^\circ$. It is nearly insoluble in water, but readily soluble in alcohol, ether, and acetone; sp.gr. 1.408 at $20^\circ C.$ It has the same percentage composition as trinitrocresol, and similar explosive properties, that is, it is less powerful and less easily detonated than picric acid, but it has an advantage over the latter in that it does not form sensitive metallic salts. It is, however, slowly hydrolysed in the presence of water to picric acid, and more rapidly in the presence of alkali.

Trinitrocresol is manufactured from metacresol similarly to picric acid, and has very similar chemical and physical properties. It melts at about 107° . It is acidic and forms explosive salts. It has explosive properties similar to picric acid, and has been used, when cast, as a high explosive for shells and torpedoes, alone and mixed with picric acid. It contains less oxygen than picric acid, is less powerful, and less readily detonated. It requires priming, and guncotton is generally used for this purpose. In France it is known as '*Cresylite*.' In Austria the name '*Ecrasite*' has been from time to time applied to high explosives of different composition used for charging shells, but apparently

always containing trinitrocresol or its ammonium salt. Trinitrocresol has been used alone or mixed with picric acid, and the ammonium salt has been used alone or mixed with nitre. The ammonium salt is a yellow crystalline solid, melting at about 100° . It burns without explosion unless strongly confined, and is insensitive to friction and percussion. It is stemmed into shells with a wooden rod, or compressed into slabs. A guncotton primer is generally used to ensure complete detonation, but it can be exploded with a 2-gram fulminate detonator. A mixture of trinitrocresol and picric acid in molecular proportions, melted together and mixed with an oxidising salt, has been proposed by Girard (U.S. Pat. 895254, 1908). The trinitrocresylates are more sensitive to friction and percussion than the parent body, and generally have properties similar to those of the corresponding picrates, the lead salt and those of the heavy metals being the most sensitive.

The *higher nitrophenols* are all more or less explosive and yield explosive salts, but they have, as yet, met with no practical use.

NITRIC ESTERS.

On nitration, the organic alcohols and carbohydrates yield true nitric esters, or organic nitrates, which are explosive compounds. The internal structure and explosive characteristics of the nitric esters are different from those of the nitro derivatives, but, unfortunately, this difference has not been recognised in the technical nomenclature. The products of nitration of all organic substances, that are explosives, are all technically known as nitro explosives.

With reducing agents, the explosive compounds of this class yield more or less the primary substance of the nitration, and not amino compounds, as do the nitro derivatives, and by the prolonged action of caustic alkalis they give the primary substance and an alkaline nitrate, together with other products of secondary reactions. A simple test serves to distinguish the two classes of nitro compounds. When shaken with sulphuric acid, in a Lunge nitrometer, the nitric esters yield their nitrogen as nitric oxide; the true nitro derivatives do not do so.

The nitric esters, generally speaking, are more powerful explosives than the nitro derivatives, but are less stable, more especially in the presence of foreign substances, such as residual traces of the nitration acids.

Alcohol Nitrates.

The *Nitroglycols* have been repeatedly suggested as explosives, usually for admixture with nitroglycerin. Matthews, Strange, and Bliss (Eng. Pat. 12770, 1912) suggested the nitration of glycols having the hydroxyl groups attached to adjacent carbon atoms, or the corresponding oxides, and the preparation of explosives by admixture of the product with equal weights of nitroglycerin or nitrocellulose, and Hough (U.S. Pat. 1206223, 1916) claims, as a method of preparation of glycol dinitrate, the nitration of 1 part of glycol with 7 parts of an acid mixture containing not less than 93 p.c., nor more than 96 p.c., of total acids,

special claim being made for a mixture containing 35 p.c. HNO_3 , 59 p.c. H_2SO_4 , and 6 p.c. H_2O . Hibbert (U.S. Pat. 1216367, &c., 1917) produces explosives by dissolving a carbohydrate in a solvent medium containing a 1.2 glycol, and nitrating the solution. Similar explosives are made with a mixture of 1.2 glycols with ethylene-, propylene-, and butylene-glycols and polyglycols, and a carbohydrate. For example, 40 parts of cane-sugar are dissolved in about 60 parts of a mixture of ethylene- and propylene-glycols, solution is effected by heating to 80° – 100° , the mixture cooled, and added slowly to 800 parts of a nitrating mixture containing equal parts of 95 p.c. nitric acid and 'oleum' containing 6–10 p.c. SO_3 , cooled to about 5° . After mixing, with constant agitation, the temperature is allowed to rise to about 15° , and the nitration completed in about 20 minutes. After cooling, the nitrated product is separated and purified by washing with dilute sodium carbonate solution, and then with water. The product forms a pale-yellow oil, and is claimed to be relatively non-volatile and of low freezing-point.

Stettbacher (Zeitsch. Ges. Scheiss- u. Sprengstoffw. 1916, 11, &c.) describes the preparation and properties of the tetranitrate of pentaerythritol $\text{C}(\text{CH}_2\text{OH})_4$. The tetrahydric alcohol is prepared readily and cheaply by a method described by Tollens, and its tetranitrate is said to be particularly stable, and to combine the explosive properties of nitromannitol and nitroglycerin, whilst being free from their disadvantages. It is very powerful, and is claimed to possess in a high degree the power of initiating detonation in other explosives, though more sensitive than tetryl, and is suggested as suitable for use in primers, percussion caps, and detonators.

Nitroglycerins.

Mono-, di-, and tri-nitric esters of glycerin are possible. Liecke, in 1865, stated that he obtained mono- and di-nitroglycerin by nitrating glycerol at 0° in a mixture of 1 volume of nitric acid, sp.gr. 1.4, and 2 volumes of strong sulphuric acid; and later said that when nitric acid of 1.3 sp.gr. is used the mononitrate is obtained, whilst the dinitrate and trinitrate are respectively obtained by using an acid of 1.4 or 1.5 sp.gr.

Henriot claimed to prepare the mono-compound by nitrating glycerol with a dilute nitric acid containing 3 parts of water to 1 of strong acid; and Wohl (Ger. Pat. 53957, 1890) suggested the use of the mono- and di- compounds for reducing the freezing-point of nitroglycerin.

Mikolajczak did considerable work in 1904 on mono- and di-nitroglycerin (Zeitsch. Gluckauf, 1904, 629); and Will made a full investigation of their preparation, properties, and uses in 1908 (Ber. 41, 1107), from which work the following short description is taken.

Dinitroglycerin. Will prepared dinitroglycerin by the following modification of Mikolajczak's method of preparation. 10 parts of glycerol are slowly stirred into 33 parts of nitric acid, sp.gr. 1.5, kept at a temperature of below 0° , and the mixture allowed to stand for several hours at 10° . The mixture is then poured into 10 parts of water and neutralised with powdered marble. On standing, the

greater part of the dinitroglycerin separates as an oil, the remainder being extracted by ether.

Will's method of preparation is to slowly run 100 parts of glycerol, with constant agitation, into 500 parts of ice-cold mixed nitric and sulphuric acids, 3 parts H_2SO_4 to 1 part HNO_3 , and 9 parts of water to 100 parts mixed acids. The mixture is then poured into 10 parts of water, and the dinitroglycerin allowed to separate. The acid solution is then neutralised, extracted with ether, the ether distilled off, the separated dinitroglycerin washed with a little water, and dried over sulphuric acid.

Dinitroglycerin can also be obtained by dissolving trinitroglycerin in strong sulphuric acid, diluting the solution with water and extracting with ether.

Dinitroglycerin is a colourless or light-yellow oil, which solidifies below -13° , and distils without appreciable decomposition at 146° ; sp.gr. 1.47. It combines with water of crystallisation, and is hygroscopic. It is poisonous like trinitroglycerin. It is soluble to the extent of about 8 p.c. in water, and in all proportions in dilute nitric and sulphuric acids. It is also soluble in ether, alcohol, chloroform, acetone, carbon tetrachloride, and petroleum spirit. In strong sulphuric acid, like the trinitrate, it is denitrated, giving first mononitroglycerin, and eventually glycerol. When dry it dissolves and gelatinises nitrocellulose.

Will succeeded in separating dinitroglycerin into two isomerides by taking advantage of the property of one of them to form a crystalline hydrate. Both isomerides, when dry, have explosive properties resembling those of trinitroglycerin, but become non-explosive in moist air through absorption of water.

Mononitroglycerin was obtained by Will, by a process of crystallisation, from the oil extracted with ether from the neutralised and concentrated aqueous mother liquor obtained in the preparation of dinitroglycerin. He obtained two isomerides, both crystalline solids, melting at 54° and 58° respectively, and freely soluble in water.

Nitrodiglycerin. When glycerol is heated for 7–8 hours at 290° – 295° , it is largely converted into diglycerin, with a little triglycerin and higher polyglycerins. The diglycerin can be separated by fractionation, and on nitration gives a product almost identical in properties with nitroglycerin. If a mixture of glycerol and a little diglycerin is nitrated, the resulting product, which contains di- and tetra-nitrodiglycerin, has all the properties of nitroglycerin, but remains fluid at -15° to -20° (Will, Zeitsch. angew. Chem. 1906, 889).

Trinitroglycerin. Ordinary trinitroglycerin is the trinitric ester of glycerol. It was discovered in 1847 by Sobrero. In a letter to Pelouze (Compt. rend. 24, 247), he states that when glycerol is poured, with stirring, into a mixture of 2 vols. of sulphuric acid of 66° Baumé, and 1 vol. of nitric acid of 43° , cooled by a freezing mixture, the glycerol dissolves therein without perceptible reaction, and that on pouring the mixture into water an oily substance, heavier than water, is precipitated.

Sobrero described some of the properties of nitroglycerin, but did not analyse it.

No practical application of importance of the

properties of nitroglycerin was made until 1863, when its preparation on a large scale was commenced by Nobel, who started two nitroglycerin factories near Stockholm and near Lauenburg. It was first called 'pyroglycerin,' afterwards 'glonoin oil,' and still later 'Nobel's blasting oil.' Between 1863 and 1865 increasingly large quantities of nitroglycerin were made and exported; but serious accidents occurred about the year 1866 in different parts of the world, whether the nitroglycerin had been exported, and were followed by legislation on the part of several governments, prohibitive of its use. This restrictive legislation was met by Nobel by the introduction of dynamite in 1866-67, the carriage and use of this preparation of nitroglycerin being comparatively safe. Mowbray, before this time, had manufactured large quantities of nitroglycerin in Massachusetts, and it had been transported for use in the mines in the frozen state.

Manufacture.—The following is a short account of the manufacturing processes in general use for the manufacture of nitroglycerin, with special reference to some improvements adopted at the Royal Gunpowder Factory, Waltham Abbey (see Nathan and Rintoul, J. Soc. Chem. Ind. 1908, 1903). The chemical basis of the processes is essentially that of Sobrero's method of preparation, but the modern manufacturing plant is of entirely different type from that in use in the earlier factories, and the output has enormously increased.

Prime materials.—The *glycerol* used in the manufacture of nitroglycerin is the purest distilled glycerol obtainable, and practically anhydrous. The presence of impurities in the glycerol leads to the formation, on nitration, of bodies, which render the product unstable and liable to spontaneous decomposition. Its sp.gr. must not be less than 1.26, and it must be free from acid, lime, chlorides, and arsenic. It should also be free from fatty acids; in the process of distillation of the glycerol, fatty acids of the same boiling-point are apt to come over, and when nitrated are difficult to remove from the nitroglycerin. The total residue, after careful evaporation of the glycerol, should be less than 0.25 p.c., of which not more than 0.10 p.c. should be inorganic. Even these tests are insufficient to ascertain the suitability of a glycerol for nitration, and the final verdict depends on a practical nitration test on the small scale; 10 grams of the glycerol are poured very slowly into a mixture of $27\frac{1}{2}$ parts of nitric acid of 1.60 sp.gr., and $72\frac{1}{2}$ parts of sulphuric acid of 1.84 sp.gr. kept quite cold during the addition. The nitroglycerin, after separation, and also the waste acids, are allowed to stand some time in long burettes and the separated nitroglycerin ultimately collected and measured. The yield should be at least 200 p.c. by weight of the glycerol, and, further, no flocculent matter should separate out during the nitration.

At the present time, the various supplies of glycerol at Waltham Abbey are carefully blended to ensure uniformity of manufacture, the blending being performed in large iron tanks holding 10 tons. The glycerol is rendered fluid by heating with steam coils, run into an elevator, a strong steel cylinder or egg-shaped vessel, and

thence forced by compressed air into a tank in the charge house, which is placed above the nitrating house. The charge of glycerol was formerly weighed, but it is now usually measured in the tank by means of a gauge glass. The glycerol must not be too heated, or, because of its reduced specific gravity, the weight of the charge deduced from the volume in the tank will be incorrect; yet, on the other hand, it must be fluid enough to easily run into the nitrating apparatus.

Acids.—To procure a good yield of pure nitroglycerin, the nitric acid should be practically anhydrous. If the nitric acid be too weak, lower nitrates are formed, which dissolve in the acid mixture. To increase the strength of the nitric acid, and to keep this strength up by removing the water liberated in the nitration, it is necessary to mix the nitric acid with strong sulphuric acid. Nitroglycerin is soluble in either acid, but not in a mixture of the two. The strengths of the two acids and their relative proportions have varied from time to time. In all early large-scale manufacture, the mixed acid was similar in strength and proportions to that used by Sobrero, but the mixture is now usually made from acids of the following description.

The *nitric acid*, prepared by the ordinary methods from sodium nitrate and sulphuric acid, or recovered from waste acids by denitrating, must be at least of 1.5 sp.gr. at 15.5°, and must not contain more than a small quantity of nitrous acid; usually not more than 1.5 p.c. is allowed, but sometimes the limit is as low as 0.5 p.c. The nitric acid should be also free from sulphates and chlorine.

Mowbray introduced the method of freeing the nitric acid from nitrous acid by heating it and passing a current of air through it. At Waltham Abbey, the nitric acid is made by the Valentiner process, which gives a product very free from nitrous acid (*v. NITRIC ACID*).

The *sulphuric acid* must be the purest and most highly concentrated obtainable. It must have a sp.gr. of at least 1.842 at 15.5°, and must contain not less than 96 p.c. by weight of the monohydrate. It should be as free from iron and arsenic as possible, as these substances cause reduction of the nitroglycerin.

Mixed acids.—These acids are mixed in the proportion of 3 parts of nitric acid to 5 parts of sulphuric acid, and glycerol is usually used in the proportion of 1.8 parts of the acid mixture, but in some factories the proportion of acid mixture is as low as 7 or $7\frac{1}{2}$ parts. In this acid mixture there is present nearly 6 p.c. of water over that giving acid monohydrate, and within the last few years it has become a common practice to add Nordhausen sulphuric acid in such quantity as to combine with nearly all this excess of water, an increased charge and yield and less waste acid resulting.

Nathan and others have patented (Eng. Pat. 6581, 1906) the nitration of glycerol with a mixture of Nordhausen sulphuric acid and nitric acid, with the object of obtaining a larger yield; but Guttman (Chem. Zeit. 1905, 939) holds that, beyond a certain point, increase in the concentration of either acid does not improve the yield of nitroglycerin, and, further, is deleterious to the quality of the product.

The Nordhausen acid is stored in iron drums,

and, like the other acids, is first transferred to a steel acid elevator or 'egg,' as it is termed, and thence forced by compressed air into the mixing tank. The large cylindrical steel mixing tanks hold about 60 tons of mixed acid. Nitric acid is run into the tank through a pipe extending to the bottom of the tank, and then the sulphuric acid added through a pipe in the cover, and the two mixed by compressed air; the fumes evolved pass through a fume pipe into condensing towers. Two tanks are used at Waltham Abbey, so that the mixed acid can be allowed to stand some days before use, in order to allow lead sulphate and other impurities to settle out, and also so that it may be analysed, and any necessary adjustment of composition made. The mixed acid is run from the tanks as required into an elevator, and forced into a cylindrical steel vessel in the charge house to a fixed level determining the charge.

Nitration.—Mowbray carried out the nitration of glycerol in earthenware pots, using a large number of them and small charges. Each pot contained about 17 lbs. of mixed acids, into which 2 lbs. of glycerol was allowed to drop by means of a siphon; the operation of nitration taking place simultaneously in all the vessels. He introduced an important improvement on the old mechanical stirrers, by using compressed air for mixing the glycerol and acids. In later factories large lead vessels with conical covers were used for the nitration, and agitation was effected by the combined use of compressed air and a stirring paddle or helix; the water working the latter being also used for cooling the mixture by passing through lead coils. The glycerol was allowed to fall on a disc fixed to the shaft of the paddles above the level of the acids, from which it was thrown in fine drops on to the surface of the acids. A process of nitration evolving new principles was introduced at Vonges in 1872 by Boutmy and Faucher, and subsequently worked on a large scale at Pembrey in South Wales. They separately mixed the glycerol with part of the sulphuric acid, forming sulphoglyceric acid, and the nitric acid with the remainder of the sulphuric acid. Each of these operations involves the liberation of heat, so that, when these cooled mixtures were themselves mixed, less heat was developed in the actual process of nitration. However, the nitration process takes some 24 hours for completion, and the danger of leaving the nitroglycerin for so long a time in contact with the mixed acids more than counterbalances any advantage derived from the smaller development of heat. Serious explosions took place in various factories using this process, and it is no longer used.

In most modern factories the nitrating apparatus (there are usually two in the building) is a large lead cylindrical tank with a convex or inclined bottom, standing in a wooden vat. Inside the former are lead cooling worms, through which cold water circulates, as well as between the tank and its wooden case. This water is, in many factories, artificially cooled by a refrigerating plant to 10° or less. The agitation is now usually performed in this country with compressed air only, at a pressure of about 20 lbs. per square inch, which is forced through pipes which are led down to and round the bottom of the tank. The tank is closed with a

dome-shaped cover of lead, provided with a number of glass inspection windows, through which the various pipes for air, water, and glycerol pass. A glass tube to allow the colour of the fumes to be seen, which is connected with a pipe to carry away the fumes, and thermometer, also pass through the cover. The mixed acids are run in, from the tank in the charge-house above, and cooled to a temperature of about 16°. The glycerol is then introduced in a spray at the bottom of the tank, compressed air and a simple injection apparatus being used to produce the spray, the contents being kept in a constant state of agitation and well cooled. The rate of flow of the glycerol is regulated so as to keep the temperature of the charge below 22°–25°. If red fumes are noticed at any time in the fume pipe, the inflow of glycerol is cut off, and additional air blown through till the fumes cease. If the evolution of red fumes cannot be stopped, or if the temperature should rise above 30°, and not fall with the full air current on, serious local decomposition is indicated and the charge is at once drowned.

Two pipes, provided with earthenware cocks, leave the nitrating tank at its lowest point, both of which can be opened, in case of danger, and the contents of the tank quickly discharged into the drowning tank—a large wooden tank filled with cold water situated immediately below the nitrating tank, the contents of which can be agitated by means of compressed air.

The whole process of nitration, including the subsequent cooling down, takes about one hour.

In the nitration of glycerol some sulphoglyceric acid is formed, the amount increasing with the quantity of sulphuric acid in the mixed acids. When the waste acids are allowed to stand, the nitric acid partly decomposes this sulphoglyceric acid, and nitroglycerin separates out.

Separation.—In early factories the separation of the nitroglycerin was effected by slowly running the nitrated charge into a large bulk of water containing in lead-lined vats, kept in a state of agitation. The bottom of the tank was inclined and led to a tap through which the nitroglycerin was drawn, after separation had taken place. This method of indirect separation involved the loss of all the waste acids, and is now replaced by the following method of direct separation.

When the nitrated charge has cooled down, one of the taps at the bottom of the nitrator is connected with a lead bend, the tap opened, and the whole of the contents run off into the separating tank placed just below the level of the nitrator. The separating tank is made of stout sheet lead, and has a pyramidal bottom leading by means of a glass inspection cylinder to a branched horizontal lead pipe with earthenware stop-cocks. The top has a cover with glass windows and fitted with a fume pipe. Air pipes are led into the separator through the cover, one round the bottom of the tank, the other ending in the glass inspection cylinder. On one side of the separator is a glass inspection window, and on another side an earthenware cock situated about 4 inches below the surface of the nitroglycerin after separation has taken place. The nitroglycerin,

sp.gr. 1.6, gradually separates and floats on the mixed acids, sp.gr. about 1.735. Two thermometers pass through the lid, one ending in the nitroglycerin, the other in the acids. The temperature is not allowed to rise above 17° ; if it shows a tendency to rise, the air current is turned on. If the temperature cannot be reduced, and red fumes are given off, the charge is led through a third cock at the bottom of the separator into the drowning tank. After the separation is complete, usually in about 40–45 minutes, the bulk of the nitroglycerin is run through the side tap into the 'preliminary washing tank.'

The waste acids are then run away through the bottom pipe to the 'after separating house.' When the nitroglycerin level is seen through the inspection cylinder, it is led through the second branch of the pipe into the pre-washing tank.

Any fatty acid impurities in the glycerol separate out as a vesicular scum, also containing silica, iron, and lead compounds, between the nitroglycerin and acid layers. Certain chemical and mechanical impurities also form a scum on the surface of the nitroglycerin. Any thick sludge collecting in the separator is led off through a fourth cock into the wash-water settling house.

Several suggestions have been patented to accelerate the separation. Möller, for the Dynamit Actien Gesellschaft of Hamburg (Eng. Pat. 13562, 1904), claims for the addition of a small quantity, 0.52 part per 100 glycerol, of fatty hydrocarbon or acid, or, preferably, high boiling paraffins, to the acids before nitration. Reese (Eng. Pat. 20310, 1905) attributes the slow separation to the presence of small quantities of colloidal silica and adds sodium fluoride to the nitrating acids, 0.002 part per 100 glycerol; on the other hand, the Westfälisch-Anhaltische Sprengstoff A. G. (Ger. Pat. 249573, 1911) add a silicate, such as kaolin or steatite, to assist separation, and the Rheinische Dynamitfabrik (Ger. Pat. 283330, 1912) use both silica, kieselguhr, and hydrofluoric acid, or sodium silicofluoride, so as to produce silicon tetrafluoride. Haddan (Eng. Pat. 18597, 1907) claims that the nitroglycerin is rapidly separated from the nitrating acids by passing an electric current through the mixture between platinum electrodes, the gas bubbles formed during the electrolysis carrying the suspended nitroglycerin to the surface.

Nitration-separation.—In 1901 Nathan, Thomson, and Rintoul (Eng. Pat. 15983) patented an improved apparatus for the manufacture of nitroglycerin, which has been since used at the Royal Gunpowder Factory. The two operations of nitration and separation are carried out in one apparatus, and all earthenware cocks, which were a constant source of danger, are done away with, the separated nitroglycerin being displaced from the top of the apparatus by introducing waste acid below its level.

The nitrator-separator (J. Soc. Chem. Ind. 1902, 927) is a cylindrical lead vessel, with a bottom sloping in one direction, with the usual cooling coils and air pipes led in through the side just below the surface of the acid mixture. The cover, which is conical, and burnt on to the body, terminates in a small cylinder, provided with an inspection window, opening at the top into a fume pipe and also laterally into a gutter

leading to the pre-wash tank. A thermometer passes through the cover. At the bottom of the tank is a pipe with three branches—one branch leads downwards to the drowning tank, another leads upwards and has two branches leading to the mixed acid and waste acid tanks respectively, the third leads to the denitrating plant.

The process is carried out as follows: After the nitrating acid is run in, and brought to the proper temperature, the glycerol injector is introduced and the nitration effected as usual. In Continental practice an injector is never used, the glycerol being introduced through a bunch of 16 or 18 small tubes. The nitric acid fumes are condensed in a Guttman's condensing tower, about 18 lbs. of nitric acid, of sp.gr. 1.320, being recovered per ton of nitroglycerin. After the nitration is completed, the mixture is allowed to stand for a few minutes, and then waste acid is gradually run in to displace the nitroglycerin as it separates. When the separation is complete, a clear line of demarcation between the nitroglycerin and the waste acid is seen in the inspection cylinder.

The apparatus is left full until required for another nitration. In this way the life of the apparatus is largely increased, as no part of the interior is left exposed to acid fumes. Removing the nitroglycerin from contact with the acid as it separates, and the cooling during separation, increase the safety of the manufacture.

Preliminary washing.—The nitroglycerin coming from the separator is run into circular lead-lined tubs filled with water. The bottom of the tank is inclined towards a cock, and there is another cock in the side of the tank above the level of the separated nitroglycerin, for drawing off the washing waters to the 'wash-water settling house.' Compressed air is blown into the tank whilst the nitroglycerin is running in in a thin stream. A thermometer is supported in the tank and the temperature is kept below 18° . After washing for a few minutes, the nitroglycerin is allowed to separate, and the wash water is run off. More water is run in and the process repeated, any further nitroglycerin from the separator being added. The washing process is performed four times, dilute sodium carbonate solution being added in the last washing, and the temperature raised to 15° . When the preliminary washing is completed, the nitroglycerin is run down a lead-lined gutter to the 'wash house.'

The pre-wash tank now in use at Waltham Abbey has a fixed cover with a fume pipe, and has no cocks. The wash water is run off by gradually depressing a rubber funnel, connected with the outlet, into the water, and the compressed air pipe is burnt to the under side of the tank, the air holes being pierced through the bottom. This does away with any possibility of friction, and the bottom of the tank is left smooth and is readily cleaned. The washed nitroglycerin is led off through a rubber tube leading on to a gutter, which carries it to the wash house. Compressed air is blown through this rubber tube into the tank during the washing, to keep it free from unwashed nitroglycerin.

Final washing.—The final purification of the nitroglycerin to remove the last traces of acid

and other impurities is effected in a lead-lined tank, over which the gutter from the pre-wash tank projects. The tank has an inclined bottom leading to the nitroglycerin draw-off cock, and is fitted with compressed air pipes for agitating the contents. The wash waters, as they separate, are run off through a pipe near the bottom, connected inside the tank by a length of india-rubber tubing with the 'skimmer,' and india-rubber-covered metal funnel that can be gradually depressed below the surface of the liquid. Cold water from the main, or warm water from an adjacent tank, can be run into the tank through india-rubber tubes. The washing tank is fixed above a large drowning tank filled with water.

The nitroglycerin is first washed with dilute soda solution, about $2\frac{1}{2}$ p.c. strength at a temperature of about 30° , hot or cold water being run in as necessary. Second, and sometimes third, washings are performed with weaker soda solution, and then lastly two washings with water only, still at the same temperature. The final washing leaves not more than 0.01 p.c. of alkali in the nitroglycerin.

The wash tank now used at Waltham Abbey is made of heavy lead without casing. The air pipe is soldered beneath the tank, there are no cocks, the skimmer is made entirely of rubber, and the nitroglycerin is run off through an india-rubber tube as from the pre-wash tank. The washing water is softened and filtered, and, like the soda solution, is stored in tanks in the charge house.

Filtration.—After the washing is complete, the nitroglycerin is usually filtered to remove moisture and suspended flocculent impurities, the operation being carried out in the washing house. The usual method is to filter through a flannel bag filled with salt, placed over a cylinder with a wire gauze bottom, into a lead-lined tank, with an inclined bottom. Sometimes two filters, one above the other, are used. The pure nitroglycerin is drawn off as required through a cock.

The present method at Waltham Abbey is to use a lead tank with a perforated false bottom, on which is placed a layer of dry sponges sewn up in flannel, and the cock is dispensed with, the rubber tube previously described being used. A sponge filter was used in the Boutmy-Faucher process.

In some factories filtering is not resorted to, but the water is removed by allowing the washed nitroglycerin to stand for some days in a warm room, when all the water rises to the surface of the nitroglycerin.

Testing.—The finished nitroglycerin is tested for moisture, alkalinity, and nitrogen content, and has to pass a specified time limit in the Abel heat test. (For a description of this test, see under stability tests, p. 92.)

Treating the wash waters.—All the wash waters, from washing the nitroglycerin or apparatus, which contain considerable quantities of nitroglycerin, are run down lead gutters into a large wooden tank in the wash-water settling house. The contents are kept in agitation during the day, and allowed to settle overnight. The separated nitroglycerin is run off in the morning, in the old form of tanks through a cock, in the new through an india-rubber tube,

into india-rubber buckets and returned to the preliminary washing tank. The wash water is drawn off from above the level of the nitroglycerin and run into a 'labyrinth' or nitroglycerin trap, a long oblong lead tank divided into a series of compartments by partitions, with rows of holes, alternately at the top or bottom, for the water to pass through. Each partition has also one hole at the bottom, through which the deposited nitroglycerin runs and collects at the lowest point of the bottom, and is drawn off and treated like that from the wash-water settling tank. The water from the labyrinth is run into ponds, and any nitroglycerin collecting there is occasionally destroyed by detonation.

At Waltham Abbey, labyrinths are now also placed in the nitrating and wash houses, through which the wash water passes before going to the wash-water settling tank. By this means the nitroglycerin reaching the latter is materially reduced.

Secondary or after-separation from the waste acids.—The waste acids from the separator contain a small quantity of nitroglycerin, and a further quantity is formed on standing, as already explained, from the sulphoglyceric acid. The waste acids are run into large cylindrical lead vessels, surrounded by a water jacket and fitted with cooling worms and compressed air pipes. The top of the tank is closed by a conical lid with a glass cylinder at the apex; the acids being filled in to about half-way up this tube. The cover has also a fume pipe and two thermometers, one in the nitroglycerin, the other reaching to the acid. As the nitroglycerin separates, it is removed and poured into a small lead tank containing water, which acts as a pre-wash tank.

The cooling jacket, worms, and air current are only used if the temperature rises considerably during the separation. When no more nitroglycerin separates on standing (sometimes a week is necessary), the acids are run off and treated by some denitrating process, and after concentration are again used in the manufacture.

The process of separation is no longer carried out at Waltham Abbey, but the waste acids are treated by a process patented by Nathan, Thomson, and Rintoul (Eng. Pat. 3020, 1903). The patentees take advantage of the facts that the addition of a small quantity of water to the waste acids not only absorbs the suspended finely-divided nitroglycerin, but also prevents the formation of more nitroglycerin on standing. The waste acids, after standing and cooling in the nitrator-separator and removing any additional nitroglycerin that separates (this separation is much more complete than ordinarily), the quantity of acid necessary for displacing the next charge is run off into an acid elevator and forced up into the displacing tank. The remainder of the waste acids is then violently agitated, but not cooled, and 2 p.c. of water is gradually added; the acid is then run off and forced into the tank in the denitrating house. On the Continent water is not added to the waste acids, but the after-separators are still retained, as they yield 0.8–0.9 p.c. nitroglycerin, calculated on the glycerin used.

Instead of the usual denitrating, Nobel (Fr. Pat. 351454, 1905) proposes to regenerate the waste acids by the addition of fresh acids, and

claims in this way to increase the yield of nitroglycerin, and states that the process of nitration is rendered less dangerous.

Yield.—From the equation representing the formation of nitroglycerin :

a theoretical yield of 247 parts of nitroglycerin should be obtained per 100 parts of glycerol. Up till recently a yield of 215 p.c. was considered very good, but now yields of 229 p.c. and over are usually obtained.

A charge of 1320 lbs. of glycerol has been used at Waltham for some years. Guttman states that it is customary in well-conducted factories to nitrate 110 kgs. of glycerol, in a mixture of 300 kgs. of nitric acid of about 93-94 p.c. monohydrate and 500 kgs. of sulphuric of 96 p.c. monohydrate. This corresponds to about 255 parts of nitric acid monohydrate, and 436.4 parts of sulphuric acid monohydrate, or a total of 691.4 parts of acid monohydrate with 35.8 parts of water, 4.9 p.c. to each 100 parts of glycerol. He also states that the largest apparatus made in lead nitrates 680 kgs. of glycerol at one operation, whilst in America and South Africa steel apparatus with mechanical stirring gear are mostly used, some nitrating 1000 kgs. at a time. Factories using the nitrator-separator process now employ a mixture of 41 p.c. of nitric acid, 57.5 p.c. sulphuric acid, and 1.5 p.c. water, corresponding to 250 lbs. nitric acid, 350 sulphuric acid, and 9 lbs. of water for each 100 lbs. of glycerol, which gives a ratio of 6.09 of acid to 1 of glycerin. The Thomson apparatus is now generally used on the Continent with slight modification in the procedure. The nitration is carried out at a temperature of from 28° to 30°, by 6 parts of an acid mixture containing 44 p.c. HNO_3 , 55 p.c. H_2SO_4 , and 1 p.c. H_2O . This more drastic nitration is stated to give a purer product by oxidation of some of the impurities usually found, with a yield of from 232 to 233 p.c. Hofwimmer (Chem. Zeit. 1912, 961) states that a maximum yield of nitroglycerin is obtained by the use of 3 molecular weights of sulphuric acid and 4 of nitric acid for the nitration of 1 molecular weight of glycerin.

Composition.—By sufficient dilution with copper oxide, the combustion of nitroglycerin can be carried out in the ordinary way. The nitrogen can be estimated by Dumas' method, or, better, by the nitrometer. The results of numerous analyses by different experimenters give figures very closely corresponding to the theoretical composition $\text{C}_3\text{H}_5(\text{NO}_3)_3$; and Perkin (Chem. Soc. Trans. 1889, 726) from determinations of the magnetic rotation of nitroglycerin, concludes that nitroglycerin must have its oxygen combined in the form $\text{O}-\text{NO}_2$.

Properties.—Nitroglycerin is a heavy oily liquid; its sp.gr. at 15.6° is 1.60. When properly made from perfectly pure and colourless glycerol and acids, it is as colourless as water; but of a yellow to pale-brown colour as obtained on the commercial scale, according to the purity of the prime materials. It is neutral in reaction, and, when quite free from water, it is transparent. When pure, nitroglycerin may be kept for an indefinitely long time without decomposition. Thus Berthelot records the keeping

of a specimen for 10 years, McRoberts one for 9 years, without any appearance of decomposition. But the presence of moisture, or of a trace of free acid, is able to start the decomposition of nitroglycerin; sunlight also causes it to decompose (Berthelot).

A mixture of ozone and oxygen, according to Beckerhinn, oxidises nitroglycerin at ordinary temperatures, with the formation of glyceric and nitric acids. When nitroglycerin does decompose at ordinary temperatures, the decomposition proceeds quietly, the liquid turns green, and NO_2 and CO_2 are evolved. After some time, the whole mass gelatinises, and contains much oxalic acid and ammonium salts. Nitroglycerin solidifies into long white prismatic needles, the temperature at which it solidifies varying with different samples between +8° and -11°; the frozen nitroglycerin melts again at about 11°. The time of exposure for solidifying or melting must be prolonged. Nauckhoff found that pure nitroglycerin could be cooled to as low a temperature as -40° to -50° without solidifying, though he states its true freezing-point to be 12.3°. When cooled by a mixture of solid carbon dioxide and ether, it solidifies to a glassy mass. Kast (Zeitsch. f. d. Ges. Scheiss u. Sprengstoffwesen, 1906, 225) has shown that nitroglycerin exists in two allotropic forms, one solidifying at 13.2°, the other at 2.1°, the melting-points being 13.5° and 2.5° respectively. Will (Ber. 1908, 1107) gives the melting-point of the labile modification as 2.2°, and of the stable modification as 12.2°. Hibbert (8th Int. Cong. App. Chem. 1912) describes the preparation of the two solid forms of nitroglycerin and states that the labile form crystallises in the triclinic system, and has a m.p. of 2.0°, and a freezing-point of 1.9°; whilst the stable form crystallises in the rhombic system, and has a m.p. of 13.2°, and a freezing-point of 13.0°. The labile form is comparatively stable below 0°, but is converted at once to the stable form with rise of temperature on addition of a crystal of the latter.

Nitroglycerin is slightly volatile at ordinary temperatures, the volatility increasing with rise of temperature. Marshall and Pease (Chem. Soc. Trans. 1916, 109, &c.) have determined the vapour pressure of nitroglycerin, by the amount volatilised from cordite at various temperatures. They obtained the following results: at 20°, 0.00026 mm.; at 30°, 0.00083 mm.; at 40°, 0.0025 mm.; at 50°, 0.0072 mm.; at 70°, 0.044 mm.; and at 80°, 0.098 mm. According to Hess, it can be completely evaporated by continuous exposure to a temperature of 70°, and it can be distilled *in vacuo* below 100°. Will states that nitroglycerin can be completely volatilised at 160° without boiling. Champion gives the boiling-point as about 185°, but de Bryn states that this temperature is too low, and that the boiling-point is over 200°.

Although perfectly pure nitroglycerin is quite stable at ordinary temperatures, it soon begins to decompose at slightly elevated temperatures, the decomposition rapidly accelerating owing to the catalytic action of the decomposition products, so that it soon becomes dangerous. According to Guttman, a temperature of between 45° and 50° is the critical one for nitroglycerin, the stability being practically

perfect below this temperature. The decomposition is accelerated by small traces of nitrous acid; by the oxidation glyceric and oxalic acids are formed.

The velocity of decomposition of nitroglycerin, when out of contact with the products of decomposition, has been examined by Robertson (Chem. Soc. Trans. 1909, 1241). He concludes that the nitrogen is disengaged almost entirely as nitrogen peroxide, in which respect the decomposition differs from that of gun cotton; that the disengagement of nitrogen peroxide proceeds in a perfectly uniform manner; that the rate of decomposition is a function of the temperature, and increases from 95° to 125°, being doubled in a rise of 5°, and that nitroglycerin has a higher rate of decomposition than gun cotton under similar conditions.

Mowbray found that his nitroglycerin contracted about $\frac{1}{13}$ of its original volume on freezing.

Beckerhinn made a number of estimations of the specific gravity of Nobel's nitroglycerin, which was procured from different factories. The specific gravity of the solid nitroglycerin was taken at +10° (nearly at its melting-point); all the nitroglycerins gave very concordant values, having a specific gravity of 1.735. The specific gravity of the liquid nitroglycerin was found by numerous estimations to be 1.599; whence, in solidifying, nitroglycerin contracts about $\frac{10}{121}$ of its original volume. Consequently, Nobel's and Mowbray's nitroglycerin agree in this respect.

Beckerhinn found for the specific heat of liquid nitroglycerin (between 9.5° and 98°) the value 0.4248, and for the latent heat of fusion of solid nitroglycerin the value 33.54 heat-units.

Perkin (*l.c.*) found the magnetic rotation of nitroglycerin to be 5407.

It is inodorous, has a sweet, pungent, aromatic flavour, and even in very small quantity has toxic properties, first noticed by Sobrero. Schuchardt (Dingl. poly. J. 180, 406) tried the effect on himself of swallowing a drop of nitroglycerin. He soon experienced vertigo, headache, lassitude, and drowsiness; and an hour later, having incautiously taken more nitroglycerin, the symptoms mentioned increased in severity, and were followed by nausea and loss of consciousness. No ill effects were, however, felt next day.

The handling of nitroglycerin is followed by similar unpleasant symptoms; but continued handling of the nitroglycerin for a day or two gives immunity from the headache. The chief symptom is usually violent headache. Fresh air, drinking black coffee, or extract of sarsaparilla, and the administration of morphine acetate, are antidotes.

Hay states that 1 gram of nitroglycerin dissolves in about 800 c.c. of water, and in 4 c.c. absolute alcohol. Will gives the solubility in water at 15° as 0.16 p.c., and the absorption of water as 0.2 p.c. It is freely soluble in methyl alcohol, ether, benzene, nitrobenzene, chloroform, acetone, glacial acetic acid, ethyl acetate, and other organic solvents.

It is practically insoluble in glycerol and in carbon disulphide. The solubility of nitroglycerin in a large number of solvents is given by Elliott, in the School of Mines Quarterly, iv. 15. Nitroglycerin is soluble in strong nitric acid,

unchanged; in strong sulphuric acid it is dissolved and gradually denitrated with the formation of glyceric sulphate.

Berthelot (Sur la Force des Matières explosifs d'après la Thermochimie, 1883) gives for the heat of formation of liquid nitroglycerin from liquid glycerol and nitric acid, +14.7 kgm.-degrees per molecule (227 grams) of nitroglycerin; and for the heat of formation of nitroglycerin from its elements (diamond carbon, gaseous hydrogen, nitrogen, and oxygen), +98 kgm.-degrees per 227 grams; or, +432 gram-degrees per 1 gram nitroglycerin.

Detection.—Nitroglycerin can be detected by its taste, and by absorbing a drop on bibulous paper; the drop produces a permanent greasy stain which explodes when struck by a hammer on an anvil, burns with a yellowish-green flame, with a cracking sound, or, when heated from below, explodes with a loud report. It is soluble in methyl alcohol, the solution becoming milky on the addition of water, and eventually depositing heavy oily drops. A solution of 1 vol. of aniline in 40 vols. of sulphuric acid, sp.gr. 1.84, gives a purple-red colouration with the smallest trace of nitroglycerin (Werber).

Reactions.—Of the reactions of nitroglycerin two may be mentioned. The decomposition of nitroglycerin by caustic potash was stated by Railton (Chem. Soc. Trans. 1855, 7, 222–224), to be:

but this was not at all justified by the results of his experiments, as only a small fraction of the nitroglycerin seems to have been decomposed, and the formation of some potassium nitrate and glycerol to have been only qualitatively determined.

Hay (*l.c.*) states that, by the action of alkalis on nitroglycerin, glycerol is not regenerated, but is oxidised at the moment of formation at the expense of the nitric acid, potassium nitrite being formed. He sums the reactions into one equation, thus:

stating that while the oxidation products of glycerol may vary as regards their nature and proportions, the above equation expresses with approximate accuracy the course of the reaction. Berthelot (Compt. rend. 1900, 131, 519) considers that the regeneration of potassium nitrate may be taken as corresponding to that of the glycerol, and, if that is so, the production of potassium nitrite implies the simultaneous formation of a more highly oxidised product, such as glyceric aldehyde, in this way:

Berthelot also considers that the poor stability of some samples of nitroglycerin, for which it is often difficult to account, may be attributed to the formation of glyceric aldehyde in the manufacture, produced in this way:

and that this nitrous acid may then form a mixed ester of the composition $\text{C}_3\text{H}_5(\text{NO}_3)_2\text{NO}_2$; both of which impurities would be difficult to detect.

In work on the hydrolysis of nitro-glycerin

in alkaline solution, Silberrad and Farmer (Chem. Soc. Trans. 1906, 1759) attribute the absence of glycerol in the products to its degradation to hydroxy-acids, &c., owing to the more reactive condition of the nitric acid when first set free on hydrolysis. Nitroglycerin is acted on by potassium hydroxide in aqueous and in alcoholic solution; but, naturally, much more slowly by aqueous potash.

The reaction of nitroglycerin with alkaline sulphides, by which glycerol is formed with reduction of the NO_2 group, and not an amido derivative, is of great theoretical interest, but has not been examined quantitatively as in the case of gun cotton.

Some experiments were made in 1883 by Bloxam (Chem. News, 47, 169), on the decomposition of nitroglycerin by alkaline sulphides, but more with the view of finding a safe means of disposing of nitroglycerin. He found that alcoholic solution of KHS , strong aqueous solution of K_2S , aqueous yellow ammonium sulphide, the orange-coloured solution of calcium sulphide formed by boiling flowers of sulphur and slaked lime with water, are all able (the last solution more slowly than the others) to effect the conversion of nitroglycerin into glycerol.

Combustion and detonation.—Heated rapidly to 200° , nitroglycerin inflames, and at a little higher temperature detonates with great violence (Berthelot, Sur la Force des Matières explosifs).

The temperature of explosion of nitroglycerin is variously stated. Nobel states that when heated to 180° , it explodes. Hagen gives 180° – 190° as the temperature of explosion of nitroglycerin; Leygue and Champion give a higher temperature. F. Hess observes that explosive substances, when slowly heated, detonate at a lower temperature than when suddenly heated. The temperature of explosion of nitroglycerin (and of explosives in general) is evidently dependent on the conditions of the experiment. McRoberts (*l.c.*) says that the explosion of nitroglycerin can be brought about by heating it to a temperature at which decomposition takes place; the decomposition itself then speedily raises the temperature to the point of explosion. Snelling and Stone (U.S. Bureau of Mines, Tech. Paper No. 12) have studied the behaviour of nitroglycerin on heating. The nitroglycerin gradually became yellow, then orange, as the temperature was raised, obvious decomposition with gas evolution and partial distillation took place at 145° , and explosion occurred at about 218° . They explain that the lower explosion temperatures given by other observers are due to the heat of decomposition of the nitroglycerin locally raising the temperature above the recorded temperature of explosion.

Nitroglycerin is not readily inflamed at atmospheric temperatures by contact with flame or with a red-hot body. Thus, Nobel in 1865 showed that nitroglycerin was not inflamed when its surface was touched with a red-hot iron rod; the flame of a burning wood-shaving set on fire nitroglycerin, which burnt without explosion with a flame that went out when the source of heat was removed; and he states that burning nitroglycerin explodes only when its temperature is raised by the combustion at least 180° .

Electric sparks will inflame nitroglycerin, but

with difficulty. Abel placed two poles connected with a Ruhmkorff's coil, in some nitroglycerin and passed sparks between them; the surface of the nitroglycerin was agitated, turned black, and after half a minute the nitroglycerin exploded.

The combustion of nitroglycerin, brought about by contact with an ignited body, gives rise to nitrous vapours and a complicated reaction; it burns with a yellow flame, but without explosion properly so called, at least in the case of small quantities. But if the quantity of nitroglycerin is too large, the combustion ends in detonation. The gases produced by burning nitroglycerin (or, rather, ordinary dynamite: nitroglycerin and silicious matter) have been analysed by Sarrau and Vieille. The gases were allowed to escape freely, under approximately atmospheric pressure; they had the following composition per 100 volumes of gas:—

NO	:	48.2	H	:	1.6
CO	:	35.9	N	:	1.3
CO_2	:	12.7	CH_4	:	0.3

The combustion, therefore, under these circumstances appears to be very incomplete.

In the early days of the use of nitroglycerin, Nobel effected its explosion in a borehole by means of the explosion of gunpowder (Nobel, Eng. Pat. 2359, 1863). The gunpowder was fired by a fuse, but the explosion of the nitroglycerin was uncertain and incomplete. Incomplete detonation of nitroglycerin leads to its combustion and the formation of nitric oxide and the deleterious higher oxides on coming in contact with the air. Subsequently (in 1864) Nobel exploded the nitroglycerin by means of the detonation of mercury fulminate contained in a strong copper cap, or detonator, as it is now termed, immersed in the liquid. The detonation was then complete, and the force developed much greater than when the nitroglycerin was fired by means of gunpowder.

The shock of two hard bodies capable of vibrating readily is able to cause the detonation of nitroglycerin coating the struck surfaces. Nobel noticed that a film of nitroglycerin on an anvil, struck lightly by a hammer, detonated only where struck by the hammer; but if struck heavily, the whole film of nitroglycerin detonated (McRoberts, *l.c.*). If the film be covered only with a sheet of paper, and struck, the detonation is propagated through the whole of the nitroglycerin (Désortiaux, Traité sur la Poudre, &c.). Reasoning that the blow of the hammer caused strong compression of the nitroglycerin, and raised its temperature to the exploding point, Nobel was led to try the effect of the blow caused by the detonation in the nitroglycerin of strongly confined detonating mixtures, in the hope that the blow thus given would raise the temperature of the nitroglycerin locally, as was done by the blow of the hammer, and would thereby cause its explosion. He eventually (in 1864) found that the detonation of nitroglycerin could be rendered certain by the use of mercury fulminate contained in a strong copper cap (McRoberts, *l.c.*). This idea of firing an explosive by initial detonation was one of the greatest improvements ever made in the use of explosives. It made the use of nitroglycerin as a blasting agent practicable, was

subsequently applied by Abel and Brown to guncotton, and is now used for firing all high explosives.

It has been mentioned that the detonation of nitroglycerin is readily caused when it is subjected to the shock of two hard sonorous bodies, as that of iron on iron. The shock of copper on copper is believed to be less dangerous, and that of wood on wood still less so; but explosions of nitroglycerin have been caused by such shocks (Berthelot, *Sur la Force des Matières explosifs*, &c.). The sensitiveness of nitroglycerin to friction and percussion increases with the temperature.

Frozen nitroglycerin is less readily detonated by a blow, or by the detonation of mercury fulminate, than when in the liquid state. This was to be expected, as detonation results in both cases from the transformation into heat of the kinetic energy imparted to the particles of nitroglycerin—heat sufficient at the part struck to raise the temperature of the nitroglycerin to the temperature of explosion; and to raise frozen nitroglycerin to that temperature, more heat would be required than in the case of the liquid, on account of the heat absorbed in melting the solid nitroglycerin. Thus, Beckerhinn states (*Sitz. W.* 72 and 73, in abstract in the *Jahresbericht der chemischen Technologie*, 1876, 22, 481–487) that quantities of mercury fulminate which would have detonated liquid nitroglycerin with certainty, did not detonate crystallised nitroglycerin; also, that when a flat anvil of Bessemer steel was thinly coated with liquid and with solid nitroglycerin, and a wrought-iron weight allowed to fall on it, the mean height of fall required to effect detonation was for liquid nitroglycerin 0.78 metre (2.6 feet), for frozen nitroglycerin 2.13 metres (7 feet). McRoberts (*l.c.*) states that a detonator containing even so much as 1 gram of mercury fulminate does not effect the detonation of thoroughly frozen nitroglycerin, while 0.1 gram of fulminate will detonate liquid nitroglycerin.

The products of the detonation of nitroglycerin are stated to be those of complete combustion, and the equation representing the change is given as:

Sarrau and Vieille (*Compt. rend.* 90, 1060) state that experiment shows that the decomposition of nitroglycerin in a closed vessel is represented by the above equation; but no analysis of the gases is given.

Calculated from the above equation, nitroglycerin contains an excess of 3.52 p.c. oxygen (per 100 nitroglycerin) above that required for complete combustion, and 100 grams of nitroglycerin would be converted into 58.15 grams CO_2 , 19.83 grams H_2O , 3.52 grams O, and 18.50 grams N.

Nobel has calculated that 1 vol. of nitroglycerin on explosion generates about 1200 vols. of gases, calculated to normal temperature and pressure, and that the heat generated expands the gases to nearly eight times this volume, and concludes that the explosive force of nitroglycerin is 13 times as great as that of an equal volume of gunpowder.

The quantity of heat evolved by the total

combustion of nitroglycerin, as represented in the above equation, is given by Berthelot (*Sur la Force des Matières explosifs*, &c.), for 227 grams nitroglycerin and in Calories (kgm.-degree units), as follows:—

The water liquid, constant pressure, +356.5 Calories; constant volume, +358.5 Calories.

The water gaseous, constant pressure, +331.1 Calories; constant volume, +335.6 Calories.

Or, per 1 kilogram of nitroglycerin:

The water liquid, constant pressure, +1570 Calories; constant volume, +1579 Calories.

Sarrau and Vieille obtained, by experiment, +1600 Calories.

The volume (at 0° and 0.76 metre pressure) of the gases produced by the detonation of nitroglycerin, calculated from the equation given above, is 714 litres per 1 kilogram nitroglycerin, the water taken as gaseous; or 1142 litres gas (under the given conditions) per 1 litre nitroglycerin. The calculated volume of the permanent gases (*i.e.* the water taken as liquid, tension of aqueous vapour at 0° disregarded) at 0° and 0.76 metre is 467.5 litres per 1 kilogram of nitroglycerin, or 748 litres per 1 litre of nitroglycerin. Berthelot mentions that Sarrau and Vieille found experimentally the volume of permanent gases to be 465 litres at 0° per 1 kilogram nitroglycerin. The gases at the moment of detonation are greatly expanded by the heat of the combustion; according to an early statement of Berthelot (in 1871), the gases are expanded to eight times their volume at 0°.

It will be convenient to requote the numbers obtained by Noble and Abel (Fired Gunpowder, No. 2, *Trans. Roy. Soc.* 1880) with Waltham Abbey fine-grain gunpowder and ordinary English mining powder.

One kilogram perfectly dry powder gave on explosion:

	W. A. fine-grain	Mining powder
Quantity of heat in Calories (kgm.-degrees)	738.3	516.8
Permanent gases in litres at 0° and 0.76 metre	263.1	360.3

The statements as to the relative power of nitroglycerin and ordinary blasting powder as blasting agents vary; partly, no doubt, on account of differences in the rocks blasted, as nitroglycerin is most effective in a compact rock, offering equal resistance in all directions to the gases produced by the explosion. Thus, Trauzl (quoted by Berthelot) stated in 1870 that nitroglycerin used for blasting in quarries produced five to six times the effect of an equal weight of blasting powder; and for equal volumes the difference would be much greater. The effects produced are those of dislocation, specially dependent on the initial pressures. Schwanert (quoted by Böckmann) states that the mean blasting power of nitroglycerin may be taken as being 3.5 to 4 times greater than that of ordinary blasting powder; equal weights being in all probability intended.

The velocity of the propagation of detonation in liquid nitroglycerin has been determined by Abel (*Trans. Roy. Soc.* 1874, 385, 386). The length of nitroglycerin used was 14 feet, the weight 3 ozs. per foot of the train. The liquid was contained in a V-shaped trough of thin sheet metal; at intervals of 2 feet, fine insulated

copper wires crossed the trough (having been passed through, and cemented into, small holes in the sides of the trough) sufficiently near the bottom to be covered by the nitroglycerin. The velocities were measured by Noble's chronoscope; the mean rate of detonation was found to be 5305 feet (1612 metres) per second, or little more than one-fourth the rate of detonation of cylinders of compressed gun-cotton in a continuous row.

Use.—Nitroglycerin, as such, is no longer used as an explosive. It was at one time used to a large extent, especially in America; for instance, about 70 tons of Mowbray's nitroglycerin, transported in the frozen state, was used in the construction of the Hoosac Tunnel in Massachusetts in 1874. Its use was prohibited in England in 1869, and then died out in Europe, but it was employed in America for some years afterwards. Since the invention of nitrogelatin, there is no incentive to use raw nitroglycerin, as the former is as powerful an explosive as the latter.

Dynamites.

It has been already mentioned that the serious accidents which, in 1864-66, attended the transport or manufacture of nitroglycerin were followed by a reaction against its use, and in this country by a prohibitive Act in 1869. To render its transport safe, Nobel introduced the use of a solution of nitroglycerin in wood-spirit (methyl alcohol); a solution which is not explosive, and from which the nitroglycerin was to be separated by precipitation by water at the place where it was to be used. This method of protection was soon abandoned, as the separation of the nitroglycerin was troublesome, and at low temperatures it crystallised out from the solution. A further disadvantage in the use of nitroglycerin is that it may run from the bore-hole into fissures in the rock, escape detonation, and either burn and give off deleterious oxides of nitrogen, or, if unburned, be a grave source of danger on removing the rock. Attempts were made to overcome this difficulty by lining the borehole with clay. Subsequently Nobel succeeded in making the use of nitroglycerin comparatively safe by employing porous substances to absorb the liquid; to these preparations he gave the name *Dynamite*.

As he had been experimenting with a mixture of nitroglycerin and gunpowder, Nobel at first used charcoal as an absorbent, and various other substances were subsequently tried, but he found 'kieselguhr,' or so-called infusorial earth, to be the best absorbent of nitroglycerin (Eng. Pat. 1345, 1867). Nobel originally intended that the nitroglycerin should be separated out again for use, but he subsequently found that the dynamite itself could be more readily detonated than the liquid nitroglycerin.

The term 'dynamite' has now a more general significance. It is applied to all mixtures of nitroglycerin with solid substances, which absorb and retain it under ordinary conditions of storage, whatever the nature of the latter; but when used specifically, 'Kieselguhr Dynamite No. 1' is meant.

The absorbent material is known as the 'base' or 'dope,' and dynamites may be classified according to the nature of the base into:

(1) those with an inert base; (2) those with a combustible base; and (3) those with an explosive base. The last class includes those with bases which are explosive mixtures (nitrate, chlorate, perchlorate, &c.), and those which are explosive compounds, either of the 'nitro' or 'nitrate' class. In the last class it will be convenient to include blasting gelatin and gelatin-dynamite, although the nitrocelluloses have not yet been considered. Explosive mixtures containing only a small percentage of nitroglycerin, added to increase the ease of detonation, have been classified under the characteristic oxygen-salt, but the line of demarcation is not sharp, and the classification is to this extent arbitrary.

The principle of most modern dynamites, which belong to the second and third classes, is to make the base contribute to the energy of the explosive, the nitroglycerin acting as detonating agent to the base. A slight further advantage is obtained in these classes, as the excess of oxygen present in the nitroglycerin is utilised. Nobel first used gunpowder as the explosive base, but safer and more regular results were obtained by replacing the sulphur and charcoal by wood pulp. Wood pulp, owing to its physical properties, has a cushioning effect in preventing accidental detonation by friction or percussion, and gives a certain compressibility to the product which is of advantage in fitting the cartridge in a bore hole. On the other hand, wood pulp renders the dynamites more susceptible to detonating vibrations, and the detonation, once started, proceeds with greater certainty and regularity. This is due to the structure given to the mixture by the pulp, which is sufficiently open and loose for the detonating vibrations to penetrate the mass, and affords a large number of points for molecular attack, whereas an ordinary blow is absorbed by the mass owing to its compressibility. Freezing interferes with the detonation of these mixtures, probably owing to the latent heat of fusion of the nitroglycerin absorbing some of the energy of the detonating wave, but the texture of the dynamite has a very great influence in this connection, the ease of detonation being less affected the more granular and open the texture. Common rosin, used in some of the earlier dynamites, has a slow hardening effect on the mixtures, and in time renders them very insensitive to detonation.

The proportion of nitroglycerin in a dynamite is limited by the possibility of exudation. In the gelatinous dynamites, exudation is prevented by the gelatinisation of the nitroglycerin by solution in it of soluble nitrocellulose. In the lower grades of these explosives wood pulp is an ingredient, and its presence not only permits less complete gelatinisation of the nitroglycerin, but also the use of sufficient nitrate, or other oxidising salt, to give complete combustion without fear of exudation.

Calcium or magnesium carbonate, up to 2 p.c., but usually about 1 p.c., is frequently added to dynamites to act as a stabiliser by neutralising any acid formed by decomposition of the nitroglycerin on storage, and so preventing catalytic acceleration of the decomposition. Zinc or magnesium oxide is also used for the same purpose. Sodium or ammonium carbonate

has been, and sometimes still is, used as a stabiliser, but the use of these soluble carbonates is not advisable, owing to their hydrolysing action on the nitroglycerin in the presence of moisture.

1. *Dynamites with an inert base.*

Dynamite No. 1 or Kieselguhr dynamite.—Kieselguhr dynamite contains from 70 to 80 p.c., usually 75 p.c., of nitroglycerin. (Dynamites with less than 30 p.c. of nitroglycerin will not explode.) A small quantity of alkali, formerly 1.5 p.c. ammonium carbonate, now 0.5–1 p.c. anhydrous sodium carbonate, is usually added to neutralise any free acid that may develop on storage; but alkali is not always added.

Kieselguhr. The earth is found in several places; that first used was obtained from Oberlohe in Hanover, where there is an extensive bed of it. It consists of the frustules of diatoms, and is mainly silica; Beckerhinn examined some kieselguhr, and found it to contain 95 p.c. SiO_2 , and its specific heat to be 0.2089. The kieselguhr is moderately calcined to remove water and organic matter, then ground and sifted. It should be free from gritty particles. The dried kieselguhr is packed in canvas bags and stored in a dry atmosphere, as it is distinctly hygroscopic. Dynamite made with a guhr containing more than about 0.5 p.c. of water will exude nitroglycerin on storage.

The kieselguhr used at Ardeer is obtained from Aberdeenshire; it absorbs three or four times its weight of nitroglycerin, retaining it under considerable pressure. The calcined material contains about 98 p.c. SiO_2 (McRoberts, *l.c.*).

Manufacture.—The nitroglycerin and kieselguhr are mixed by hand in shallow lead tanks. Any stabiliser is added to the kieselguhr before impregnation. The guhr is weighed out into the tank, the weighed charge of nitroglycerin poured over it from a bucket of indiarubber, gutta-percha, or similar material, the ingredients kneaded, and then rubbed through the meshes of a coarse wire sieve, to complete the admixture. Sometimes two sieves are used, a coarse one with about 3 meshes to the inch, and a finer one with 7 meshes to the inch. The dynamite is then in the form of plastic grains. These must neither be dry enough to crumble nor decidedly greasy, or the cartridges will not be satisfactory. If the guhr be too absorbent, the mixture will be too dry for pressing, and in this case a small quantity of barium sulphate is usually added, or, sometimes, mica, talc, or ochre up to 8 p.c. replacing an equal weight of kieselguhr.

The dynamite cartridges are small cylinders, in which form they are squeezed out from the cartridge machine; the latter is a cylindrical metal tube, in which a wooden piston works, pressure being applied to the piston by means of a lever. One end of the tube is terminated by a funnel-shaped piece with orifice of the same diameter as that of the cartridges. The operation is a dangerous one, and every care must be taken to avoid undue friction in the machine, and the paste must never be worked if frozen. The cartridges, usually either $\frac{3}{4}$ or $\frac{7}{8}$ of an inch in diameter, but sometimes 1 inch, are sent out wrapped in parchment or paraffined paper.

Properties.—Kieselguhr dynamite is a plastic, pasty substance, the colour of which varies from pink or grey to a dark-brown, according to the colour of the base, and whether ochre has been added or not. The paste is stiff, or soft and greasy, according to the absorbing power of the kieselguhr. It is slightly compressible, and this property renders it quite safe from detonation by ordinary shocks.

Water separates the nitroglycerin from ordinary kieselguhr dynamite. The specific gravity of dynamite is about 1.6. When unfrozen dynamite is set fire to by application of flame, the nitroglycerin burns quickly with yellowish flame, giving off nitrous fumes. Large quantities can thus be burnt without explosion; but eventually the unburnt portion becomes heated to the temperature of explosion, and explodes. When exposed to a slowly rising temperature, dynamite fires at about 180°. It can be safely destroyed by laying it in a long thin train, pouring any waste oil over the train, and firing it. Dynamite freezes more readily than liquid nitroglycerin, usually at about 4°. Frozen dynamite burns very slowly, thawing preceding combustion. When a comparatively small heap of frozen dynamite cartridges is set fire to, an explosion often ensues. Like nitroglycerin, frozen dynamite is less sensitive to shock than unfrozen, and the ordinary detonator does not explode thoroughly frozen dynamite, although one-tenth part of the detonator charge is sufficient to cause the detonation of unfrozen dynamite (McRoberts, *l.c.*). Since frozen dynamite is comparatively useless as an explosive, it must be thawed or 'tempered' before being used, and this only takes place at temperatures considerably above the freezing-point. Thawing is done in special warming pans, in which the vessel containing the dynamite is surrounded by a jacket containing warm water (at a temperature not above 70°) and this in turn by a layer of felt or other non-conducting material. When a cartridge of dynamite has once been frozen, it has a greater tendency to freeze again without any supercooling. This is probably due to the separation of pure nitroglycerin from its impurities when first frozen, and only very slow readmixture after thawing. Dynamite is less sensitive to shock than nitroglycerin; the sensitiveness increases with the percentage of nitroglycerin in the dynamite, and (like explosives in general) with increase of temperature. It is detonated by the shock of iron on iron, or of iron on stone, but not by that of wood on wood. Dynamite between steel and steel, according to Hess, requires a blow of 0.75 kgm.-metre for detonation; when frozen it requires 1 kgm.-metre. In the unfrozen state it is readily detonated by the shock of a rifle-bullet; Berthelot states that it detonates under the direct blow of the bullet when fired at 50 metres' (164 feet) distance, and even more. Placed on an anvil and struck, it requires a smart blow of the hammer to cause an explosion, and then only the portions directly struck detonate, the rest being scattered without exploding. The silicious skeletons of the frustules of diatoms composing the kieselguhr form separate receptacles for the nitroglycerin, and have a cushioning effect towards a mechanical blow, the energy thereby imparted being

divided between the absorbent and the nitroglycerin. Berthelot (Sur la Force des Matières explosifs, &c.) remarks that dynamite is less crushing in its action than nitroglycerin, because the heat evolved on its detonation is shared between the products of the explosion and the inert substance, the latter by its presence lowering the temperature. Thus, the specific heat of kieselguhr (0.2) is almost the same as the mean specific heat of the gaseous products of explosion of nitroglycerin at constant volume; in the case of No. 1 dynamite with 25 p.c. kieselguhr, in a vessel completely filled by it, and too strong to be burst by its detonation, the kieselguhr would lower the temperature of the gases by one-fourth, and consequently diminish the initial pressure. In blasting, the condition of the gases of explosion would be intermediate between constant volume and constant pressure. In using dynamite, its detonation is effected by means of the explosion of a mercury fulminate detonator and fired by an electric current or by means of Bickford fuse, the cap being embedded in the dynamite. The detonator must be sufficiently powerful to ensure complete detonation of the nitroglycerin, or nitrous fumes will be generated in the mine workings. The detonator supplied for the purpose by Nobel's Explosive Company contains about 0.5 gram of a mixture of 70 p.c. mercury fulminate and 30 p.c. potassium chlorate.

The velocity of propagation of the detonation of this dynamite was found by Abel (Trans. Roy. Soc. 1874, 384, 385) to be 20,000 feet per second. The experiment was made with half-inch cartridges of dynamite in a continuous train of 42 feet, the rate being measured at intervals of 6 feet by means of Noble's chronoscope.

Abbot (U.S. Engineers) obtained from his experiments (Report upon a System of Submarine Mines, &c., 1881, 111) the remarkable result that the intensity of action of ordinary kieselguhr dynamite containing 75 p.c. nitroglycerin, fired under water, is greater than that of nitroglycerin. Thus, in a series of experiments he found the intensity of action of nitroglycerin detonated under water to be 81, that of an equal weight of dynamite being 100. To confirm the results, nitroglycerin was mixed, under Abbot's supervision, with prepared kieselguhr into dynamite of 75 p.c., and shots were immediately fired under water with this dynamite, and with the nitroglycerin from which it had been made. The mean of five shots gave the intensity of the liquid nitroglycerin as 85, that of the dynamite being 100 (equal weights compared). Abbot remarks that in blasting hard rock, nitroglycerin is admitted to be by far stronger than dynamite; in explanation he supposes that in dynamite the particles of kieselguhr slightly retard chemical action, and that the resistance opposed by water being of a slightly yielding character, may exact more time than is required by pure nitroglycerin. According to Abel's experiments, however, the rate of detonation of dynamite is very much quicker than that of liquid nitroglycerin,—a result agreeing with those of Abbot's experiments, but not with his explanation of them. It is true, as Abel points out, that the determination of the rate of detonation of liquid nitroglycerin (which was contained in an open

trough) was likely to be given too low, owing to the tendency of the liquid particles to escape from the blow of the detonation, and that experiments with confined nitroglycerin would be desirable.

Tested by the lead cylinder method, the intensity of action of nitroglycerin is 1.4 when that of No. 1 dynamite is unity. Von Pischoff, in Austria in 1869, comparing the relative values of dynamite and gunpowder, found that the former was roughly three times as strong as gunpowder, variations from 2.4 to 3.3 being obtained according to the nature of the rock. The nature of the kieselguhr has some influence on the explosive power of the dynamite; the guhrs containing most tubular structures not only absorb better, but each of these tubes offers resistance on detonation, and confers greater intensity of action by its tamping effect.

Dynamite of Vonges.—Instead of kieselguhr, in France a similar silicious earth called *Randanite* (from Randan in the Puy-de-Dôme) is used as the absorbent in the Vonges make of dynamite. Tripoli and the ashes of Boghead coal have also there been employed as substitutes for kieselguhr. Analysis of a modern sample gave 75 p.c. nitroglycerin, 20.8 p.c. randanite, 3.8 p.c. quartz, and 0.4 p.c. magnesium carbonate. More rarely *Dynamites Nos. 2 and 3* are used in France, containing 35 and 25 p.c. nitroglycerin respectively. The American *Giant powder No. 1* is dynamite No. 1 containing 0.5 p.c. sodium carbonate.

Magnesia alba has also been used as the absorbent of nitroglycerin, its absorptive power being said to exceed that of kieselguhr, and it is also said to increase the intensity of action of the dynamite by the expulsion of its carbon dioxide. The combination was proposed in 1879, by Jones of Caerphilly, and named *Nitromagnite* or *Dynamagnite*. Its manufacture was abandoned, as it was decided that it conflicted with the existing patents of Nobel.

Modifications of kieselguhr dynamite have been proposed, more especially on the Continent, with a view of rendering it safe to use in fiery mines: various additions, such as salts containing much water of crystallisation, being made to reduce the temperature of the flame. Such explosives are naturally less powerful than ordinary dynamite.

In *Weiter dynamite*, proposed by Müller of the Cologne dynamite factory (Eng. Pat. 12424, 1887), crystallised sodium carbonate is used. Composition 52 p.c. nitroglycerin, 14 p.c. kieselguhr, and 34 p.c. soda crystals.

Grisoutite contains magnesium sulphate. It is composed of 53 p.c. nitroglycerin, 14.5 p.c. kieselguhr, and 32.5 p.c. magnesium sulphate.

Nobel Ardeer powder is a dynamite of this class, for although it contains nitre, it has no added combustible. Composition: 33 p.c. nitroglycerin, 49 p.c. magnesium sulphate, 13 p.c. kieselguhr, and 5 p.c. nitre.

Mica powder (Abbot, Report upon a System of Submarine Mines, &c., 93, 110) consists of finely divided mica scales and nitroglycerin. It was made in the United States by Mowbray, and was largely used, with good results, in completing the Hoosac Tunnel. The nitroglycerin adheres to the scales, but is not absorbed by them. Mowbray claimed that, owing to the very

large surface exposed, a more instantaneous reaction is secured than with liquid nitroglycerin. He estimates the interstitial spaces at one-fourth the volume of the powder when tolerably well rammed.

Abbot experimented with a No. 1 mica powder containing 52 p.c. nitroglycerin, and with a No. 2 containing 40 p.c.; the charges being detonated under water. He found the intensity of action of No. 1 to be 83, of No. 2 to be 62; that of liquid nitroglycerin, in the same circumstances, being 81, and that of kieselguhr dynamite No. 1, containing 75 p.c. nitroglycerin, being 100 (equal weights compared). The result is remarkable, as it gives the intensity of action of the nitroglycerin in mica powder as double that of an equal weight of liquid nitroglycerin.

2. *Dynamites with a Combustible Base.*

In this class the explosive power of the nitroglycerin is enhanced by the utilisation of its excess of oxygen for combustion of part of the base. There is, however, a considerable excess of combustible matter, leading to the formation of carbon monoxide on detonation, and the dynamites containing an oxygen salt in addition are more usual.

Cork charcoal is very absorptive but costly, and the more usual combustible absorbents are wood meal, flour, and starch.

Carbodynamite is a preparation introduced by Messrs. W. D. Borland and W. F. Reid (Eng. Pat. 758, 1886). It consists of 10 p.c. cork charcoal, which has absorbed 90 p.c. nitroglycerin. Sodium or ammonium carbonates and water may or may not be present.

It is claimed for carbodynamite that it can be kept under water for weeks without losing its nitroglycerin, which would be a great advantage over kieselguhr dynamite.

As was to be expected from the high percentage of nitroglycerin, the intensity of action of carbodynamite is very high—much higher than that of kieselguhr dynamite. In one variety of carbodynamite, water was added to render the explosive safe enough to use in fiery mines. Another variety, No. 2, belongs to the third class of dynamites, as it contains 80 p.c. nitroglycerin, 14 p.c. nitre, and 6 p.c. cork charcoal.

Grisoutite.—Another form of this safety explosive contains wood meal as the absorbent, instead of kieselguhr. Composition: 44 p.c. nitroglycerin, 12 p.c. wood meal, 44 p.c. magnesium sulphate. This explosive is on the Belgian permitted list. Another explosive of this class on the same list is *Dynamite antigrisoutite V*, which has the same composition except that sodium sulphate replaces the magnesium sulphate as restrainer and temperature reducer. The limit charge of the former is 300 grams, and of the latter 650 grams.

Forcite is the name given to explosives manufactured in various grades by the American Forcite Company, New Jersey. The original patent (of 1881) describes forcite as consisting of nitroglycerin incorporated with unnitratized gelatinised cellulose and with nitre. Cotton or other form of cellulose was to be purified chemically as in paper making, to be reduced to powder and to be subjected to the action of high-pressure steam, by which it was converted into a

gelatinous mass. It was then allowed to cool, and was to be incorporated at 40° with nitroglycerin and with nitre. One of the best compositions was stated to be: nitroglycerin, 75 p.c.; gelatinised cotton, 7 p.c.; nitre, 18 p.c. Dextrin and ordinary cellulose in powder might partly replace the gelatinised cotton.

Forcite is described as a hard plastic substance, having very much the appearance and toughness of indiarubber. Economy, non-exudation of nitroglycerin, and imperviousness to water, were claimed for it. There is considerable variation in the statements as to the composition of forcite; thus, in one kind the gelatinised nitroglycerin is said to be incorporated with a mixture composed of sodium nitrate, wood tar, a little sulphur and wood pulp. It is made in various grades containing different amounts of nitroglycerin. Eissler states that the type mostly in use (in the United States, and in 1886), and which possesses the best qualities, is the No. 1, containing from 65 to 85 p.c. nitroglycerin; also that the quantity of nitroglycerin in different grades varies from the large amount mentioned to only 20–25 p.c. He states that quadruple-force caps are employed to explode forcite.

Abbot (U.S. Engineers) made estimations of the intensity of forcite exploded under water; the intensity varied with the grade, between 88 and 133, ordinary kieselguhr dynamite No. 1 being 100 (Addendum II. to Report on Submarine Mines). Belgian and other continental makes of forcite contain nitrocellulose, and come in class 3 of dynamites.

Forcite antigrisoutite No. 2 has a similar composition to 'grisoutite.'

Rhenish dynamite consists of 75 p.c. of a solution of naphthalene in nitroglycerin, 25 p.c. of kieselguhr, and a little chalk or barium sulphate.

3. *Dynamites with an Explosive Base.*

Kieselguhr dynamite is much too violent and local in its effects to be used in most mining operations, such as in coal-mines or slate and granite quarries, where great power and shattering effects are undesirable. As the force cannot be moderated by reducing the proportion of nitroglycerin without increasing the difficulty of detonation, the dynamites with an explosive base have gradually superseded it for mining purposes.

i. *Dynamites with a Potassium Nitrate Mixture Base.*

In many of these mixtures the proportion of combustible matter is so high that a large proportion of the carbon is only oxidised to monoxide on detonation. This is objectionable in explosives to be used in mines. The paper wrapper of the cartridge has also to be considered as combustible matter in this connection.

Dynamite No. 2 is black in colour, and is milder and slower in its action than No. 1. It was introduced to imitate the explosive characteristics of gunpowder. It consists of (not more than) 18 p.c. of nitroglycerin, uniformly mixed with 82 p.c. of a pulverised preparation, composed of 71 p.c. potassium nitrate, 10 p.c.

charcoal, 1 p.c. paraffin. Scarcely used at all in this country.

Dynamite No. 3 was intermediate in power between No. 1 and No. 2. It consisted of a mixture of equal parts of No. 1 and a mixture of potassium nitrate and wood meal.

Britonite No. 2, an English permitted explosive, contains on the average 24 p.c. nitroglycerin, 30 p.c. potassium nitrate, 38 p.c. wood meal, and 8 p.c. ammonium oxalate. Limit charge 24 ozs., pendulum swing 2.26 inches.

Rend rock is a modern modification of 'Lithofracteur,' having the composition 40 p.c. nitroglycerin, 40 p.c. nitre, 13 p.c. wood pulp, and 7 p.c. pitch.

Atlas powders B+ and C+, as used in the construction of the Panama Canal, contained B+, 60 p.c. nitroglycerin, with wood pulp and nitre, and 3 p.c. of magnesia; C+, 45 p.c. nitroglycerin, with wood pulp and nitre and 2 p.c. of chalk.

Some forms of *Wetter dynamite* contain a similar mixture. A sample from Wittenberg contained 25 p.c. nitroglycerin, 35 p.c. mixed nitrates of potassium and barium, and 40 p.c. wood meal.

Cambrite, on the English authorised list, contains 22-24 p.c. nitroglycerin, 26-29 p.c. potassium nitrate, 3-4.5 p.c. barium nitrate, 32-35 p.c. wood meal, 0-0.5 p.c. calcium carbonate, 7-9 p.c. ammonium oxalate, and 3.5-6 p.c. moisture. Limit charge 30 ozs., pendulum swing 1.98 inches, No. 6 detonator.

Carbite, a French dynamite of this class, contains 25 p.c. nitroglycerin, 34 p.c. potassium nitrate, 1 p.c. barium nitrate, 38.5 p.c. flour, 1 p.c. powdered bark, and 0.5 p.c. sodium carbonate.

Carbonite, made by Bichel and Schmidt of Schlebusch, one of the first and most successful of safety explosives for use in fiery mines. It contains 25-27 p.c. nitroglycerin, 30-36 p.c. of a mixture of potassium and barium nitrates, and 40-43 p.c. starch and wood meal, with 0.5 p.c. sodium carbonate, and 0.5 p.c. of sulphuretted benzene. An actual sample contained 25 p.c. nitroglycerin, 34 p.c. potassium nitrate, 1 p.c. barium nitrate, 10 p.c. wood meal, 29.5 p.c. rye flour, and 0.5 p.c. sodium carbonate.

Kolax, an English permitted explosive, contains on the average 25 p.c. nitroglycerin, 26 p.c. potassium nitrate, 5 p.c. barium nitrate, 34 p.c. wood meal, and 10 p.c. starch.

Super-Kolax is of similar composition, but to enable it to pass the severer Rotherham test, about 10 p.c. of the explosive base is replaced by ammonium oxalate.

Pit-it No. 2, on the English permitted list, contains 23-25 p.c. nitroglycerin, 28-31 p.c. potassium nitrate, 33-36 p.c. wood meal, 7-9 p.c. ammonium oxalate, and 2.5-5 p.c. water. Limit charge 32 ozs., pendulum swing 2.15 inches, detonator No. 6.

Stonite, also made by Bichel and Schmidt, consists of 68 p.c. nitroglycerin, 20 p.c. kieselguhr, 8 p.c. potassium nitrate, and 4 p.c. wood meal.

Tutol, on the English permitted list, contains on the average 25 p.c. nitroglycerin, 33 p.c. potassium nitrate, 2 p.c. barium nitrate, 40 p.c. wood meal, and up to 0.5 p.c. sodium bicarbonate.

Kynite is a safety explosive of similar composition to carbonite. One analysed sample contained 25 p.c. nitroglycerin, 35 p.c. barium and potassium nitrates, and 40 p.c. starch and wood meal. As licensed, *Kynite condensed* contains 24-26 p.c. nitroglycerin, 32.5-35 p.c. starch, 2.5-3.5 p.c. wood meal, 31.5-34.5 p.c. barium nitrate, and 0-0.5 p.c. calcium carbonate; the explosive to be used only in a non-waterproofed parchment-paper wrapper.

Kohlen-carbonite, a Belgian permitted explosive, contains on the average 25 p.c. nitroglycerin, 34 p.c. potassium nitrate, 1 p.c. barium nitrate, 38.5 p.c. flour, 1 p.c. tan meal, and 0.5 p.c. sodium carbonate. Limit charge 900 grams.

Minite is a similar explosive without the barium nitrate and tan meal.

Dualine contains 50 p.c. nitroglycerin, 20 p.c. potassium nitrate, and 30 p.c. sawdust.

ii. *Dynamites with a Sodium Nitrate Mixture Base.*

The dynamites of this class, like those with an ammonium nitrate base, are hygroscopic. Under damp atmospheric conditions the nitrate deliquesces, and its solution displaces the nitroglycerin, and causes it to exude. These dynamites are consequently liable to become dangerous, and although largely used elsewhere, were for a long time not licensed in England. Several examples both of this and the ammonium nitrate class have, however, recently been permitted.

Judson powder is an explosive which has been largely used in the United States in quarrying and railway work; it is a roughly made sodium nitrate blasting powder, the grains of which are coated with nitroglycerin. The grade R.R.P. is the one most commonly used, and is sold at the price of common saltpetre blasting powder; it is composed of sodium nitrate 64 p.c., sulphur 16 p.c., cannel coal 15 p.c., nitroglycerin 5 p.c. The nitrate, sulphur, and coal are thoroughly mixed in fine powder, and the mixture heated on a pan by steam under pressure, and constantly stirred until the sulphur melts. The mass is then allowed to cool, when it is found agglomerated in grains, which are sorted by sieves and coated with nitroglycerin by stirring. The object of coating the powder grains with the nitroglycerin was to promote the quickness of explosion. It is exploded by the detonation of a primer of Giant or Atlas powder. These low-grade dynamites are readily detonated even in the coldest weather, probably owing to their loose and open texture. Abbot (*op. supra*) found the intensity of action of the R.R.P. grade, exploded under water, to be 38-39, kieselguhr dynamite No. 1 being 100. Other brands now in use with their percentages of nitroglycerin are: F. 10 p.c., F.F. 15 p.c., F.F.F. 20 p.c., Dbl. Ex. 27 p.c., and Tpl. Ex. 33 p.c.

Giant powder No. 2, supplied by the Atlantic Giant Powder Company, and composed of nitroglycerin 36 p.c., potassium or sodium nitrate 48 p.c., sulphur 8 p.c., resin, powdered coal or charcoal 8 p.c. Exploded under water, its intensity of action was 83 p.c. of that of dynamite No. 1. A more modern composition is 40 p.c. nitroglycerin, 40 p.c. sodium nitrate,

8 p.c. kieselguhr, and 6 p.c. sulphur. There are six or more other brands with percentages of nitroglycerin varying from 20 to 50.

Vigorite contains 30 p.c. nitroglycerin, 60 p.c. sodium nitrate, 5 p.c. charcoal, and 5 p.c. sawdust.

Vulcan powder was used in some of the earlier blasting work at Hellgate, New York Harbour. The usual trade explosive, of the composition nitroglycerin 30 p.c., sodium nitrate 52.5 p.c., charcoal 10.5 p.c., sulphur 7 p.c., fired under water gave intensity = 78 p.c.; and a No. 2 sample containing 35 p.c. nitroglycerin, gave intensity = 82 p.c. compared with the usual standard (Abbot).

Lithofracteur, invented by Engels, and made by Krebs & Co., of Cologne, is said to consist of 55 p.c. nitroglycerin, 21 p.c. kieselguhr, and 24 p.c. of charcoal (bran or sawdust), barium nitrate, bicarbonate of soda, peroxide of manganese, and sulphur; the latter ingredients in such proportion as to give the highest temperature and greatest quantity of gas. Stated to be nearly equal in intensity to kieselguhr dynamite No. 1 (Böckmann, *Die explosiven Stoffe*). One sample gave on analysis 52 p.c. nitroglycerin, 30 p.c. kieselguhr, 12 p.c. powdered coal, 4 p.c. sodium nitrate, and 2 p.c. sulphur; another sample contained 70 p.c. nitroglycerin, 23 p.c. kieselguhr, 2 p.c. powdered coal, and 5 p.c. barium nitrate. This explosive was formerly on the list of 'authorised' explosives, but is not now used in this country.

Lignin dynamites. In the United States, large quantities of nitroglycerin preparations are used in rock-blasting, consisting of nitroglycerin absorbed by a mixture of wood pulp (or of sawdust in some of the lower grades) and a nitrate, usually sodium nitrate. For the complete combustion of wood with formation of sodium carbonate, about 2.5 parts by weight of sodium nitrate are required to 1 of wood. General Abbot, in 1885, says, 'Development in the United States is at present most actively directed to the dynamites with explosive bases, economy being sought in making use of the least possible percentage of nitroglycerin.' At the present time these dynamites are very largely used under the name *Straight Dynamites*. They are graded as of 10 p.c., 15 p.c., 20 p.c., &c., up to 75 p.c. strength, according to the percentage of nitroglycerin they contain, but the actual nitroglycerin content frequently varies to a considerable extent from the nominal. The sodium nitrate content varies from about 16 to 64 p.c., the wood pulp from 8 to 20 p.c., and the moisture from 1 to 3 p.c. Calcium or magnesium carbonate is usually present to the extent of about 1 to 2 p.c. For the lower grades the combustible matter frequently contains flour and sulphur in addition to the wood pulp, but sulphur is objectionable in dynamites to be used underground, owing to the sulphur dioxide present in the products of explosion. Their velocity of detonation varies with the percentage of nitroglycerin, being, in metres per second, about 2100 for the 10 p.c., 4200 for the 30 p.c., 4800 for the 40 p.c., and 6300 for the 75 p.c.

Lignin dynamites are largely manufactured by the Cape Explosives Works and used in South Africa under the name *Ligdyns*. They can be detonated with a No. 5, 0.8 gram,

detonator, and this apparently brings out their full power; but it is more usual to use a No. 6, 1.0 gram, detonator, as the action is then more certain. The ligdyns can still be detonated when frozen, but their full force is not attained.

Atlas powder may be taken as a type of several American preparations. It consists essentially of sodium nitrate, wood pulp (or sometimes of sawdust), magnesium carbonate, and nitroglycerin. A series of grades is made, containing 75 p.c. to 20 p.c. nitroglycerin.

Abbot experimented with two grades, A and B, of Atlas powder; they were composed of:

	Grade A	Grade B
Sodium nitrate	2	34
Wood fibre	21	11
Magnesium carbonate . .	2	2
Nitroglycerin	75	50

Fired under water, the intensity of grade A was just that of an equal weight of kieselguhr dynamite No. 1 (75 p.c. nitroglycerin); whilst the intensity of Atlas B was = 99 p.c. of the same standard (Abbot, Addendum II. to Report on Submarine Mines). Grade A shows no economy in nitroglycerin over kieselguhr dynamite of the same percentage, probably owing to the too low ratio of sodium nitrate to wood fibre. Grade B, in which the ratio of nitrate to wood is that of complete combustion, shows a great economy in nitroglycerin.

Abel found (by the lead cylinder method) the intensity of an Atlas powder of American make to be 106, kieselguhr dynamite No. 1 being = 100.

Hercules powder has essentially the same composition as Atlas powder. Several grades of it are made in the United States, containing from 75 p.c. to 20 p.c. nitroglycerin. Some years since, two grades were tried by Abbot, and fired under water; their composition and intensity of action were:

	No. 1	No. 2
Nitroglycerin	77 p.c.	42.0 p.c.
Sodium nitrate	1	43.5
Wood pulp	2	11.0
Magnesium carbonate . .	20	3.5
Intensity	106	83.0

(Kieselguhr dynamite No. 1 being = 100).

Similar American lignin dynamites of this class are the various *Giant powders*, with quantities of nitroglycerin, varying from 20–50 p.c. (exclusive of the giant powders 1 and 2 already mentioned); *Safety nitro powder*, containing 69 p.c. nitroglycerin, 18 p.c. sodium nitrate, and 13 p.c. wood pulp; *Hecla powder*, made in seven grades, containing 75–20 p.c. nitroglycerin; *Miner's friend*, and others.

Rhexite is manufactured by the Borkenstein Co. in Styria. One sample contained 64 p.c. nitroglycerin, 18 p.c. sodium nitrate, 11 p.c. decayed wood, and 7 p.c. wood meal.

Rexite as licensed by the Home Office, the explosive contains 64–68 p.c. ammonium nitrate, 13–16 p.c. sodium nitrate, 6.5–8.5 nitroglycerin, 6.5–8.5 trinitrotoluene, 3–5 p.c. wood meal, and 0.5–1.5 p.c. moisture, used in a stout paper case waterproofed with ceresin and wax.

Tutol No. 2 is a variety of this explosive containing sodium nitrate instead of potassium nitrate, and in which about 12 p.c. of the explosive base is replaced by sodium chloride.

Some forms of *Carbonite* contain sodium

nitrate instead of nitre. *Coal carbonites I. and II.* contain respectively 25 and 30 p.c. nitroglycerin, 30.5 and 24.5 p.c. sodium nitrate, 39.5 and 40.5 p.c. rye flour (containing about 2.5 p.c. water), and 5 and 5 p.c. potassium dichromate. *Carbonite I.A* contains sodium chloride instead of potassium dichromate.

Phoenix powders resemble the above forms of carbonite. They are manufactured in various brands:

	I.	II	III.
Nitroglycerin . . .	30	25	25
Sodium nitrate . . .	30	1	35
Barium and potassium nitrates . . .	—	34	—
Rye flour . . .	40	—	40
Wood meal . . .	—	40	—
	100	100	100

Sometimes a little nitro cotton is added to gelatinise the nitroglycerin.

iii. *Dynamites with an Ammonium Nitrate Mixture Base.*

Ammonia dynamite was a nitroglycerin preparation proposed and patented in 1872 by Ohlson and Norrbm, which consisted of nitroglycerin 10 p.c. to 20 p.c., ammonium nitrate 80 p.c., charcoal 6 p.c. The material is deliquescent, and paraffin was added to the mixture to waterproof it. Berthelot states that practical tests have shown ordinary dynamite of 60 p.c. nitroglycerin, and the preparation consisting of 75 p.c. ammonium nitrate, 3 p.c. charcoal, 4 p.c. paraffin, and 18 p.c. nitroglycerin, to be approximately equal in intensity of action.

In 1873 the British Dynamite Co. (now Nobel's Explosive Co.) submitted two samples of ammonia dynamite to the special War Office Committee on Guncotton, &c., containing respectively 18 and 13 p.c. nitroglycerin, 75 and 70 p.c. ammonium nitrate, 4 and 7 p.c. paraffin, and 3 and 10 p.c. charcoal dust. They were unfavourably reported on, on account of the possibility of exudation of nitroglycerin on storage, due to the deliquescent nature of the ammonium nitrate. As permitted for manufacture in this country, Nobel's ammonia powder had the composition:

	No. 1	No. 2
Ammonium nitrate . . .	82-86 p.c.	78-82 p.c.
Nitroglycerin . . .	7-9 "	9-11 "
Wood meal . . .	6-8 "	8-10 "
Moisture . . .	0.5-2 "	0.5-2.5 "

A recent sample of *Pulverulent ammonium dynamite* contained 20 p.c. nitroglycerin, 25 p.c. ammonium nitrate, 36 p.c. sodium nitrate, and 19 p.c. dry rye flour.

'Ammonia dynamites,' in which part of the nitroglycerin in the earlier lignin dynamites is replaced by ammonium nitrate, are used to some extent in the United States. They are graded in per cent. strengths like the more usual simple nitroglycerin mixtures. The nitroglycerin and ammonium nitrate are present in roughly equal proportions, and the sum of their percentages corresponds to the grade strength in the lower grades, but in the higher grades their combined percentages are somewhat higher than that of nitroglycerin in the 'straight

dynamites,' so as to give comparable strengths. Their velocities of detonation increase with the strength, but, as would be expected, are lower than those of the corresponding 'straight dynamites.' According to Corney, the velocity of detonation of the 30 p.c. grade is about 3500, the 40 p.c. about 4100, and the 50 p.c. about 4400 metres per second. His result for the 60 p.c. strength was anomalous, being only 3000 metres per second.

Du Pont Permissible No. 1, manufactured in the United States and on the English permitted list, contains 9 p.c. nitroglycerin, 68 p.c. ammonium nitrate, 8 p.c. wood pulp, and 15 p.c. sodium chloride. Limit charge 18 ozs., pendulum swing 2.82 inches.

Haylite No. 3, manufactured by the National Explosives Co., and also on the permitted list, contains approximately 9.5 p.c. nitroglycerin, 60 p.c. ammonium nitrate, 5 p.c. wood meal, 19.5 p.c. sodium chloride, 5 p.c. ammonium oxalate, and 1 p.c. moisture. Limit charge 16 ozs., pendulum swing 2.44 inches.

Most modern dynamites containing ammonium nitrate also contain nitro cotton, which serves to protect them from the action of moisture.

iv. *Dynamites with a Barium Nitrate Mixture Base.*

Some dynamites, for example, 'Haylite No. 1,' 'Kolax,' and 'Tutol,' contain barium nitrate in admixture with other oxygen salts in their base.

Nitro Dense is an English permitted explosive containing 17-19 p.c. nitroglycerin, 24-26 p.c. barium nitrate, 4-6 p.c. wood meal, 24-27 p.c. starch, 22-24 p.c. French chalk, and 2-5 p.c. moisture. Limit charge 28 ozs., pendulum swing 1.47 inches, detonator No. 6.

v. *Dynamites with a Chlorate Mixture Base.*

Although the substitution of a chlorate for a nitrate mixture, as an absorbent for nitroglycerin, increases the power of the resultant explosive, it adds to the cost, and the explosives possess the dangerous properties inherent in chlorate mixtures. They are not used in this country.

An early example of this class of dynamite was proposed by Horsley, in 1872, in which a mixture of finely ground gall nuts and potassium chlorate, in the proportion of 1 to 3, was impregnated with 20 p.c. nitroglycerin.

Some modern grades of the American *Hercules powders* contain potassium chlorate and sugar instead of the older wood pulp, their composition being: 40-75 p.c. nitroglycerin, 1-16 p.c. sugar, 1-3.5 p.c. potassium chlorate, 2-30 p.c. potassium nitrate, and 10-20 p.c. magnesium carbonate.

vi. *Dynamites with a Perchlorate Mixture Base.*

Several explosives containing a considerable proportion of nitroglycerin, partly gelatinised with a small quantity of soluble nitro cotton, and with a mixture of potassium perchlorate and wood meal as a base, have during the last few years passed the English tests and have been placed on the list of permitted explosives. These have been classified separately, as they

are characterised by the perchlorate, though they also belong to Class VIII.

Ammonium oxalate is present as a cooling agent instead of the previously more common ammonium nitrate, and this obviates the fault of hygroscopicity. The small proportion of nitrohydrocarbon frequently present is not intended primarily as a combustible, but is added to lower the freezing-point of the nitroglycerin.

The method of manufacture is to first sift the perchlorate, oxalate, and wood meal, the two former through a 50-100-mesh sieve, the latter through a 20-50-mesh sieve, roughly mix them by hand in a pan, then to pour over the mixture the partially gelatinised nitroglycerin, and again roughly mix. The final incorporation is carried out in a nitrogelatin incorporator at a temperature not above 30°.

Ajax powder contains on the average 22.5 p.c. nitroglycerin, 0.8 p.c. soluble nitrocotton, 37.2 p.c. potassium perchlorate, 25 p.c. ammonium oxalate, 11 p.c. wood meal, and 3.5 p.c. di- or tri-nitrotoluene. Limit charge 12 ozs., pendulum swing 2.69 inches.

Dynobel, manufactured by Nobel's Explosives Co., contains 31.5-33.5 p.c. nitroglycerin, 0.5-1 p.c. collodion cotton, 26-28 p.c. potassium perchlorate, 28.5-30.5 p.c. ammonium oxalate, 8.5-10.5 p.c. wood meal, and 0-1.5 p.c. moisture. Limit charge 22 ozs., pendulum swing 2.61 inches, detonator No. 6.

Neonal is manufactured by the New Explosives Co. in two varieties. *Neonal* contains 20-22 p.c. nitroglycerin, 0.5-1.5 p.c. collodion cotton, 36-38 p.c. potassium perchlorate, 24-26 p.c. ammonium oxalate, 14-16 p.c. wood meal, 0-0.4 p.c. di- or tri-nitrotoluene, and 0-2 p.c. moisture. Limit charge 16 ozs., pendulum swing 2.56 inches, detonator No. 6; and *Neonal* No. 1 contains 40 p.c. nitroglycerin, 2.8 p.c. collodion cotton, 14 p.c. potassium perchlorate, 39 p.c. ammonium oxalate, and 5 p.c. wood meal. Limit charge 30 ozs., pendulum swing 2.51 inches.

Swale powder is, on the average, a mixture of 19 p.c. nitroglycerin, 1 p.c. soluble nitrocotton, 37.5 p.c. potassium perchlorate, 10.5 p.c. wood meal, 28 p.c. ammonium oxalate, and 4 p.c. di- or tri-nitrotoluene. Limit charge 20 ozs., pendulum swing 2.50 inches.

vii. *Dynamites containing a Nitro Derivative.*

Castellanos powder was an early dynamite of this class which contained nitroglycerin, nitrobenzene, fibrous material, and kieselguhr. It was claimed to burn easily and rapidly without explosion, and to be less liable to freeze than ordinary dynamite.

Many dynamites contain a small proportion of nitrohydrocarbon, added simply for the purpose of reducing the freezing-point of the nitroglycerin.

Rexite, already mentioned, contains tri-nitrotoluene.

Melling powder, an explosive on the English permitted list, contains 4-6 p.c. nitroglycerin, 5-7 p.c. trinitrotoluene, 51-55 p.c. ammonium nitrate, 11-13 p.c. sodium nitrate, 3-5 p.c. wood meal, 18-20 p.c. ammonium oxalate, and up to 2 p.c. moisture. Limit charge 12 ozs., pendulum swing 2.62 inches, detonator No. 6.

Antigel de Sûreté, on the Belgian permitted list, contains 25 p.c. nitroglycerin and 15 p.c. dinitrotoluene, with sodium nitrate, wood meal, and a little ammonium sulphate.

viii. *Dynamites containing Nitric Esters.*

The nitric ester almost invariably used is soluble nitrocotton.

Blasting gelatin. Owing to the tendency of nitroglycerin to exude from the dynamites containing a base of either kieselguhr or an explosive mixture, Nobel continually experimented in the direction of thickening the nitroglycerin by dissolving some substance in it; preferably an explosive. He tried guncotton as early as 1867, but it was not until accident led him, in 1875, to try collodion with the assistance of a solvent, that the problem was solved. He found that 7-8 p.c. of collodion cotton could be dissolved in nitroglycerin to form a plastic jelly which was impervious to water (Fr. Pat. 106384; Eng. Pat. 4179, 1875). Subsequently, Nobel found that warm nitroglycerin would itself dissolve the collodion cotton without the assistance of a solvent. The resulting explosive was known as 'blasting gelatin' or 'nitrogelatin.' It has been mentioned that nitroglycerin contains an excess of 3.52 p.c. of oxygen above that required for the complete combustion of the carbon and hydrogen of the nitroglycerin; this oxygen is utilised in effecting the complete combustion of the nitrocotton, itself deficient in oxygen. The composition is consequently most powerful, and it is also proof against the action of water. For the purpose of blasting hard rock, this class of dynamite has now practically displaced the previous types of dynamite in England and most continental countries.

Composition.—The relative proportions of the two ingredients vary somewhat. Blasting gelatin was first experimented with on the large scale in Austria, and the usual proportion there is 7 p.c. nitrocotton to 93 p.c. nitroglycerin. The same proportions are used in Germany. In England and Switzerland, the nitrocotton varies between 5 and 10 p.c., usually about 7 p.c. With only 4 p.c. nitrocotton the resultant product is a thin liquid jelly. In Italy 8 parts of nitrocotton are dissolved in 90 parts of nitroglycerin, with the aid of methyl alcohol.

The nitrocotton used is the so-called collodion cotton or soluble nitrocellulose, which should be as dry and as free from insoluble nitrocotton as possible. It should have as high a nitrogen content as is compatible with complete solubility in nitroglycerin. The nitrocotton, for this purpose, requires very special preparation, and even now the conditions are not perfectly understood for the preparation of a nitrocotton fulfilling the above requirements, and also giving a perfectly stiff and dry blasting gelatin, that will not exude nitroglycerin when stored in hot climates. A nitrocotton of the correct type is, however, essential: stiffening by the addition of more nitrocotton of a poor quality is of no value, as the gelatin resulting, though hard when first manufactured, rapidly deteriorates, and exudes nitroglycerin on storage, especially in hot climates. It is frequently stabilised by the addition of up to 2 p.c. of calcium or magnesium carbonate. A very small

quantity of mineral jelly is sometimes added for the same purpose.

Manufacture.—In the preparation of small quantities, the weighed charge of nitroglycerin is introduced into a square, jacketed copper or lead trough, heated by the circulation of hot water. When the nitroglycerin is hot, the charge of finely divided and thoroughly dried collodion cotton is gradually added, the mixture being stirred with a wooden paddle from time to time for 2 hours until the gelatinisation is complete and the jelly in the tanks is semi-transparent. The mass is then kneaded by hand until perfectly uniform. By using mechanically worked wooden paddles revolving very slowly, a charge of 2 cwts. of the explosive can be thoroughly gelatinised in about 1 hour. The temperature of the nitroglycerin is usually kept between 35° and 40°; occasionally, temperatures approaching 45°–50° are used, but the operation becomes very dangerous at the higher temperature, and this is only used under exceptional circumstances, when the solution of the nitrocotton is sluggish, usually due to the nitrocotton being damp.

On a larger scale, the kneading is done mechanically. The apparatus in use at Ardeer at the time is described by McRoberts in a paper read before the Society of Chemical Industry in May, 1890 (*J. Soc. Chem. Ind.* 1890, 267), but most factories now use the 'nitro-universal incorporator' kneading machines of Werner, Pfeleiderer, and Perkins, such as are used in the manufacture of smokeless powders (*q.v.*).

The use of a solvent such as methyl alcohol, ethyl alcohol, acetone, or acetic ether does away with the necessity for heat in the process, and also renders the explosive less sensitive and less liable to freeze, but the explosive power of the product is also lowered and the addition is not usual.

The gelatin paste whilst still warm is finally worked into cartridges by some form of Archimedeian-screw machine, the mass being too stiff for the presses used for ordinary dynamite, such as that described by McRoberts (*l.c.*), the resulting rod of gelatin being cut across by bronze knives into cylinders of the requisite length, 3–4 inches, and wrapped in parchment- or paraffined paper.

Cocking and Kynoch, Ltd. (*Eng. Pat.* 28178, 1911), manufacture blasting gelatin from wet nitrocotton, containing 20–30 p.c. water, by mixing with the nitroglycerin at a temperature of 40°–60°. The water is driven off by drawing the product to and fro between two chambers through narrow-diameter jacketed tubes heated to the desired temperature.

Properties.—Blasting gelatin is a translucent, elastic semi-solid of light-yellow colour and of sp.gr. 1.55 to 1.59. It does not deteriorate by submergence in water, though it becomes paler in colour and more opaque, water not separating the nitroglycerin—an advantage over kieselguhr dynamite No. 1. It freezes at low temperatures; but while some cartridges freeze readily at about 2° to 4°, others are sometimes found which are not frozen by 24 hours' exposure to the temperature of a mixture of ice and salt. If well made, blasting gelatin exudes no nitroglycerin even after repeated freezing and thawing, but pressure tends to cause exudation, more so in

some products than in others. Exudation has frequently been traced to the use in manufacture of nitrocotton containing even small proportions of moisture. It usually shows first as a narrow line of free nitroglycerin along the edge of the inner fold of the wrapper. In the frozen state, blasting gelatin is more sensitive to shock; a rifle bullet can be fired through any number of unfrozen cartridges without exploding them, but similarly fired through frozen cartridges never fails to cause their explosion. In the frozen state it is even more sensitive than ordinary dynamite. For purposes of manipulation, it is usually considered necessary to thaw frozen cartridges before using them, and this is carried out in the same apparatus and with the same precautions as with kieselguhr dynamite. The transmission of detonation through unfrozen blasting gelatin is much slower than through either nitroglycerin or dynamite, but the frozen gelatin cartridges appear to detonate as quickly as those of dynamite. Blasting gelatin cannot be exploded in trains in the open like dynamite, but it explodes readily when confined in boreholes, and its comparatively slow detonation makes it especially useful in blasting soft rock. Between steel and steel, blasting gelatin explodes under a blow of 25.3 foot-lbs. Soft blasting gelatin has been exploded between brass plates by a 56-lb. weight falling 12 feet, the height required when the blasting gelatin was frozen being only 1 foot. From experiments made at Ardeer, it was found that while kieselguhr dynamite No. 1 could be unfailingly exploded by a detonator containing 0.05 gram of cap mixture (70 p.c. mercury fulminate and 30 p.c. potassium chlorate), the least quantity required to detonate the best blasting gelatin is 0.2 gram; and if the latter is tough, with an extra proportion of nitrocotton (*e.g.* with 9 p.c. or 10 p.c.), it fails to detonate completely even with a 0.8 gram charge of cap composition. The velocity of detonation varies with the composition and physical condition. With a 20-grain detonator, Corney found that the velocity of detonation rapidly rose from about 2000 near the point of detonation to about 6800 metres per second. Under poor confinement the detonating wave is subject to a steady fall off after reaching a maximum, and a sudden stop may occur if there is any break in the continuity of the explosive. Soft plastic products are more easily detonated than hard elastic ones. It is necessary, therefore, in order to get unfailing detonations with tough blasting gelatin, to use in actual mining a detonator with at least 1 gram of cap composition, or to use a dynamite primer. Blasting gelatins which are of normal consistency when first manufactured, are liable to become hard and insensitive on storage. The opinion usually held is that blasting gelatin has a webbed structure, and that the product is not sufficiently sensitive unless a considerable proportion of the nitroglycerin exists in the ungelatinised condition between the webs of jelly. Hargreaves, who first propounded this theory, considers that blasting gelatin is best made by first forming a jelly with part of the nitroglycerin, and then adding the remainder without gelatinisation. He claims that the product manufactured in this way does not become insensitive on storage, and has less

tendency to exude under warm storage conditions. The hardening and insensitiveness usually developed on storage, which appear to take place most readily at moderate temperatures, are attributed to the slow absorption of the free nitroglycerin by the collodion cotton. In small quantities, blasting gelatin burns away in the open without explosion. When gradually heated up, it explodes at about 204° ; on rapid heating, it explodes at 240° . Blasting gelatin containing camphor cannot be exploded by gradual heating, but burns quickly away (Hess).

The addition of camphor (about 4 p.c.) to blasting gelatin deadens the sensitiveness of the latter to shock to a very remarkable extent. Rifle shots will not explode soft blasting gelatin containing 4 p.c. camphor at a distance of 150 paces. Berthelot attributes this effect to a certain amount of elasticity and solidity caused in the gelatin by the added camphor, on account of which the energy of the shock of the detonator, and the heat into which some of it is converted, are imparted to a much greater mass of substance than when no camphor is present—a condition unfavourable to a sudden and local rise of temperature. Before the introduction of 'cerasite,' blasting gelatin containing 4 p.c. of camphor was used in Austria for military purposes as a high explosive. In Italy, 5 parts of camphor were added to 100 parts of nitro-gelatin containing 8 p.c. of nitrocotton. These mixtures were so insensitive to shock that a special primer had to be used—in Austria, a mixture of nitroglycerin and nitrohydrocellulose; in Italy, guncotton. The French 'Dynamite-gomme, extra forte,' is a blasting gelatin containing 7-8 p.c. nitrocellulose.

Abel found (by the work done in expanding the bore of a lead cylinder) the intensity of action of Nobel's blasting gelatin to be about 160 when a sufficiently strong detonator was used, kieselguhr dynamite No. 1, exploded by the same detonator, being equal to 100. Abbot found the intensity of the same kind of blasting gelatin, detonated under water and referred to the same standard, to be 142. Hence it is not surprising that, although higher in price, blasting gelatin has to a large extent replaced kieselguhr dynamite.

According to Berthelot, the equation for the combustion of blasting gelatin containing 91.6 p.c. nitroglycerin and 8.4 p.c. nitrocellulose, the proportion for complete combustion is :

The heat liberated by the equivalent weight, 12,360 grams, being 19,381 cals., or 1535 cal. per kilo.

Testing : Heat test.—50 grains of blasting gelatin intimately mixed with 100 grains of French chalk must withstand the Abel heat test at 160° for at least 10 minutes.

Liquefaction test.—A cylinder, of equal height and diameter, exposed to a temperature of 85° to $90^{\circ}F.$ for 144 consecutive hours, must not diminish in height more than one-fourth of its original height, nor lose the sharpness of its edges.

Exudation test.—On subjecting, three times in succession, to alternate freezing and thawing, and in the liquefaction test, no substance of a

less consistency than the bulk must separate out.

Although suitable in tunnelling for blasting hard rock and for military purposes, blasting gelatin is too local and violent in its effects for most mining operations, and various modifications were soon made to reduce its power. The usual way of doing this is to make a thinner gelatin and knead it into an absorbing powder. The earlier absorbents were usually a mixture of wood pulp or rye flour and either potassium or sodium nitrate. Many recent continental dynamites of this class contain ammonium nitrate, the explosives being then more powerful. The manufacture of these dynamites, which are also cheaper than blasting gelatin, is essentially the same as that of blasting gelatin.

Gelatin dynamite, made by Nobel's Explosives Company, consists of thin blasting gelatin mixed with wood meal and potassium nitrate. Its composition is : gelatinised nitroglycerin, 65 p.c. ; potassium nitrate, 26.25 p.c. ; 8.4 p.c. wood meal ; 0.35 p.c. soda. The gelatinised nitroglycerin consists of 97.5 nitroglycerin and 2.5 p.c. soluble nitrocellulose. As usual, the proportions of the constituents vary in different samples : another gelatin dynamite containing nearly 80 p.c. gelatinised nitroglycerin, of about blasting gelatin composition, 16 p.c. nitre and 4 p.c. wood pulp. As made at Ardeer, the finished explosive is of pale buff colour and is very elastic. Abel, by the lead-cylinder method, found its intensity of action, when suitably detonated, to be 127 and 123 (mean 125), ordinary kieselguhr dynamite being 100.

The French 'Dynamite-Gomme,' 'Potasse,' and 'Soude' contain 82-83 p.c. nitroglycerin, 5-6 p.c. collodion cotton, 2-3 p.c. wood meal, and 9-10 p.c. potassium nitrate or sodium nitrate respectively.

The manufacture of dynamites of this class with wet collodion cotton was patented by Schachtebeck (Ger. Pat. 172651, 1905), the wet nitrocotton being treated with glue, dextrin, starch, or similar substance to absorb the moisture. An example given is 60 p.c. nitroglycerin, 7 p.c. collodion cotton containing 35 p.c. water, 3 p.c. glue, 7 p.c. wood meal, 20 p.c. sodium nitrate, and 3 p.c. ammonium nitrate. The Soc. Dynamit Akt. Ges. (Fr. Pat. 333443, 1903) suggests the use of carbohydrates soluble or partially soluble in water, such as sugar starch, dextrin, &c., in gelatin explosives, a plastic instead of a friable product with a low percentage of nitroglycerin being claimed. A composition given is 32 p.c. nitroglycerin, 0.7 p.c. collodion cotton, 18.5 p.c. dextrin, 1 p.c. vegetable oil, 35.8 p.c. ammonium nitrate, 3 p.c. ammonium oxalate, 2 p.c. wood meal, 2 p.c. sodium chloride, and 5 p.c. alum.

Gelignite is a weaker modification of gelatin dynamite, its composition being 60-61 p.c. nitroglycerin, 4-5 p.c. nitrocotton, 7-9 p.c. wood pulp, and about 27 p.c. potassium nitrate. This explosive is very largely used. It is frequently stabilised as in the case of blasting gelatin. An estimation by Abel of its intensity of action, suitably detonated in a lead cylinder, makes it 100, i.e. the same as the Ardeer kieselguhr dynamite No. 1.

The French 'Gélatines' are of this class. A contains 64 p.c. nitroglycerin, 3 p.c. collodion

cotton, 25 p.c. sodium nitrate, and 8 p.c. wood meal. *B-potasse*, or *-soudre*, contains about 57 p.c. nitroglycerin, 2.5-3 p.c. collodion cotton, 6-8 p.c. wood meal, and 32-34 p.c. potassium nitrate, or sodium nitrate, and *Gomme E* contains 49 p.c. nitroglycerin, 2 p.c. collodion cotton, 36 p.c. potassium nitrate, 10 p.c. wood meal, and 3 p.c. flour. French 'Gelnignite' contains 58 p.c. nitroglycerin, 2 p.c. collodion cotton, 28 p.c. potassium nitrate, 9 p.c. wood meal, and 3 p.c. flour.

Ammonia gelatin A contains 30 p.c. nitroglycerin, 3 p.c. nitrocotton, and 67 p.c. ammonium nitrate.

Ammonia gelignite contains 29.3 p.c. nitroglycerin, 0.7 p.c. nitrocotton, and 70 p.c. ammonium nitrate.

Grisoutine Favier, a French safety explosive, contains 29.1 p.c. nitroglycerin, 0.9 p.c. collodion cotton, 69.5 p.c. ammonium nitrate, and 0.5 p.c. sodium carbonate.

Antigrison contains 27 p.c. nitroglycerin, 1 p.c. nitrocotton, and 72 p.c. ammonium nitrate.

Arkite No. 2, an English permitted explosive, contains on the average 32 p.c. nitroglycerin, 1 p.c. nitrocellulose, 27 p.c. potassium nitrate, 10 p.c. wood meal, and 30 p.c. ammonium oxalate. Limit charge 40 ozs., pendulum swing 2.41 inches.

Forcite. Although the early American for-cites contained unnitrated cellulose, more recent samples, such as the Belgian, contain nitrocellulose, and are simply gelatin dynamites, containing from 40 to 65 p.c. of gelatinised nitroglycerin, 4-8 p.c. nitrocotton mixed with wood meal, rye flour or tar, and usually sodium nitrate, but in some cases ammonium nitrate or potassium nitrate; 1 p.c. magnesia and sulphur are also usually present. *Forcite antigrisouteuse* contains 29.4 p.c. nitroglycerin, 0.6 p.c. nitrocotton, and 70 p.c. ammonium nitrate.

Carbogelatin contains 38.5 p.c. of nitrogelatin, 49.5 p.c. nitre, 10.5 p.c. wood meal and charcoal, and 1.5 p.c. of magnesium carbonate.

Coronite contains 38-40 p.c. nitroglycerin, 1-1.5 p.c. nitrocotton, 26-28 p.c. ammonium nitrate, 3-5 p.c. potassium nitrate, 11-14 p.c. aluminium stearate, 8-11 p.c. rye flour, 2-4 p.c. wood meal, 2.4 p.c. liquid paraffin, and 0-2.5 p.c. moisture.

Duxite, on the English permitted list, contains, on the average, 32 p.c. nitroglycerin, 1 p.c. nitrocotton, 28 p.c. sodium nitrate, 10 p.c. wood meal, and 29 p.c. ammonium oxalate. Limit charge 12 ozs., pendulum swing 2.45 inches.

Two English explosives of this class on the permitted list, manufactured by Nobel's Explosives Company, are *Dynobel No. 3*, containing 14-16 p.c. nitroglycerin, 0.25-0.75 p.c. collodion cotton, 0.5-2.5 p.c. dinitrobenzene, di- and trinitrotoluene together, 51-54 p.c. ammonium nitrate, 4-6 p.c. wood meal, 24-26 p.c. sodium chloride, 0-1 p.c. magnesium carbonate, and 0-2 p.c. moisture. Limit charge 18 ozs., pendulum swing 2.50 inches; and *Dynobel No. 4*, a weaker variety, containing the same ingredients, but with less ammonium nitrate and more sodium chloride. Limit charge 30 ozs., pendulum swing 2.35 inches.

Essex powder, an English permitted explosive, contains 22-24 p.c. nitroglycerin, 0.5-1.5

p.c. collodion cotton, 33-35 p.c. potassium nitrate, 33-35 p.c. wheat flour, 5-7 p.c. ammonium chloride, and 2-5 p.c. moisture. Limit charge 38 ozs., pendulum swing 2.17 inches, detonator No. 6.

Geslit is a modern German safety explosive. No. 1 contains 30.75 p.c. nitroglycerin jelly, 5.25 p.c. dinitrotoluene, 7 p.c. sodium chloride, 18 p.c. sodium nitrate, 39 p.c. dextrin. No. 2 contains 30.75 p.c. nitroglycerin jelly, 5.25 p.c. dinitrotoluene, 22 p.c. ammonium nitrate, 21 p.c. sodium chloride, and 21 p.c. dextrin.

Forlit, a similar explosive, contains 24 p.c. nitroglycerin, 1 p.c. nitrocotton, 34 p.c. nitrotoluene, 2 p.c. flour, 2 p.c. dextrin, 5 p.c. glycerin, and 32 p.c. ammonium nitrate; to this mixture is added 30 p.c. potassium chloride.

Celtite is a gelatin dynamite, with the addition of ammonium oxalate, having the composition 56-59 p.c. nitroglycerin, 2-3.5 p.c. nitrocotton, 17-21 p.c. potassium nitrate, 8-9 p.c. wood meal, 11-13 p.c. ammonium oxalate, and 0.5-1.5 p.c. moisture.

Geloxite is a similar explosive which contains 54-64 p.c. nitroglycerin, 4-5 p.c. nitrocotton, 13-22 p.c. potassium nitrate, 4-7 p.c. wood meal, containing not more than 15 p.c. and not less than 5 p.c. moisture, 12-15 p.c. ammonium oxalate, and 1 p.c. red ochre. Ochre is sometimes added to dynamites to make them resemble ordinary dynamites in appearance.

Haylite No. 1, an English permitted explosive, contains 25-27 p.c. nitroglycerin, 0.5-1.5 p.c. collodion cotton, 19-21 p.c. potassium nitrate, 19-21 p.c. barium nitrate, 12-14 p.c. wood meal, 6-8 p.c. mineral jelly, 10-12 p.c. ammonium oxalate, and 0.5-2.5 p.c. moisture. Limit charge 10 ozs., pendulum swing 2.18 inches, detonator No. 6.

Rippite, an English authorised explosive, contains 56-63 p.c. nitroglycerin, gelatinised with a small quantity of collodion cotton, potassium nitrate, wood meal, castor oil, and ammonium oxalate, and is stabilised by the addition of a little calcium or magnesium carbonate, or mineral jelly.

Saxonite, manufactured by Nobel's Explosives Company, was at one time on the permitted list, and the most extensively used of safety explosives in this country. It contains 42.5-62 p.c. nitroglycerin, 2.5-5 p.c. collodion cotton, 16-27.5 p.c. potassium nitrate, 3.5-8 p.c. wood meal, 9-27 p.c. ammonium oxalate, and 0-0.5 p.c. calcium carbonate. It failed to pass the Rotherham test, but is still used for purposes other than in fiery mines.

Samsonite, an explosive of closer limits, was designed by Nobel's to replace 'Saxonite,' and is at present on the permitted list. Its composition is: 57-60 p.c. nitroglycerin, 3-4 p.c. collodion cotton, 17-19 p.c. potassium nitrate, 5-7 p.c. wood meal, 12.5-14.5 p.c. ammonium oxalate, and 0-1.5 p.c. moisture.

Stowite contains 58-61 p.c. nitroglycerin, 4.5-5 p.c. nitrocotton, 18-20 p.c. potassium nitrate, 6-7 p.c. wood meal specified as in geloxite, and 11-15 p.c. ammonium oxalate. A non-waterproofed wrapper of parchment is used, and a No. 6 detonator.

Syndite is on the English permitted list. It contains 10-22 p.c. nitroglycerin, 0.1-0.3 p.c.

collodion cotton, 45-49 p.c. ammonium nitrate, 7-9 p.c. sodium nitrate, 2-5 p.c. glycerin, 2-5 p.c. starch, 26-28 p.c. sodium chloride, and 0-2 p.c. moisture. Limit charge 40 ozs., pendulum swing 2.22 inches, detonator No. 7.

Super-Cliffite is manufactured by Curtis's and Harvey in two varieties. No. 1 contains 10 p.c. nitroglycerin, less than 1 p.c. collodion cotton, 60 p.c. ammonium nitrate, 16 p.c. sodium chloride, 11 p.c. ammonium oxalate, 6 p.c. wood meal, and 2 p.c. moisture; limit charge 26 ozs., pendulum swing 2.53 ins.; and No. 2 of similar composition, except that the sodium chloride is increased to 20 p.c. and the ammonium oxalate reduced to 6 p.c.; limit charge 30 ozs., pendulum swing 2.53 ins.

The permitted composition for *Phoenix powder* is 28-31 p.c. nitroglycerin, 0-1 p.c. nitrocotton, 30-34 p.c. potassium nitrate, 33-37 p.c. wood meal, and 2-6 p.c. moisture.

Safety dynamite contains 24 p.c. nitroglycerin, 1 p.c. nitrocotton, and 75 p.c. ammonium nitrate.

The *wood pulp*, so frequently used as an ingredient in these dynamites, is made from logs usually of pine wood, but occasionally from other woods. The logs are freed from bark and sawn into boards; the boards, free from knots, broken by a machine into small pieces and then crushed between rollers. Where available in sufficient quantity, shavings are used. The powder is boiled under pressure with a solution of sodium bisulphite for 10 to 12 hours. The pulp is then washed and dried. The pulp must not be exposed to acid vapours or overheated in drying, and should all pass through a sieve of 50 meshes to the inch. It should not be too fine, or the resulting dynamites are too dense in character and difficult to detonate.

The use of non-fermentable *starch* was proposed by Kynoch (Eng. Pat. 22966, 1901) as a substitute for wood meal, in order to reduce the bulk of the explosive.

Cocconut fibre has been suggested by Gon-salves (Eng. Pat. 4968, 1905) as an absorbent for this class of dynamite, and it is claimed that it prevents the freezing of the nitroglycerin.

Guncotton dynamite. In 1867 mixtures of nitroglycerin with pulped guncotton, which, unlike collodion cotton, does not dissolve in and gelatinise nitroglycerin, were proposed by Abel and Trauzl. Abel's mixture was called *gly-cexiline*, and was prepared by soaking guncotton, with or without nitre, in nitroglycerin.

Trauzl's dynamite consisted of 75 p.c. nitroglycerin, 25 p.c. guncotton, and 2 pts. charcoal to every 100 of mixture. In 1868 Schultze proposed a mixture of nitrated wood cellulose soaked in nitroglycerin under the name of '*dualine*.'

These explosives, like most other dynamites, have been superseded by the gelatin dynamite class.

Freezing of dynamites.—The comparatively high freezing-point of nitroglycerin, and the difficulty in thawing, is a great objection to the use of nitroglycerin explosives. Numerous attempts have been made to overcome the difficulty by lowering the freezing-point, by suitable additions, but with very limited success. In England it is usual to take pre-

cautions to prevent freezing by suitable storage in warm magazines, but in the United States and on the Continent additions to the nitroglycerin to prevent freezing are common. The addition of nitrohydrocarbons such as nitrobenzene was tried by Nobel and Guttman, but they found that so large a quantity was required to produce any sensible reduction of the freezing-point, that the power and sensitiveness of the explosive were seriously reduced. This reduction of power is of advantage in safety explosives, and nitrohydrocarbons in small amount are frequently constituents in dynamites of this class. The lower the molecular weight of the nitro body the smaller the percentage necessary to effect a given reduction of freezing-point, but the nitrohydrocarbons of low molecular weight have the disadvantage of being volatile. The addition of nitrobenzene had been previously patented in Sweden by Rudberg in 1866, and von Dahmen in Austria patented a process for nitrating glycerin mixed with a small percentage of nitrobenzene. Dinitrotoluene was found more efficient, and its use was patented by the Société des Poudres, &c. Dynamites, of Arendonck in 1903 (Eng. Pat. 14827, 1903) and a mixture of solid di- and trinitrotoluene was suggested by Johnson (Eng. Pat. 25797, 1904). In the United States low-freezing dynamites, such as the Red Cross Dynamites of the E. I. du Pont de Nemours Company, are manufactured by replacing about one-fourth of the nitroglycerin of the 'straight dynamites' by a nitrohydrocarbon.

Wohl, in 1890, had suggested the use of mono- and dinitroglycerin for reducing the freezing-point of nitroglycerin, and in 1904 Mikolajczak patented the use of dinitroglycerin (Eng. Pat. 8041, 1904); but mono- and dinitroglycerin are hygroscopic, soluble in water, and expensive, and moreover Will has shown that their addition is not very effective.

The Westfälisch-Anhaltische Sprengstoff-Gesellschaft, in 1906, patented the use of nitrochlorhydrins and subsequently the nitropolyglycerins (Eng. Pat. 4057 and 6314, 1906). Dinitrochlorhydrin is now used to a large extent in German nitroglycerin explosives, such as 'Gelatin Astralit,' 'Gelatin Donarit,' and 'Gelatin Westfalit,' for this purpose. It is easy and cheap to manufacture, and mixes with nitroglycerin in all proportions, and gelatinises collodion cotton equally well. Its admixture up to 20 p.c. of the nitroglycerin has very little effect on the explosive properties of the dynamites. The mixture is made by nitrating a mixture of glycerin and chlorhydrin in the usual way. Dinitrochlorhydrin is practically insoluble in water, and is not hygroscopic, but it has the disadvantage that it gives off hydrochloric acid on explosion, and necessitates the use of an alkaline nitrate in dynamites containing it, if for use underground. Vender proposed dinitroacetin and dinitroformin (Eng. Pat. 9791, 1906), which have the advantage that hydrochloric acid is not one of the products of explosion, and Escales (Eng. Pat. 2117, 1907) used a nitrated complex mixture of mono- and di-chlorhydrin, di- and tri-glycerin and the chlorhydrins of these bodies.

The subject of the lowering of the freezing-point of nitroglycerin has been investigated by

Nauckhoff (Zeitsch. angew. Chem. 1905, 11, 53). He showed that the freezing-point of a nitro-glycerin explosive can be calculated from its composition, by means of Raoult's formula, and that the value of a substance for depressing the freezing-point of nitroglycerin depended on its molecular weight and not on its own freezing-point. He pointed out, further, that the resistance to freezing depended, not only on the true freezing-point of the mixture, but also on its property of undergoing cooling below its freezing-point without solidifying, and found that the property was best shown in more plastic explosives.

NITROCELLULOSES.

Braconnot, in 1832, observed that starch, woody fibre, and other similar substances, are converted by the action of strong nitric acid into a combustible product, which he called *xyloïtine*. Pelouze, in 1838, found that starch treated with strong nitric acid increased in weight; and that paper, cotton, and linen, immersed in nitric acid of 1.5 sp.gr., become easily combustible. Schönbein, towards the end of 1845, announced the discovery of a new explosive substance, which he subsequently stated to have been obtained by treating cotton with a mixture of nitric and sulphuric acids. Böttger, in August, 1846, found out the method of making guncotton, which Schönbein was keeping secret. The two chemists jointly submitted their discovery to the Germanic Confederation, but reserved the publication of their method of preparing guncotton. Several chemists having in 1847 independently discovered the method of preparing guncotton by means of a mixture of nitric and sulphuric acids, Schönbein and Böttger then stated this to be their process. The manufacture of guncotton was undertaken in England, France, and Russia; but the earlier attempts at manufacture were not satisfactory, the importance of purifying the cotton from fatty matter, and of washing the guncotton thoroughly free from acid, not having at first been sufficiently felt to be essential to obtaining a safe and stable guncotton.

Von Lenk, in Austria, between 1849 and 1852, made great improvements in the manufacture of guncotton; and in 1853 a factory was erected under his direction at Hirtenberg, near Vienna, in which (and at Reny in Vienna) the manufacture was continued until 1865, when the manufacture and use of guncotton were officially put a stop to in consequence of the explosion of two magazines. Von Lenk used the cotton in the form of yarn; his principal improvements were the purification of the cotton from oily and other matters by boiling with caustic alkali, the nitration of the cotton in separate small charges, the dividing the operation of nitration into two stages: a short immersion (of some minutes) of the cotton in the mixed acids, the removal of the cotton with a sufficiency of absorbed acids, and allowing a long time (24 to 48 hours) for the completion of the nitration, also the careful washing of the guncotton to remove free acid. To remove acid, the guncotton after its nitration was whirled in a centrifugal machine, washed in copper drums with a large quantity of water, then placed in boxes in running water for three to six weeks, after which it was treated

with a hot weak solution of potash, and again water-washed.

Von Lenk's guncotton was used in the form of yarn.

Abel, adopting Von Lenk's method of nitrating the cotton, made very important improvements in the processes of manufacture. He introduced the use of cleaned cotton waste, and by converting the guncotton into pulp so facilitated the washing that it could be effected in two or three days instead of in six or more weeks as in Von Lenk's process. Further, by compressing the finished pulp by hydraulic pressure, he rendered it possible to detonate it in an unconfined state. The pulping and compressing of the guncotton were introduced in 1865 (Eng. Pat. 1102, 1865).

Composition.—Guncotton, when the process of manufacture has been well conducted, and when the strongest acids have been used, has the composition of trinitrocellulose $C_6H_7O_2(NO_3)_3$, when cellulose is $C_6H_{10}O_5$.

This composition was deduced by Abel from the results of a large number of analyses (in which C, H, and N were determined) of guncotton of Waltham Abbey make. The mean numbers given by these analyses of the dry guncotton, ash deducted, are given below, and are compared with the percentages calculated for trinitrocellulose:

	Mean of analyses	$C_6H_7O_2(NO_3)_3$
Carbon . . .	24.57	24.24
Hydrogen . . .	2.46	2.36
Nitrogen . . .	13.83	14.14
Oxygen . . .	59.14	59.26

The percentage of carbon is slightly raised, and that of nitrogen slightly depressed, by the presence in the guncotton of a few per cents. of less highly nitrated cellulose than the trinitro derivative, and soluble in ether alcohol (Abel, Phil. Trans. 1866, 156, 269-308).

The formation of trinitrocellulose from cellulose is represented by the equation:

from which 100 parts by weight of cotton should give 183.3 parts by weight of trinitrocotton.

Abel (*l.c.*), as the result of a large number of experiments, found a maximum increase of 82.6 p.c., which is a close approach to the theoretical 83.3 p.c., and confirms Hadow's previously observed increase of 81.3 p.c.

Soluble nitrocellulose.—Abel found that the part of guncotton soluble in a mixture of alcohol and ether is a less highly nitrated compound than his trinitrocellulose; it approaches in composition dinitrocellulose (Proc. Roy. Soc. 1866). In a further series of experiments, in 1868, Abel examined the influence on the nitration of the cotton of an addition of water to the acids. Using mixtures of 60 lbs. nitric acid, sp.gr. 1.42, and 65½ lbs. sulphuric acid, sp.gr. 1.835, without addition of water, and also with the addition of 3 lbs. of water, he obtained nitrocottons, which, after reprecipitation from solution in ether-alcohol, had percentages of carbon 28.56 and 28.13 respectively: the calculated percentage in dinitrocellulose $C_6H_8O_4(NO_3)_2$ being 28.57.

For a long time, nitrocelluloses were divided into two kinds only—trinitrocellulose, guncotton,

or insoluble nitrocellulose, and dinitrocellulose, collodion cotton, or soluble nitrocellulose; but it was clearly shown in the cordite case, Nobel v. Anderson, 1894, that there are certainly more than two cellulose nitrates, and, further, that the solubility of the nitrocellulose is not invariably related to the degree of nitration, but that soluble nitrocellulose can be prepared containing almost as much nitrogen as guncotton.

Roscoe prepared, for example, a soluble nitrocellulose containing 12.73 p.c. of nitrogen, and an insoluble nitrocellulose with 12.83 p.c. of nitrocellulose.

Eder, as he was able to prepare nitrocottons in which the percentage of nitrogen is between those corresponding to the above tri- and dinitrocellulose, doubled Abel's formulae, and claimed to have prepared the following five varieties of nitrocellulose:—

	P.c. of nitrogen
$C_{12}H_{14}O_4(NO_3)_6$ Hexa-nitrocellulose, containing 14.14	
$C_{12}H_{15}O_5(NO_3)_5$ Penta- " "	12.75
$C_{12}H_{16}O_6(NO_3)_4$ Tetra- " "	11.11
$C_{12}H_{17}O_7(NO_3)_3$ Tri- " "	9.15
$C_{12}H_{18}O_8(NO_3)_2$ Di- " "	6.76

His hexanitrocellulose only was insoluble in ether-alcohol, and is ordinary guncotton.

Vieille (Compt. rend. 1882, 132) prepared nitrocottons under the most varying conditions, and stated that the nitration of cellulose, which he assumed to be $C_{34}H_{40}O_{20}$, took place in eight stages, the products being:

	P.c. of nitrogen
$C_{24}H_{29}O_9(NO_3)_{11}$ Endeca-nitrocellulose, containing 13.50	
$C_{24}H_{30}O_{10}(NO_3)_{10}$ Deca- " "	12.78
$C_{24}H_{31}O_{11}(NO_3)_9$ Ennea- " "	11.98
$C_{24}H_{32}O_{12}(NO_3)_8$ Octo- " "	11.13
$C_{24}H_{33}O_{13}(NO_3)_7$ Hepta- " "	10.19
$C_{24}H_{34}O_{14}(NO_3)_6$ Hexa- " "	9.17
$C_{24}H_{35}O_{15}(NO_3)_5$ Penta- " "	8.04
$C_{24}H_{36}O_{16}(NO_3)_4$ Tetra- " "	6.77

Of these, the endeca- and deca-nitrocelluloses were insoluble in ether-alcohol.

Berthelot, following Vieille, regards guncotton as $C_{24}H_{29}(NO_3)_{11}O_{20}$ (mol. wt. 1143).

He finds the heat evolved by the nitration of cotton in accordance with the equation:

$C_{24}H_{40}O_{20} + 11HNO_3 = C_{24}H_{29}O_9(NO_3)_{11} + 11H_2O$
to be $11 \times 11.4 = 125.4$ kgm.-degrees per 1.143 kgm. of guncotton formed. The heat of formation of endecanitrocellulose from its elements (diamond carbon, gaseous hydrogen, oxygen, and nitrogen), Berthelot finds to be +624 kgm.-degrees per 1.143 kgm., or +546 kgm.-degrees per 1 kgm.

These formulae of Vieille were soon contested. Guttman claimed to have made guncotton on the large scale containing 13.65 p.c.

nitrogen; Hoitsema (Zeitsch. angew. Chem. 1898, 173) obtained a product containing 13.9 p.c. nitrogen; and Lunge (J. Amer. Chem. Soc. 1901, 527), with an acid mixture containing 63.35 p.c. H_2SO_4 , 25.31 p.c. HNO_3 , and 11.34 p.c. water, prepared nitrocellulose with 13.92 p.c. nitrogen, corresponding very closely to

dodecanitrocellulose, containing 14.16 p.c. nitrogen; but this substance, like that with a similar nitrogen content, obtained by nitrating cotton with a mixture of equal parts of nitrogen pentoxide and phosphorus pentoxide (*cp.* Hoitsema, *l.c.*), was not stable, and on keeping, the nitrogen content fell to 13.5 p.c., at which point it remained constant. In a further series of experiments, Lunge found that when all water was eliminated by adding fuming sulphuric acid, the p.c. of nitrogen was not altered, even when such varying ratios of H_2SO_4 to HNO_3 as 3:3:1 to 2:1 were used. Tassart (Bull. Soc. chim. 1912, 1009), by the successive action of cold sulphuric and nitric acids on cotton, has prepared a product which he terms *α-nitrocellulose*, containing 13.5 p.c. nitrogen. It is white, easily powdered, insoluble in water, but soluble in methyl and ethyl alcohols, and very unstable.

Lunge found that with nitrocellulose of less than 10 p.c. nitrogen, the solubility rapidly decreased and confirmed Vieille's results that below $C_{24}H_{32}O_{14}(NO_3)_8$ the products are insoluble. He also found that with dilute acids, the products contained oxycellulose, the proportion of the latter gradually increasing until eventually it was the only product. Saposchnikoff (Zeitsch. ges. Schiess- u. Sprengstoffwesen, 1906, 453) shows a close relationship between the vapour pressure of the nitric acid in the mixed acids and the nitrogen content of the products.

Berl and Klaye (Zeitsch. ges. Schiess- u. Sprengstoffwesen, 1907, 403) show that the process of nitration of cellulose is a reversible reaction, represented by the equation:

and that after a certain maximum substitution is obtained, about 13.5 p.c. nitrogen, the sulphuric acid of the nitrating mixture acts as a hydrolysing agent.

Berl and Smith (Ber. 1907, 1903) prepared esters of cellulose in order to show the number of free hydroxyl- groups in the cellulose molecule. They found it impossible to introduce more than twelve substituted groups into the cellulose molecule of $C_{24}H_{40}O_{20}$, which agrees with the results of Ost (Zeitsch. angew. Chem. 1906, 992), and Green and Perkin (Chem. Soc. Trans. 1906, 811), but did not succeed in obtaining a nitrocellulose with a higher nitrogen content than 13.50 p.c.

Any preparation of nitrocellulose is a mixture of definite nitrates, the nature of which depends on the nature of the nitrating mixture, the time and temperature of nitration, and the method of purification. Vieille (Compt. rend. 1862, 132) prepared nitrocellulose containing up to 12.7 p.c. nitrogen by the use of nitric acid alone in large excess, but the nitration is slow and difficult, and it is the invariable custom to use a mixture of nitric and sulphuric acids. It

is probable that the cellulose first reacts with the sulphuric acid, and that the product in turn reacts with the nitric acid to form nitro-cellulose. When much water or sulphuric acid is present the process is slow and the nitration low. A higher degree of nitration is obtained by raising the temperature, but this can only be done within limits, or oxycellulose and nitro-oxycellulose are formed, and part of the cellulose is completely broken down at high temperatures. The effect of a high proportion of water in breaking down the cotton is particularly noticeable.

A large excess of mixed acids is necessary in the nitration of cellulose, partly because of the bulk of the latter, but also to obtain products of constant composition. The acid mixture is diluted during nitration, both by the formation of water and by the abstraction of nitric acid during the nitration, and both these factors tend to lower the nitrogen content of the product, unless the bulk of the mixed acids is large. The speed of nitration is diminished with increase in the quantity of sulphuric acid.

As far as explosives are concerned, only two forms of nitrocellulose need be distinguished: guncotton or insoluble nitrocellotton, and collodion or soluble nitrocellotton. The explosive power of the nitrocellulose is dependent on the degree of nitration, and each variety is prepared of definite nitrogen content according to its use. When the soluble nitrocellulose is referred to in this article without qualification, solubility in ether-alcohol is always inferred.

Nitrohydrocellulose and *nitrooxycellulose*. Hydrocellulose $C_{12}H_{22}O_{11}$, cellulose being $C_{12}H_{20}O_{10}$, is prepared by soaking cotton for 12 hours in sulphuric acid of 1.45 sp.gr. at 15°, or for 24 hours in hydrochloric acid of 1.17 sp.gr. (Girard). Cross and Bevan prepared oxycellulose by boiling cellulose with nitric acid, and found its composition to be $C_{18}H_{26}O_{16}$. The nitro body obtained from it by nitration with a mixture of equal volumes of strong sulphuric and nitric acids, contained 6.48 p.c. nitrogen, and was given the formula:

(Chem. Soc. Trans. 1883, 22).

Vignon (Compt. rend. 1898, 136) found that oxycellulose, prepared by the action of a mixture of hydrochloric acid and potassium chlorate on cellulose, had a constant composition represented by $3C_6H_{10}O_5 + C_6H_{10}O_6 = C_{24}H_{40}O_{21}$.

Both these bodies, which may be formed in the nitration of cellulose, can be themselves nitrated. Hydrocellulose nitrates more slowly than cellulose, giving stable but rather sensitive products, and oxycellulose gives an unstable nitro product. Amorphous nitro products of oxy- and hydro-cellulose can be prepared by treating cellulose with sulphuric acid containing a little nitric acid at a low temperature until the mass becomes pasty, then nitrating and purifying as usual. Crane and Joyce (J. Soc. Chem. Ind. 1910, 540), by nitrating cotton with an acid mixture containing 9.0 p.c. HNO_3 , 65.5 p.c. H_2SO_4 , and 25.5 p.c. H_2O , obtained a nitrohydrocellulose of the composition

which was insoluble in acetone and ether-alcohol, but soluble in strong acids and caustic alkali.

Vignon (*l.c.*) found that nitrocellulose, prepared according to Lunge's formula for highest nitration, gave on determination of their C, H, and N, results agreeing with the formula

He concludes from this that this so-called nitrocellulose is an oxycellulose derivative, and attributes discrepancies in the results of others to the fact that the nitrogen only is estimated.

Later (Compt. rend. 1900, 509), Vignon determined the copper-reducing powers of nitrated cellulose and nitrooxycellulose, and found them identical and independent of the degree of nitration, and as oxycellulose reduces cupric potash solution, whilst cellulose and hydrocellulose do not, concludes that, on the nitration of cellulose, oxycellulose is formed, and that the product is really nitrooxycellulose.

Guncotton.

Manufacture.—The only process of manufacture of guncotton, with some modification in detail, was for some years the process of Von Lenk, as modified and improved by Abel. Other processes, notably the 'Thomson displacement process,' introduced at Waltham Abbey in 1905, and the 'nitrating centrifugal process,' are now more generally used.

Prime materials: Cellulose.—Although many forms of fibrous cellulose materials have been from time to time tried, practically the only form of cellulose in general use for the manufacture of guncotton is the cotton waste from spinning mills and other sources. New cotton would be the best raw material for use, but it is too expensive. 'Cop-bottoms,' the last portion of cotton left on the spindles, and usually in a tangled condition, are frequently used for the manufacture of collodion cotton, but this again is too expensive for general use. 'Linters,' the last portion of cotton from the seed, is largely used in the United States and on the Continent for the manufacture of soluble nitrocellotton, but the drastic treatment necessary for the removal of the adherent seed-husk and resinous matter, and the fermentative changes that take place in the cotton if left in contact with the husk, adversely affect the quality of the guncotton manufactured from 'linters.' 'Weaving mill waste' is contaminated with starch, as this is applied to the warps to strengthen them, and can only be used for the manufacture of nitrocellotton after the starch has been suitably removed, as the nitration products of starch are unstable. The quality of the waste from different sources varies considerably, and it is important that it should be as pure as possible in order to obtain a good yield of pure guncotton. The previous treatment of the cellulose has been shown by Piest (Zeitsch. angew. Chem. 1909, 215) to have considerable influence on the preparation and properties of nitrocellulose. The product from strongly bleached or mercerised cotton has a lower nitrogen content and higher solubility, and is more difficult to stabilise than that from ordinary cotton. Hake and Bell (J. Soc. Chem. Ind. 1909, 460) showed that the physical condition of the cellulose affects the nitration. If the cotton is dense the nitration is slow, and a larger proportion of the sulphuric

ester is formed with resultant loss in yield. Lunge showed that the source of the cotton has little effect on the product. The viscosities of solutions of cotton have been investigated by Ost (Zeitsch. angew. Chem. 1911, 1892) and others with a view to determining the suitability of the cottons for nitration, and to establishing a relationship with the stability of the nitro-products. Solutions in cuprammonium are used. New cotton gives more viscous solutions than cotton waste, especially when this has been chemically treated and bleached, no doubt owing to a greater molecular complexity, and the nitrocottons prepared from them give solutions in acetone differing in viscosity in the same direction. Piest (Zeitsch. angew. Chem. 1913, 26, &c.) showed that nitrocellulose solutions become less viscous on standing to an increasing extent the more the cellulose has been bleached. This he attributes to the presence of impurities, such as the esters of oxycellulose.

Formerly the waste was purified by boiling with a 2 p.c. solution of sodium carbonate and subsequent washing, but the modern purification process is more complicated. The waste is first of all de-greased by means of a solvent, then boiled in a kier with a weak solution of sodium carbonate or caustic soda, bleached with bleaching powder or calcium sulphide, washed, neutralised with sulphuric or hydrochloric acid, washed again, and finally dried. In detail, the process of purification varies with the type of waste being treated. Levine (J. Ind. Eng. Chem. 1916, 298) suggests the removal of impurities by bacterial treatment. The resultant cotton is nearly pure cellulose, with little or no altered, oxy-, or hydro-cellulose. It should contain no chloride, sulphate, or sulphide of lime, and be free from starch, and from cotton dust, or 'fly.' It contains less than 0.3 p.c. of fatty matter, but usually the uncarded waste used in the manufacture of guncotton contains a considerable quantity of impurities, such as wood, cane, string, coloured threads, metal, indiarubber, &c. These impurities and any hard knots of cotton are removed as far as possible by handpicking, and the cotton is then passed through a 'teasing machine' or 'willow,' a combination of drums armed with sharp-pointed teeth, which tear the threads apart and open out the knots and lumps. The cotton is picked over again as it leaves the machine, dried until the moisture content is about 0.5 p.c. on an endless band in a current of hot air, which is often first dried over sulphuric acid or calcium chloride, and then weighed out in charges, placed in tightly closed receptacles, and allowed to cool.

Mixed acids.—The acids used in the manufacture of guncotton are of a high degree of purity, free from solids, and of maximum concentration. The proportions of acid employed until recently were those used by Von Lenk, namely, 1 part of nitric acid of 1.5 sp.gr., containing not more than 1.5 p.c. of nitrous acid, and 3 parts of sulphuric acid of 1.84–1.85 sp.gr. In other words, the nitric acid contained at least 93 p.c. of monohydrate, and the sulphuric acid 95–96 p.c. of monohydrate. The more modern mixtures vary slightly in composition according to the method of nitration, and are given under these various methods.

The experiments of Lunge (*l.c.*) have shown that it is not necessary to have acid mixtures containing only a few per cents. of water, and that with acids of the proportion of $3\text{H}_2\text{SO}_4$ to HNO_3 , it is possible to work with as much as 12 p.c. of water. Not only is the acid mixture cheaper, but Lunge agrees with Will that the nitrocellulose manufactured with the more dilute mixtures is more stable than when produced by highly concentrated acids. Lunge also investigated the influence of nitrous acid on the quality of the product, and found that with contents of nitrous acid up to 6 p.c. of the mixed acid there was practically no influence on the nitrogen content, the solubility or stability of the product, but there is some doubt as to whether the stability of the product is not adversely affected to a slight extent when the proportion of nitrous acid is unduly high.

Most explosive factories have plant for the manufacture of the nitric acid, and for the recovery of waste acids, the latter being re-vivified and used again. The acids are mixed in large quantities, analysed, and the composition adjusted to that required, by the addition of strong acids in the requisite proportions. Nordhausen sulphuric acid or 'oleum' is now in common use for decreasing the proportion of water.

Mechanical mixing of the acids was at one time generally practised, but it was subsequently found that a perfect admixture was obtained by running the sulphuric into the nitric acid. However, the acids are now frequently mixed by means of compressed air, means being adopted to condense the nitric acid vapours.

The acids are stored and transferred from place to place as already described in the manufacture of nitroglycerin.

Nitration.—Lunge (*l.c.*) has shown that the speed of nitration increases rapidly, but the yield falls, owing to solution of the product in the mixed acids, with rise in temperature, the nitrogen content of the product varying but slightly. He concludes that the ordinary method of nitrating at a temperature not exceeding 25° is correct for obtaining maximum nitration and maximum yield. An outline of the nitration process used by Von Lenk has already been given.

Abel's nitration process, as formerly carried out at the Royal Gunpowder Factory, Waltham Abbey, and still used in many factories in England and abroad, is shortly as follows:—

The mixed acids are drawn off from the store tanks into a tank in connection with the dipping pans. These latter are of cast iron, arranged in a tank through which cold water is circulated to keep the temperature during the nitration below 22° ; each holds about 220 lbs. of mixed acids, and is provided with a grating. The charge of $1\frac{1}{2}$ lb. of cotton is then, by small portions, quickly immersed in the mixed acids, which at Waltham Abbey was composed of 3 parts of sulphuric acid, 96 p.c., and 1 part of nitric acid, 91 p.c., mixed and thoroughly cooled. After an immersion of 5 or 6 minutes, the cotton is removed to the grating, and squeezed by means of a lever with a plate at one end. The charge, which with the acid now weighs about 15 lbs., is placed in a closely covered earthen pot, in which it is

allowed to remain for from 12 to 24 hours, during which time the pots are placed in constantly flowing cold water. By this prolonged action, the nitration of the cotton is completed; the cooling is needed to prevent complete decomposition of the product by oxidation, and the maintenance of a low temperature is said to be favourable to the production of guncotton with a low percentage of soluble nitrocotton.

Much of the acids is then removed from the guncotton by means of the centrifugal machine made entirely of iron, the contents of six pots being whirled for 10 minutes at the rate of about 1200 revolutions per minute. The guncotton is then, carried in small quantities in galvanised iron pans, emptied out and plunged by means of an iron fork or wooden paddle beneath a cascade of water, which carries it into a large cistern, where it is kept stirred by a paddle wheel, and is washed by fresh water continually admitted, until the guncotton has no perceptible acid taste, when it is whirled in a centrifugal machine, with a short washing with water at the end of the whirling, after which it is ready for the boiling process. The immersion in the water has to be carried out quickly, as the acid guncotton is liable to 'fume off' on slow contact with water. The yield by this process is about 164 p.c. of the cotton nitrated.

In the Abel process, there is considerable wear and tear of the plant, and there is occasionally loss of guncotton owing to decomposition or 'fuming off' taking place in the digesting pots. Moreover, there is a considerable expenditure of labour and power involved, and improvements have been made to overcome these disadvantages.

Direct-dipping process.—In the direct-dipping process, as used at Nobel's factory at Ardeer, the operation of nitration is completed in one stage. The nitration is carried out in a series of iron pots, termed 'dippers,' standing in cold water contained in long cooling tanks, the pots being closed by covers which lead away the acid fumes to exhaust pipes. Each dipper is fed with 127 lbs. of mixed acid, the temperature of the acid is adjusted to 15°, and the charge of 4½ lbs. of cotton gradually added, the temperature rising to 25°. The nitration is allowed to proceed for from 8 to 24 hours, according to the composition of the nitrating mixture, the temperature gradually falling to 20°. The mixed acid for a 12 hours' immersion is 75 p.c. sulphuric acid, 15.75 p.c. nitric acid (monohydrate) and 9.25 p.c. water. The more rapid the nitration, the higher the proportion of nitric acid and the less the proportion of water used.

When the nitration is complete, the contents of the dippers are transferred to centrifugals, and the waste acids whirled out. The guncotton is then treated as in the Abel process. The yield by this process is about 159 p.c. of the cotton nitrated.

Centrifugal process.—In this process, largely used on the Continent, the nitration is carried on in a perforated iron basket, rotating in an outer iron casing, the centrifugal being jacketed for temperature control by water circulation and covered with a lid fitted with a fume pipe. The nitrating acid is run in and the cotton charge of 17½ lbs., or in a large-sized centrifugal 26½ lbs., gradually added whilst the basket is slowly

rotating. The effect of the rotation is to produce better contact between the cotton and acids, and the nitration only occupies from 30 minutes to an hour. When the nitration is complete, the bulk of the waste acid is drawn off, and the centrifugal set rotating rapidly, the guncotton being afterwards 'pre-washed' as usual. It is necessary not to reduce the acid content too far in the wringing, otherwise the charge is liable to 'fume off.' The nitrated charge is removed by tongs to an automatic conveyor, which transfers it at once to the drowning tank.

In this process the nitrating acid is about fifty times the weight of the cotton charge, the composition of the acid being about 23.15 p.c. HNO_3 , 69.35 p.c. H_2SO_4 , and 7.5 p.c. water. As this process is more rapid than the 'Abel process,' and since the velocity of nitration is decreased by a high content of sulphuric acid, it is necessary that the proportion of nitric acid in the mixed acid should be higher.

The usual forms of nitrating centrifugal used are those of Messrs. Selwig and Lange, of Brunswick, who, in 1904, patented an improved form in which the acid is caused to circulate continuously through the material by means of a pump, for the purpose of producing a more uniform nitration and avoiding local centres of heating.

Guttmann suggested the use of aluminium baskets, but, although more acid-resisting than the usual cast-iron baskets, the metal was found to be too soft and to get out of shape. The yield by this process of nitration is 160 p.c. of the cotton nitrated.

Displacement process.—In 1903 (Eng. Pat. 8278) J. M. and W. T. Thomson, of the Royal Gunpowder Factory, patented a new method for the nitration of cotton which has been used at Waltham Abbey since 1905. The apparatus consists of sets of four circular earthenware pans, 3 feet 6 inches in diameter and 10 inches deep at the side, with a slight fall towards the centre of the bottom. They are furnished with perforated false bottoms, and are connected at their lowest points with a lead pipe provided with a stopcock, which leads to the acid supply pipes, the waste acid pipe and the waste water pipe. The pans are covered by aluminium hoods with fume pipes. The process is as follows: 650 lbs. of nitrating acid of the composition 70.5 p.c. H_2SO_4 , 21 p.c. HNO_3 , 0.6 p.c. nitrous acid, and 7.9 p.c. water, adjusted to a temperature of from 10° to 15°, is run into one of the pans, and the charge of 20 lbs. of cotton is gradually added and pushed below the surface of the acid. The contents are then covered with a perforated plate in sections, a flow of water carefully run over the plate, and the fume hoods removed. When nitration is complete, after about 2½ hours, water is slowly run over the surface of the acids in the nitrating vessel, and by opening the stopcock the acids are allowed to be displaced at an equal rate of about 17 lbs. per minute. Most, about 80 p.c., of the waste acid is allowed to flow back to the store tanks, where it is revived with strong nitric acid and Nordhausen sulphuric acids, the remaining weaker acid being denitrated and concentrated. When the whole of the acid is displaced, which takes about 3 hours, the water

is allowed to run off through the guncotton, and the latter, after draining, is apparently neutral, and is ready for the boiling process. The yield in this process is about 170 p.c. of the cotton nitrated, and the product is more evenly nitrated than by the Abel process.

The advantages of the displacement process are that the cotton is dipped more quickly, that the processes of dipping, nitration, removal of waste acid, draining, and water centrifugating are conducted more quickly, and in one apparatus, that there is no loss of product by occasional 'fuming off,' that the exposure of workmen to fumes is done away with, that there is less loss of acid, and the recovered acid is cleaner, that less water is used, that the cost of labour and upkeep of apparatus is considerably reduced, and that the yield is higher, and the product is more uniform and stable.

The improved stability of the product is attributed by MacDonald (J. Soc. Chem. Ind. 1911, 251) to the fact that unstable nitro-compounds are decomposed during the displacement, as evidenced by a rise in proportion of nitric acid in the displaced acid, after a fall, towards the end of the process.

De Brailles (Fr. Pat. 364349, 1906) has patented a system of concentrating the acids in the nitrator by electrolysis. Voigt (U.S. Pat. 855869, 1907) disintegrates the cotton fibre before nitration by immersing in sulphuric acid with only 3 p.c. nitric acid at 2°, and ultimately obtains the nitrocellulose in the form of a fine powder.

Boiling.—After the nitration and preliminary washing, the guncotton is 'boiled' in order to purify and stabilise it. The impurities removed are the last traces of free acid and unstable products of the nitration. Amongst the latter are ill-defined unstable bodies, such as nitrosaccharoses, formed by the action of the nitrating acids on the impurities in the cotton, and cellulose esters, other than the higher nitrates, such as the sulphuric esters, mixed nitrosulphuric esters, and possibly nitrous esters and low nitric esters. The possibility of the presence of sulphuric esters in unstabilised nitro cotton was pointed out by Cross and Bevan in 1901; and Hake and Bell examined their mode of formation and influence on the stability of nitrocellulose (J. Soc. Chem. Ind. 1905, 374; 1909, 457). Hake and Bell conclude that mixed sulphuric esters exist in all products of the nitration of cellulose, and that they are formed owing to delayed nitration, caused by partial solution or gelatinisation of the cellulose by sulphuric acid and subsequent fixation by nitric acid. The amount of sulphuric acid normally fixed during nitration is about 1 p.c., but this is reduced during the stabilisation to about 0.1 to 0.3 p.c.

Will found that the stability of nitrocellulose was increased by increasing the amount of water in the nitrating mixture, whilst insufficient washing lowers the stability, and that the stability decreases with increase of nitrogen content. The degree of comminution of the cotton was found to have but little effect on the stability, which was contrary to the opinion generally held at the time as to the value of the pulping process in effectively stabilising guncotton, and he also found that there is a limit to

the boiling process, beyond which there is no increase in the stability.

Berthelot, in 1900, pointed out the possibility of the formation of nitrous esters, and Lunge and Bebie have examined their influence on the stability of nitrocellulose (Zeitsch. angew. Chem. 1901, 539). The nitrous esters are probably partly formed in the nitration process, but to a larger extent by subsequent hydrolytic decomposition of the nitrocellulose. They are so unstable that they very rarely occur in the finished nitrocellulose.

In the old Abel process, the guncotton received two boilings by means of steam in wooden vats, the water being separated by centrifugal machines after each boiling. In many factories, a 2 p.c. solution of soda was used in order to reduce the time of boiling, the function of the alkali being not so much to neutralise residual traces of acid as to decompose and dissolve unstable impurities; but this was found to decompose the guncotton, and was abandoned in England, and water only used. The boiling was subsequently extended; several boilings were used, and the boiling process sometimes lasted 4 or 5 days in all. At Waltham Abbey, previous to the introduction of the displacement process, a system of twelve short boilings of gradually increased duration was practised.

Robertson (J. Soc. Chem. Ind. 1906, 624), as the result of numerous experiments at Waltham Abbey, in 1905, with displacement guncotton, found that boiling in dilute acid at the beginning of the process is superior to an alkaline treatment for the elimination of impurities. He found that good results were obtained when the wash water contained acid equal to 1 p.c. of H_2SO_4 on the guncotton present, and sufficient should be left in the guncotton to give this result. At Waltham, the water is hard and the dissolved chalk makes the water sufficiently alkaline for the subsequent boiling. He also found that a better yield and a more stable product was obtained by longer periods in the early, and shorter periods in the later, boilings, and that a displacement washing at an early stage was beneficial. As a result of Robertson's experiments, the Waltham Abbey system of boiling was for some time a series of two 12, five 4, and three 2 hours' boiling, with a cold-water washing after each of the first two boilings. At the present time a still shorter period of boiling has been introduced without affecting the stability of the product.

The best system of boiling for any particular factory has to be determined by trial, and depends on the nature of the product and of the water supply. Too prolonged boiling causes loss of nitrogen and increase in the percentage of the lower nitrates constituting soluble nitrocellulose (Bruely, Mem. des Poudres et Salpêtres, 1895-6, 131).

In some factories stabilisation is effected by carrying out some of the boilings with water made very slightly alkaline with sodium carbonate, and in the United States official method of stabilisation the water is made just alkaline for the pulping and the first of the poaching operations, but not in the preliminary boiling. Delpach (Fr. Pat. 441841, 1912) claims to

obtain a more stable product by treatment of the washed product with a current of carefully neutralised superheated water in an autoclave.

Many suggestions have been made for improving on the boiling process for stabilising guncotton. Luck and Cross claim that, for the production of nitrocellulose for industrial purposes, washing with dilute acetone stabilises more quickly than the ordinary boiling process. Haddan (Eng. Pat. 5830, 1900) claims that heating for 6 hours with water under pressure at 135° is equivalent to 100 hours' ordinary boiling. Du Pont (U.S. Pat. 724932, 1903) suggests agitating with water and air under pressure and suddenly releasing the pressure; and Selwig and Lunge (Fr. Pat. 327803, 1902) introduce steam into the pulped guncotton whilst it is being rotated in centrifugals, and claim that stabilisation is very rapidly effected in this way.

Pulping.—The next operation to which the guncotton is subjected is that of pulping, which is done by means of a slight modification of the machine like that known as 'the beater,' which is used in paper making for pulping rags. The pulping takes 5 hours, and has to be so conducted that the pulp is not too coarse nor too fine. The reduction in the length of the fibres allows of the last traces of acid being washed out of the fibre canals. Guttman first introduced live steam into beaters, and so enabled the previous boiling to be considerably reduced. In modern beaters, the water is constantly renewed during the pulping, and the pulp is frequently pumped over a strainer or 'knottter,' to remove large pieces. After pulping, mechanical impurities are removed from the guncotton, usually by passing the guncotton suspended in a large bulk of water, through long troughs in which the grit settles, and is caught in traps, and over electromagnets to remove any particles of iron.

Poaching.—The guncotton is then led into large oval tanks called 'poachers,' each holding about 10 cwt. of guncotton and 1100 gallons of water, in which a paddle wheel rotates and keeps the pulp in agitation. The pulp is washed at least three times, being allowed to settle, and the washing water containing suspended impurities removed by a skimmer between each operation.

Moulding and pressing.—The treatment in the poacher serves not only to complete the washing, but also to thoroughly mix the products of a large number of nitrating operations, thus securing uniformity of product. If the pulp passes the heat test after this treatment, it receives an addition of alkali sufficient to leave in the finished guncotton from 1 p.c. to 2 p.c. alkaline matter, calculated as CaCO_3 . By means of vacuum pressure, the pulp is then drawn up into the 'stuff chest,' a cylindrical iron tank, large enough to hold the contents of one poacher, and in which revolving arms keep the pulp uniformly mixed with the water, so that it can be drawn off as required to be moulded into cylinders and slabs. The requisite quantity of suspended pulp is found by means of small measuring tanks, and is run into moulds of the required size and shape. The moulds have bottoms of fine wire gauze, through which a large part of the water is sucked from

the pulp by evacuation. Hydraulic pressure of about 34 lbs. per square inch is then applied, which squeezes out some of the water, and gives sufficient consistency to the guncotton to allow of careful handling. The mass is then removed to the press-house, and there subjected to powerful hydraulic pressure of about 5 to 6 tons per square inch.

Those slabs and cylinders which are to serve as primers (*i.e.* which are dried and receive the fulminate charge, and by their own detonation cause that of the moist guncotton) have holes bored in them while moist, to receive the tube of the detonator; and the slabs of wet guncotton may be sawn, or turned on a lathe to any required shape. Primers are dried at a low temperature and usually waterproofed by dipping momentarily in acetone or molten paraffin. No alkali is added to guncotton when it is to be used for the manufacture of smokeless powders.

Hollings (Eng. Pat. 23449, 1899) has patented a process of compression whereby large blocks of guncotton, such as are required as a charge for large shells and torpedoes, can be made in one piece of uniform density.

Testing: Moisture is best determined by placing the sample over sulphuric acid until it is of a constant weight.

Ash.—2 grams are heated with about 10 grams of paraffin wax, added as a restrainer, first on a water-bath till the guncotton has soaked up the wax, then gently over a flame until the mass inflames. The source of heat is then removed, and when the flame dies out the residual carbon is burned off as usual. The ash is recarbonated.

Alkalinity.—10 grams are well shaken with an excess of decinormal hydrochloric acid, allowed to settle, and the excess of acid determined in an aliquot portion of the clear supernatant fluid with standard alkali.

Soluble nitrocellulose.—5 grams of the sample are well shaken for some time in a stoppered cylinder with 200 c.c. of a mixture of 2 parts of ether and 1 part of alcohol, of 0.83 sp.gr., and allowed to settle. An aliquot part of the clear solution is drawn off, carefully evaporated in a platinum dish, and the residue dried at a temperature not above 50° .

Unconverted cotton.—5 grams are well shaken for some time in a conical flask with a large bulk of acetone, and allowed to settle. The clear liquid is decanted off, the residue diluted with acetone, filtered on a tared paper, washed, and dried. The ash is then determined and deducted. Boiling with a solution of sodium sulphide is frequently used instead of solution in acetone.

Nitrogen is determined by nitrometer (with 100 c.c. bulb and graduated to 150 c.c.), 0.5–0.6 gram is dissolved in about 5 c.c. of 96 p.c. strong sulphuric acid in the cold, washed into the nitrometer with a further 10 c.c. of acid, &c.

Heat test.—The dried guncotton should withstand the Abel heat test (*see Stability tests*) at 76.6°C . (170°F .) for at least 10 minutes.

Properties.—Guncotton is an odourless, tasteless, and neutral solid, having an absolute (*i.e.* when freed from air) specific gravity of 1.66 at 15.6° . The apparent specific gravity (*i.e.*

with the included air) of dry compressed Waltham Abbey guncotton at 15.6° is about 1 or a little higher than 1; even after very considerable pressure, a density higher than 1.4 cannot be obtained. When dry, guncotton is readily electrified by friction.

Guncotton retains the structure of the un-nitrated cotton. Under polarised light, nitro-cotton exhibits colours which both Chardonnet and Liebschütz state are determined by the nitrogen content, but De Mosenthal and Lunge find that Chardonnet's colours are not always confirmed, the colour depending not only on the nitrogen content, but also on the method of preparation. Lunge, however, states that blue colours are characteristic of nitrocellulose containing upwards of 12.75 p.c. nitrogen. De Mosenthal gives the refraction, μ_D , of guncotton, of 13.5 p.c. nitrogen, as 1.5059, and confirms Vignon in his statement that guncotton is dextro-rotatory.

Guncotton is insoluble in hot and cold water, alcohol, ether, glacial acetic acid, and (except the collodion cotton content), in a mixture of alcohol and ether. It is also insoluble in nitroglycerin. It is readily soluble in acetone, ethyl acetate, amyl acetate, nitrobenzene, &c.

Guncotton is not attacked by dilute acids, but it slowly dissolves in strong sulphuric acid with the formation of cellulose sulphate and liberation of nitric acid. Strong nitric acid violently oxidises, and may inflame, guncotton. Dilute alkalis, especially ammonia, and alkaline carbonates, decompose guncotton slowly, especially when warm. Even chalk influences guncotton unfavourably, but it is the least unsatisfactory of the neutralising agents added to guncotton, and quantities up to 2 p.c. have no appreciable effect on the stable life of a wet guncotton; its neutralising effect on any acid liberated during the storage of guncotton outweighs its slight saponifying action.

Silberrad and Farmer (Chem. Soc. Trans. 1906, 1759) have examined the hydrolysis of guncotton in alkaline solution. They find the reaction complicated by the reduction of some of the nitrate to nitrite, and the degradation of the cellulose to hydroxy-acids, &c.

Guncotton is reconverted into cotton by the action on it of alcoholic potassium sulphhydrate. This reaction, due to Hadow, was found by Abel (*l.c.*) to give 53.6 p.c. to 55.4 p.c. cotton; trinitrocellulose should give 54.54 p.c. cotton. This reaction is of great importance, as it shows that guncotton (like nitroglycerin) is a nitric ester, yielding on reduction the hydroxylic body from which it was formed, and not an amino derivative. It can therefore be represented as:

Air-dried (air under ordinary conditions) guncotton retains between 1.5 and 2 p.c. of moisture. In this condition, on application of flame, a cylinder of compressed guncotton burns in the open air very rapidly with a long and fierce flame without smoke; the flame being coloured yellow by the sodium salts. The rate of combustion of the guncotton varies with its condition; thus, guncotton plait in the form of a flat tube burns very much more quickly than guncotton yarn. When dry and heated to about 100° , guncotton

burns with almost explosive violence. The guncotton, as it leaves the hydraulic press, contains about 15 to 17 p.c. water, and is then not combustible; when held in a flame, it only smoulders as it partially dries.

Briskly heated in small quantity in the form of loosely twisted yarn, guncotton was found to explode at 150° (Abel). The exact ignition point varies with the physical condition of the guncotton and the method of determination.

Guncotton can be exploded by percussion; but when struck by an iron hammer on an iron anvil, the portions directly struck by the hammer detonate, but the rest of the guncotton remains unexploded. Wooden boxes containing dry compressed guncotton, both closely and loosely packed, have been repeatedly fired at from rifles, the result being that the contents of the box were generally inflamed, but never exploded; while similar packages containing dynamite or other nitroglycerin preparations were always violently exploded by being fired at (Abel, Trans. Roy. Soc. 1874, 359-362). The use of moist guncotton has rendered any danger from shock still more remote.

Properly stabilised guncotton is a safe and permanent explosive when stored under normal conditions, especially when wet; many samples, well over 30 years old, have shown practically no signs of deterioration. Wet guncotton stored in air-tight vessels, especially wooden ones, is liable to the formation of fungoid and mould growths on its surface. The guncotton is frequently dipped in a weak alkaline solution of phenol to prevent these growths.

Under certain conditions, as when stored in contact with organic substances at rather elevated temperatures, guncotton may be decomposed by denitrifying bacteria, with the production of ammonia, nitrogen, and carbonic acid.

Products and heat of combustion. Guncotton does not contain sufficient oxygen for complete combustion into CO_2 , H_2O , and N; the equation

shows that cellulose trinitrate requires 24.3 p.c. more oxygen for complete combustion. Carbonic oxide and hydrogen are, therefore, naturally to be expected in quantity in the gases of combustion.

In the flaming combustion of guncotton, when the gases were allowed to escape freely at nearly atmospheric pressure, Sarrau and Vicielle found a large quantity of nitric oxide, NO, in the gases; about one-fourth of the volume of the dry gases.

When the guncotton is inflamed in a closed vessel, in which the gases of combustion cause a moderate pressure, no oxide of nitrogen is formed. Von Karolyi exploded guncotton, in quantities of 10 grams, in small cast-iron cylinders of such strength as just to yield to the pressure of the gases produced by the combustion. These cylinders containing the guncotton were made air-tight, provided with the means of inflaming the guncotton by an electrically heated platinum wire, and enclosed in a spherical shell of about 5 litres capacity, which was exhausted before the explosion, and

in which the permanent explosion gases of the guncotton produced an excess of pressure of about half an atmosphere, which enabled portions of the gases to be removed, by means of a stop-cock, for analysis. Von Karolyi found the permanent gases to consist of CO_2 28.5, CO 39.8, CH_4 9.9, H 4.4, N 17.4 volumes per 100 (Pogg. Ann. April, 1863). Abel repeated Von Karolyi's experiments, and found acetylene always present in considerable quantity in the gases; an analysis of the permanent gases obtained from 10 grams of guncotton in two different experiments is given:—

Experiment 1: CO_2 19.69, CO 39.87, C_2H_2 7.85, CH_4 3.45, H 15.82, N 13.32 vols. per 100.

Experiment 2: CO_2 18.97, CO 41.80, C_2H_2 6.36, CH_4 3.87, H 17.02, N 11.98 vols. per 100.

Sarrau and Vieille (Compt. rend. 90, 1058) have ascertained the volume (at 0° and 760 mm.) and the composition of the permanent gases produced by the explosion of guncotton in a closed vessel, and find that both vary with the density of the charge ($\frac{\text{volume of guncotton}}{\text{capacity of vessel}}$), i.e.

with the pressure ensuing on the explosion. The following are some of the results obtained:—

	Density of charge	Volume of gases (at 0° and 760 mm.) given by 1 gram guncotton
(1) . . .	0.01	658.5 c.c.
(2) . . .	0.023	670.8 „
(3) . . .	0.2	682.4 „
(4) . . .	0.3	—

Composition of the gases per 100 volumes.

	(1)	(2)	(3)	(4)
CO_2 . . .	21.7	24.6	27.7	30.6
CO . . .	49.3	43.3	37.6	34.8
H . . .	12.7	16.2	18.4	17.4
N . . .	16.3	15.9	15.7	15.6
CH_4 . . .	none	trace	0.6	1.6

With these higher pressures, equivalent to higher temperatures, the composition of the gases is simpler; they contain neither acetylene nor oxide of nitrogen, and with increase of pressure there is increase of CO_2 and H and decrease of CO ; oxidation of CO by H_2O evidently occurring, and the composition of the gases being the result of a balance between the oxidising action of H_2O on CO , and of the reducing action of H on CO_2 .

Sarrau and Vieille, using Berthelot's formula for guncotton, equate its decomposition by explosion thus: $\text{C}_{24}\text{H}_{29}(\text{NO}_2)_{11}\text{O}_{20}$:

(a) When density of charge is 0.023:

(b) When density of charge is 0.3:

the reaction with high density of charge (which would be the condition in actual use) tends to approach the result:

The agreement of the equations with the results

of analysis is, however, only moderately approximate.

For equation (a) the calculated quantity of heat evolved for constant pressure (for constant volume, the quantities of heat are about $\frac{1}{10}$ higher), and the volume of the gases reduced to 0° and 760 mm. (per 1 kilogram of dry and ash-free guncotton), are as follows, compared with Sarrau and Vieille's experimental values:—

	Quantity heat calculated	Calories found	Volume gas calculated	Litres found
Water, liquid	1076	1071	684	687.5 ¹
Water, gaseous	997.7	—	859	—
For equation (c):				
Water, liquid	1074	—	743	—
Water, gaseous	1022	—	859	—

Guncotton, therefore, on explosion, gives (for equal weights) more gas and a greater quantity of heat than gunpowder or mining powder, more gas but a smaller quantity of heat than nitroglycerin.

The heat evolved by the complete combustion of guncotton in oxygen gas, and under constant pressure, was found by Sarrau and Vieille to be per 1 kilogram of guncotton 2302 kgm.-degrees when the water formed was liquid, 2177 when gaseous.

Noble (Lecture to Inst. Civil Engin. April 3, 1884) obtained more permanent gases from detonated pellet guncotton than did Sarrau and Vieille with low densities of charge. Thus he states that 1 kilogram of guncotton (containing 2.36 p.c. moisture and 0.36 p.c. ash) produces, at 0° and 760 mm. pressure, about 730 litres of permanent gases (water, liquid); or, per 1 kilogram of dry and ash-free guncotton, about 750 litres of permanent gases. The gases were produced in the steel explosion vessel under very high pressure. The volume of gases agrees fairly well with that calculated for Sarrau and Vieille's equation (c) for high density of charge.

Noble states that the temperature of explosion of guncotton is at least double that of gunpowder; the latter temperature he estimates for ordinary English gunpowder at about 2200° .

The composition of the gases produced by the detonation of dry and of moist guncotton is given on p. 64.

Detonation.—Nobel, in 1864, had discovered that nitroglycerin could be detonated by means of mercury fulminate; and in 1868, Abel found that air-dry compressed guncotton (like nitroglycerin) could be detonated by the explosion in close contact with it of 5 grains (0.32 gram) of mercury fulminate, contained in a thin metal case (Trans. Roy. Soc. 1869, 159, 498). He subsequently (*ibid.* 1874, 337–395) found that by increasing the strength of the envelope, viz. by making the case for the fulminate of stout sheet iron, and inserting it in a closely fitting hole in the guncotton, the latter could be detonated with certainty with only 2 grains (0.13 gram) of the fulminate. In practice, however, much larger quantities of fulminate are used, in order to have a good initial detonation, and to provide for the possibility of the detonator tube fitting too easily into the hole in the guncotton.

¹ 671 litres from guncotton containing 2.4 p.c. ash.

The explosion of the guncotton thus caused by that of the fulminate has been called *detonation* on account of the loud sound by which it is followed; it differs from the flaming combustion of guncotton by the immensely greater speed at which chemical action (oxidation of one part of the compound, the C and H, by another part, the NO_3) progresses in the guncotton, and by the consequent powerful mechanical effects produced by the gases formed. Abel found the velocity of detonation of air-dry compressed guncotton to be about 18,000 feet per second; consequently, the large volumes of heated gases produced at this great rate work destructively on nearer objects, and give rise to a condensed wave in the air, propagated with great velocity. Moreover, the air offers resistance to the motion of the gases produced at so great a rate, consequently the gases exert pressure on the guncotton and on the ground or other support on which it rests, producing powerful reaction effects.

For the detonation of unconfined guncotton by mercury fulminate, it is essential that the former shall be in a condition to offer resistance to the shock of the fulminate, so that the energy of the shock shall heat the guncotton, not disperse it. Compressed guncotton meets this requirement, while in the form of wool or loose yarn it is scattered or inflamed, but not detonated.

Threlfall (Phil. Mag. 1886, 172) thus gives Berthelot's views on the theory of detonation: 'The kinetic energy of the shock of the explosion (by the detonator) is transformed into heat at the point (of the explosive) struck; the temperature of this point is thus raised to the temperature of explosion, a new shock is produced which raises the temperature of the neighbouring portions to the same degree; they then explode, and the action is thus propagated with an ever-increasing velocity.' The 'ever-increasing velocity' must refer to the commencing stage of the detonation, as Abel's measurements of the rate of detonation of guncotton and dynamite do not bear it out.

The detonation of guncotton is transmissible across an intervening air space which varies with the weight of the charge; thus the detonation of a $\frac{1}{2}$ lb. cylinder of compressed guncotton, 3 inches in diameter, will cause the detonation of another similar cylinder placed on the ground at a distance of 1 inch, but not at a distance of 2 inches.

Silver fulminate is in no way superior to mercury fulminate in causing the detonation of guncotton. Nitroglycerin, nitrogen chloride and iodide show a remarkable want of reciprocity in their behaviour to guncotton as regards detonation. Thus, while the detonation of $\frac{1}{2}$ oz. of guncotton caused the simultaneous detonation of a charge of nitroglycerin in a tin-plate vessel at the distance of 1 inch, and $\frac{1}{2}$ oz. produced the same result across an air space of 3 inches, 1 oz. of nitroglycerin detonated in close contact with a disc of compressed guncotton did not detonate it, but only dispersed it. 100 grains of dry nitrogen iodide was unable to cause the detonation of a pellet of dry compressed guncotton on which it rested; and 50 grains of nitrogen chloride (covered with a film of water and contained in a thin watch-

glass resting on the guncotton) was about the minimum quantity required to effect the detonation of the latter (Abel, Trans. Roy. Soc. 1869, 489).

With increase in the amount of water in the compressed guncotton, more mercury fulminate is needed to effect detonation; the fulminate as usual being contained in a tin-plate tube and fitting closely in a central hole in the guncotton. With a total of 5 p.c. of water (*i.e.* 3 p.c. above the 2 p.c. of normal air-dry guncotton), detonation by 15 grains of mercury fulminate is doubtful. Moist guncotton containing 12 p.c. water was detonated only once in seven experiments by a detonator containing 100 grains of fulminate; when the guncotton contained 17 p.c. water, it required 200 grains of fulminate to detonate it with certainty.

Guncotton as it leaves the press, containing about 15 p.c. water, although quite unflammable, can be readily exploded by the detonation in contact with it of about half an ounce of air-dry compressed guncotton. For the certain detonation of guncotton containing 20 p.c. water, a primer of about 1 oz. of dry guncotton is required; and when the guncotton has absorbed the maximum amount of water it is capable of doing (30–35 p.c.), for its certain detonation 4 ounces air-dry guncotton applied in close contact are necessary (Abel, Trans. Roy. Soc. 1874, 337). This discovery (which was due to Brown, of Woolwich Arsenal) has been of the greatest practical importance, as it has rendered the use of guncotton for military purposes very safe; permitting the great bulk of the guncotton to be kept in a moist and unflammable state, while a relatively small quantity only of dry guncotton is needed for 'primers,' the dry primers being detonated by a suitable mercury fulminate detonator.

The velocity of detonation of moist guncotton is greater than that of the dry, and the work done by the same weight of guncotton appears to be equal, whether it be employed in the dry or moist state.

As in the case of dry guncotton, detonation is propagated in masses of moist compressed guncotton in contact, provided the piece first detonated does not contain less water than the others; but for transmission of detonation in the open air through any considerable number of cylinders or slabs of moist guncotton, it is essential that they should be in contact, much shorter air spaces than in the case of dry guncotton stopping the detonation.

The rate of detonation of moist guncotton is a little quicker than that of dry guncotton; and that of guncotton saturated with water (containing about 30 p.c. of it) is considerably quicker than that of the dry. Abel (Roy. Soc. 1874) measured (by means of Noble's chronoscope) the rate of detonation of guncotton under different conditions, of dynamite, and of nitroglycerin.

Cylinders of compressed guncotton 3 inches in diameter were employed; they were placed on their bases, and, when in a continuous train, with their circumferences touching, and the measurements of velocity of detonation were made at intervals of 6 feet, or sometimes of 4 feet, in the train of guncotton. The following are some of the results obtained:—

	Rate of progression of the detonation: feet per second		
	First 6 feet	Last 6 feet	Mean (of all the measurements)
Dry guncotton, 170 cylinders, touching	17,466	17,738	17,122
„ „ ½-inch air spaces, 28 feet	4 feet 15,676	4 feet 16,218	16,776
Moist guncotton (15 p.c. water), 28 feet, touching .	18,416	18,040	18,375
Wet guncotton (30 p.c. water), 36 feet, touching .	22,574	19,240	19,948
Dry guncotton, containing 38 p.c. KNO ₃ , touching .	—	—	15,981

The above results show that there is a decided increase in the rate of detonation of guncotton, when the air in the latter is replaced by the very slightly compressible water—a behaviour recalling the greater velocity of propagation of sound in water than in air.

The velocity of propagation of sound, too, comes nearest to the detonation-velocities just given; thus the experimental values for sound (of low intensity) in water at 8° is 4708 feet per second, and in ice is 9512 feet.

Wet guncotton, when frozen, is detonated with certainty by the fulminate detonators ordinarily used for dry guncotton (Abel, *v. supra*).

The gases resulting from the detonation of dry and of wet compressed guncotton were examined by Noble and Abel, and from their results the two following analyses are taken. The detonation was effected in a very strong steel explosion vessel, in which the gases were formed under very great pressure. A correction should be made in the dry guncotton gases for the permanent gases (2CO+2N) of the mercury fulminate detonator, and for the same and those from the small quantity of dry guncotton priming in the case of the wet guncotton gases; but as the CO would be oxidised by the gaseous water to an unknown extent, the direct results are given.

Composition of the permanent gases, vols. per 100.

	Dry guncotton, 1620 grains pellet, 130 grains mercury fulminate detonator	Wet guncotton
CO ₂ .	24.24 .	32.14
CO .	40.50 .	27.12
H .	20.20 .	26.74
N .	14.86 .	14.00
CH ₄ .	0.20 .	none
	100.00	100.00

It is noticeable that Sarrau and Vieille's results for the composition of the gases of explosion of guncotton for the lower density of charge (*v. supra*) approach the composition of these detonation gases of dry guncotton. The influence of the additional water on the gases of detonated wet guncotton, in oxidising CO to CO₂ with formation of H₂, is very marked.

For the condition of gaseous water, a greater quantity of heat will be evolved by the detonation of dry guncotton than by that of moist guncotton containing the same weight of the dry material; the volume of the gases will, however, be greater from the moist than from

the dry guncotton. The volume of the permanent gases also will be greater with moist guncotton, owing to the H formed from the water.

Von Forster, in Germany, for special military use, coats pieces of moist compressed guncotton with a skin of dry guncotton by immersing them for about a quarter of a minute in ethyl acetate.

It has also been proposed to use paraffined guncotton instead of moist guncotton, prepared by immersing dry compressed guncotton in melted paraffin. The paraffin has the advantage over water that it does not evaporate; it is said to make dry guncotton less sensitive to shock, but it lowers the percentage of oxygen, and is stated to be inflammable.

Intensity of action.—Abbot, in his Report, gives the intensity of action of compressed guncotton, detonated under water, as 87, kieselguhr dynamite No. 1 being 100. In comparative experiments made in this country, under different conditions to Abbot's, guncotton has shown a slightly greater intensity than dynamite; as, for instance, in the displacement of earth by the detonation of buried charges, and in the work of excavation done by their detonation in the bore-hole of lead cylinders. Abel's experiments, by the latter method, give the intensity of action of guncotton as 101, the dynamite being 100; experiments in which the same weight of fulminate was used being compared.

Uses.—Guncotton is almost exclusively employed for military purposes, for use in offensive torpedoes and in submarine mines, and for demolitions on land. It is also used in the manufacture of smokeless powders, both military and sporting, and in certain fuses and fuse compositions.

Guncotton mixtures. It has already been mentioned that 100 lbs. C₆H₇O₂(NO₃)₃ require 24.3 lbs. additional oxygen for complete combustion into CO₂ and H₂O; and guncotton, on account of the lower nitrates present, would require more oxygen. At an early period in the history of guncotton, this oxygen was supplied in the form of potassium or other nitrate. Potassium chlorate was also suggested but abandoned, owing to the lack of stability of the mixture, although the explosive effect of the guncotton was largely increased.

Potentite is a mixture of guncotton and potassium nitrate.

Tonite, invented by Trench, is manufactured by the Cotton Powder Co. at Faversham, and also at San Francisco. It was originally

intended to be used as a propellant, but is now only used as a disruptive explosive. No. 1 is an intimate mixture of about equal weights of wet guncotton pulp and barium nitrate, the paste being compressed into cartridges with the usual recess for the detonator, and wrapped in paraffined paper. No. 2 is a mixture of guncotton, potassium and sodium nitrates, charcoal, and sulphur; and No. 3, a mixture of 18–20 p.c. guncotton, 11–13 p.c. dinitrobenzene, and 67–70 p.c. barium nitrate, and 0.5–1 p.c. moisture. Tonite was used in the construction of the Manchester Ship Canal. No. 1 is used for blasting hard rock. No. 3 is slower in its action, and is used for soft rocks. It is also used for military purposes.

Tonite burns slowly and without tendency to explosion on ignition. It detonates readily and completely, and there is practically no carbonic oxide in the products of detonation.

Abel found its intensity of action, by the lead cylinder method, to be 84, kieselguhr dynamite No. 1 being 100.

Abbot (Addendum I. to his Report) examined tonite of San Francisco make, consisting of 52.5 p.c. guncotton and 47.5 p.c. barium nitrate. Detonated under water, it gave intensity 81, dynamite being 100.

Whilst the intensity is lower than that of guncotton, these values show that the guncotton is remarkably economised in tonite. To render tonite safe for use in fiery mines, the cartridges are surrounded by a layer of 'Trench's Fire-extinguishing Compound.' This is sawdust impregnated with a mixture of alum, ammonium chloride and sodium chloride, and extinguishes all flame from the tonite on detonation of the latter.

Other guncotton mixtures are included under 'Smokeless Powders.'

Collodion cotton.—By collodion cotton, for the purposes of explosives, is meant soluble nitrocollodion. It is less highly nitrated than guncotton, and at the present time is looked upon as a mixture, in varying proportions, of the di-, tri-, tetra-, and penta-nitrocelluloses of Eder's classification.

It is possible to prepare soluble nitrocollodion of a definite nitrogen content, by working under definite conditions as to composition of acid mixture, and temperature, and time of nitration. For smokeless powders and the gelatin dynamites, a nitrocellulose soluble in nitroglycerin or other solvents, containing as high a percentage of nitrogen as possible, 12.5 to 12.7 p.c., is desirable, and also one capable of holding the nitroglycerin bound, so that it does not exude under varying climatic conditions. The limit of nitrogen permitted by H.M. Inspectors of Explosives in collodion cotton for gelatinous explosives is 12.3 p.c., and the usual content 11.5 to 12 p.c.

Manufacture.—In the manufacture of collodion cotton, the finer qualities of white cotton waste are used. The mixed acids are much weaker than in the manufacture of guncotton, and the temperature of nitration is higher. Lunge, however (*l.c.*), found that the quality of the cotton, provided that it has not been altered by drastic chemical or heat treatment, had little or no effect on the quality of the collodion cotton obtained. He also concludes

that 40° is the most suitable temperature for obtaining a maximum yield of maximum degree of nitration and solubility, and that the maximum content of nitrogen in the product is obtained when the ratio of sulphuric acid to nitric acid is not less than 0.25 : 1, and not more than 3 : 1.

The acid mixture usually used contains about 66 p.c. H_2SO_4 , 23 p.c. HNO_3 , and 11 p.c. H_2O ; and the nitration is usually carried on for between 1 and 1½ hours at a temperature of about 40°. To obtain a completely soluble nitrocollodion it is best for the acid mixture to contain sufficient water to form $\text{HNO}_3 \cdot \text{H}_2\text{O}$ and $\text{H}_2\text{SO}_4 \cdot \text{H}_2\text{O}$, but slightly more water is usually present. However, the exact acid mixture and temperature and time of nitration vary considerably in different factories, and sometimes collodion cotton is made in the cold by using an appropriate nitrating mixture.

The nitration is performed in either lead or iron nitrating pots or tanks, or in centrifugals and the extraction of acid, washing, pulping, and other processes are carried out in the same way as with guncotton, except that in the production of collodion cotton for gelatinous explosives it is usual to soak the nitrocollodion in water at about 90°, instead of submitting it to a boiling process.

Claissen has claimed (D. R. P. 163688, 904) the preparation of a nitrocollodion completely soluble in alcohol of 96 p.c. by vol. strength, by nitrating cotton with 30 times its weight of a mixed acid containing 35–45 p.c. HNO_3 , 25–46 p.c. H_2SO_4 , and 18–20 p.c. H_2O at a temperature of 40°–50°.

Properties.—Collodion cotton should be completely soluble in ether-alcohol and in nitroglycerin. It is also soluble in the solvents of guncotton. Bernadou states that when collodion cotton is immersed in ether and kept at a temperature below 0°, it passes into solution or forms a colloidal jelly. Its exploding temperature is higher than that of guncotton, and its explosive effect much less.

Collodion cotton, besides being used in the manufacture of smokeless powders and the gelatinous dynamites, is sometimes used in other explosive mixtures. For example, the Soc. Universelle d'Explosifs (Fr. Pat. 432863, 1910) suggests an explosive containing 'liquid trinitrotoluene,' gelatinised with collodion cotton at about 40°–50°, incorporated with three times its weight of a perchlorate, or a mixture of ammonium perchlorate and ammonium nitrate.

Partially soluble nitrocollodion. Nitrocollotons intermediate in nitrogen content between that of guncotton, of about 13 p.c., and that of completely soluble nitrocollodion, of about 12 p.c. or less, are required for certain smokeless powders. These are manufactured by varying the conditions of nitration, composition of nitrating acids, proportion of acid to cotton, and time and temperature of nitration, or sometimes by carefully blending the requisite proportions of guncotton and soluble nitrocollodion.

Lunge showed that guncottons with more than 13.5 p.c. nitrogen are unstable, and Mendeléeff, by nitrating at a comparatively high temperature, obtained a soluble nitrocellulose containing as much as 12.5 p.c. nitrogen, and this was adopted for use in the manufacture of

Russian military smokeless powders. A nitro-cotton of similar composition is also used by the United States Government. This nitrocotton has been called *Pyrocollodion*, and, as Mendeleff pointed out, is approximately of the composition required for the conversion of all its carbon to monoxide on explosion.

Smokeless Powders.

History.—Attempts were made by the inventors and early workers in guncotton, notably in Austria, to adopt it as a propellant. Schönbein and Otto, in 1846, attempted to use guncotton in rifles, and von Lenk, in 1862, prepared cartridges of spun and woven guncotton for use in cannons. The guncotton was much too rapid and violent in its action, even when woven or compressed, and none of these early experiments was successful.

Abel, in 1865 (Eng. Pat. 1102, 1865), patented a process for granulating guncotton with a solution of gum, and also proposed to use a mixture of guncotton and collodion cotton treated with a solvent; and Kellner, of Woolwich Arsenal, at about the same time, made a granular smokeless powder from guncotton; but these powders did not get beyond the experimental stage.

A semi-smokeless powder was invented by Schultze, of the Prussian artillery, in 1865, who used nitrated wood granulated with a saturated solution of barium and potassium nitrates; and Volkmann, in 1870, who worked Schultze's patent near Vienna, treated the grains with a mixture of ether and alcohol, and practically made a modern gelatinised smokeless powder. The manufacture of this powder, however, was prohibited, in 1875, as it infringed the gunpowder monopoly of the Austrian Government. Schultze's powder was manufactured by an English company at Eyeworth in the New Forest, in 1865, and, with modifications, is still in use for sporting purposes.

The difficulty in adopting guncotton as a propellant was its porosity, for when the powder was ignited, the flame was forced into the interior of the grains, and caused the whole charge to explode, instead of burning progressively. Many attempts were made to reduce the rate of combustion by compression, and by mixing the guncotton with inert ingredients, such as un-nitrated cotton, or coating the grains with paraffin, stearin, or indiarubber, and more or less successful sporting powders were produced in this way. Prentice, in 1866 (Eng. Pat. 953) suggested a sporting powder made of pyropaper, containing 15 parts of unnitrated cellulose; and Punchon proposed to regulate the speed of combustion of guncotton by soaking in a solution of sugar, and added nitrates to increase the explosive force (Eng. Pat. 2867, 1870).

In 1882 Reid (Eng. Pat. 619, 1882) patented a process for the granulation of a mixture of soluble and insoluble nitrocellulose, and hardening the grains with ether-alcohol; the product, known as 'E. C. Powder,' is too violent in its action for military purposes, but is still largely used as a sporting powder. 'J. B. Sporting Powder,' afterwards introduced by Johnson and Borland (Eng. Pat. 8951, 1885), was a mixture of collodion cotton with potassium and barium

nitrates, hardened by a solvent of the nitro-cellulose and subsequent drying.

Some form of military smokeless powder became essential on the introduction of small-bore magazine rifles, and efforts were again made in 1885 to retard and regulate the combustion of nitrocellulose by converting it into a product absolutely devoid of all porosity. The sporting powders in use at the time were only superficially hardened, and contained fibrous nitro-cellulose, but eventually Vieille, in 1886, introduced 'Poudre B,' named after General Boulanger, a completely gelatinised, dense, horny, and non-porous explosive, made by treating a mixture of guncotton and collodion cotton with ether-alcohol, the resulting paste being rolled into thin sheets, cut into small squares, and dried, and this was adopted by France as a propellant for the Lebel rifle.

Other countries at once began to work on similar lines, and Germany adopted a similar powder, in 1889. But Nobel, after the invention of blasting gelatine, tried to utilise nitroglycerin as an ingredient for a smokeless propellant, and eventually patented 'Ballistite' in 1888 (Eng. Pat. 1471, 1888), a colloid mixture of collodion cotton and nitroglycerin, which at first also contained camphor. This powder was adopted by the Italian Government. About the same time, an English Explosives Committee was working on the same subject at Woolwich, and gradually evolved a nitroglycerin smokeless propellant, which was adopted by the British Government under the name of 'Cordite' (Eng. Pats. 5614, 1889; and 11664, 1890). Cordite is a mixture of guncotton and nitroglycerin, with a small proportion of mineral jelly. A nitroglycerin powder similar in composition to cordite was adopted by Austria-Hungary in 1893.

Some form of smokeless powder was rapidly adopted by all civilised countries for small-arm purposes, and since that time the manufacture, composition, and form of the explosives have been gradually modified and so perfected that, at the present time, accurate and reliable smokeless powders are available and solely used as propellants even for the heaviest ordnance.

The general principle in the manufacture of all these smokeless powders is to thoroughly gelatinise the nitrocellulose by means of some solvent, so that its fibrous character is destroyed.

The powders are more or less hard, homogeneous colloids, which only burn progressively from the surface, so that their combustion is completely under control. They are never absolutely smokeless, as even if they give no solid products of combustion, the steam produced always gives a smoke varying in amount with the atmospheric conditions.

Composition.—Smokeless and semi-smokeless powders can be roughly divided into the following classes, according to their composition: (1) Nitrocellulose powders, which may be composed of collodion cotton or guncotton or a mixture of the two. (2) Nitrocellulose powders with oxidising salts, in which one of the divisions of class (1) is mixed with a metallic nitrate, and perhaps other ingredients. (3) Nitrocellulose-nitroglycerin powders, where one of the divisions of class (1) is combined with nitroglycerin. (4) Nitrocellulose powders combined with another

nitro derivative, with or without nitroglycerin and metallic nitrates.

Military smokeless powders.—The desirable properties in a military smokeless powder are numerous. It should be smokeless and flameless, should not cause erosion of the bore of the gun, or leave any quantity of residue, particularly of a corrosive nature. It should be readily and uniformly ignitable, and should burn in such a way that the pressure should be slowly developed and well sustained whilst the projectile is in the gun, but no unconsumed powder should be projected from the muzzle. It should give products of combustion as free as possible from combustible gases, for example, carbon monoxide, as these tend to ignite at the muzzle of the gun and give a 'back-flash,' which may be dangerous. It should give a high muzzle velocity without excessive pressures, and it must give accurate firing results, as a result of uniform internal ballistics. It should be chemically and physically stable under all practical conditions of storage, so as neither to become dangerous nor give irregular, and possibly dangerous, pressures. It should be insensitive to variations in atmospheric temperature and moisture, and not be affected by being fired from a hot gun chamber. Some of these properties are more necessary than others. It is impossible to combine all the desirable properties in one propellant, and all propellants in use are compromises, according to their use.

A completely gelatinised powder burns away in layers from the ignited surface, the rate of burning varying directly with the pressure. In the open the powders burn rapidly but quietly, but in the closed chamber of a gun the products of combustion soon raise the pressure, and explosive burning is soon reached. The rate of burning of a complete charge of given composition depends on the size, shape, and consistency of the grains, ignition of the grains usually taking place simultaneously over their entire surfaces. The shape of grain should be such that it gives as large a burning surface as possible until the combustion is complete. A cubical or spherical shape is, therefore, of the worst type, a rod-shaped grain is a little better, but either a long tubular grain or large flat strip is better still, as the burning surface is then practically the same at the end as at the beginning of the combustion. Flat strips, however, give irregular ignition at times, owing to the way the strips pack together. For large calibre guns a multi-perforated grain is best, as the burning surface increases as the grain burns away, but if the grains are too long they are liable to break up during burning. Some modern 'progressive propellants' are so manufactured that the interior material has a more rapid rate of burning than the surface layers. The rate of combustion may be tamed or moderated by chemical as well as by physical means. Although powders belonging to all the above classes have been tried for sporting purposes, and many of them also for military purposes, so far as the latter are concerned, there are to-day only two varieties of smokeless powders, nitrocellulose powders and nitrocellulose-nitroglycerin powders.

The smokeless powders of the latter class are more powerful than the pure nitrocellulose

powders, for the nitroglycerin supplies the oxygen, that is deficient in guncotton, for complete combustion. A smaller charge and consequently a smaller gun chamber are necessary with the nitroglycerin powders for equal ballistic results. The solvent is more readily eliminated when the powder contains nitroglycerin, and the powders are cheaper; but the temperature of combustion is higher, and, with a large proportion of nitroglycerin, the consequent erosion of the gun is serious. The erosion can be minimised by the inclusion of a moderant in the composition, such as the 5 p.c. of mineral jelly in cordite and the metallic nitrates in certain sporting powders. The nitroglycerin powders are decidedly more stable than the pure nitrocellulose powders. Nitrocellulose powders tend to give irregular ballistics, owing to their sometimes more porous nature and frequent physical instability on storage, and sometimes quite a small proportion of nitroglycerin is added to remedy this defect. They also have a relatively rapid rate of decomposition on storage, but this may be counteracted to some extent by the use of a stabiliser. Their great advantage, particularly for small arms, machine and quick-firing guns, is that they are relatively cool burning, and give considerably less erosion than the nitroglycerin powders.

Nitrocellulose powders are, at the present time, generally made entirely or largely of soluble nitrocotton, otherwise acetone has to be used for complete gelatinisation, and the finished grains are then harder and more brittle, particularly if the elimination of the solvent is carried too far. These tend to break up on storage or in the gun, and give irregular ballistics, and sometimes dangerous pressures. Nitrocellulose powders containing much insoluble nitrocotton are sometimes used, as in France, but they are incompletely colloided by the ether-alcohol used as solvent, are more porous, and are liable to gain or lose moisture, according to the storage conditions, with consequent irregular firing results. Generally, the powders with lowest normal moisture content are least prone to alteration of this content with varying storage conditions. The nitrocellulose powders are more bulky than the nitroglycerin powders.

Secondary ingredients.—Besides the main ingredients, nitrocellulose and nitroglycerin, military smokeless powders usually contain small quantities of other substances added for attaining some special purpose. These secondary ingredients may be added as moderants or deadeners, stabilisers, or cooling agents.

Moderants or deadeners are added to reduce or control the rate of combustion of the explosive. Amongst these substances may be mentioned camphor, vegetable oils, such as castor oil; and mineral hydrocarbons, such as paraffin and vaseline.

Stabilisers.—The addition of a small quantity of alkali was frequently made in the early days of smokeless powders to combine with any acid developed in them on storage. This addition of alkaline neutralising agents was, however, soon shown to be harmful, because they are liable, under certain conditions, to hydrolyse the nitro-compounds.

This is true even of so mild an alkali as calcium carbonate. Alkaline neutralisers yield

nitrites, which decompose again at elevated temperatures, and so act catalytically in decomposing the nitrocellulose.

Residual solvent was found to stabilise the powders to a considerable extent by absorbing the products of decomposition; and to prevent rapid loss by evaporation, solvents of high boiling-point were used, for instance, a little amyl alcohol was added to an ether-alcohol solvent. The elimination of the solvent leaves the powder porous and so accelerates the rate of decomposition.

The more usual method of stabilising is to add a small quantity of some substance that will form a stable compound by chemically combining with any liberated peroxide of nitrogen, and so act so long as any of the free substance is left. Aniline, diphenylamine, aminoazobenzene, nitroguanidine, phenanthrene, the higher alkyl derivatives of the anilides of organic acids, and similar compounds are added for this purpose. The vaseline in cordite, although originally added for another purpose, has been proved to have a marked stabilising influence. Soaps, resins, and oils have also been suggested as stabilisers.

The French Commission, on the explosion of smokeless powder on the 'Jena' in 1907, drew attention to the fact that substances like diphenylamine and aniline not only act as stabilisers, but also as *indicators* of decomposition, owing to the formation of local spots or patches of peculiar colours, and such substances have been increasingly used for this purpose since that time.

Cooling agents.—Most smokeless powders have a high temperature of explosion, which not only causes erosion of the bore of the gun, but also gives a strong and readily visible flame. The more complete the combustion, the higher the temperature of explosion, and simple alteration of proportions of the ingredients of a nitro-glycerin and nitrocellulose explosive, so as to render the combustion less complete, will give a lower temperature and less flame, as is instanced by 'modified cordite.' The substances added as moderants (metallic nitrates, oils, fatty and mineral, wax, resin, camphor, &c.) tend in the same direction, and the addition of charcoal has also been proposed. With these additions, the products of combustion contain more carbonic oxide and hydrogen, and the actual temperature of explosion is less. The addition of a sufficient quantity of these substances to adequately reduce the temperature of explosion frequently causes a serious reduction of the explosive power, and in some cases is objectionable through rendering the grains brittle. The 5 p.c. of mineral jelly in cordite effects a considerable reduction of the temperature of explosion without serious effect on the ballistics, for, although the temperature is reduced, the volume of gas is increased. The use, in comparatively large quantity, of substances like guanidine nitrate, nitroguanidine, and substituted ureas, has been claimed to reduce the temperature of explosion without reducing the ballistics of the powder.

With incomplete combustion, however, the carbon monoxide and hydrogen inflame on coming in contact with the air, and, burning together with any unburnt charge, produces a very

decided flame. To produce a *flameless explosive*, substances are added so as to mix the products of explosion with a sufficient proportion of non-inflammable gas to protect the inflammable gases from the atmosphere until their temperature has fallen below their ignition-point. The problem is similar to the production of a safety detonating explosive for use in fiery coal-mines, and similar remedies have been proposed.

Duttenhofer (Eng. Pat. 24782, 1904) proposed the addition of an alkaline bicarbonate, claiming that it had no detrimental effect on the stability of the explosive, as is the case with the normal carbonate. It cools the flame by the liberation of its water of crystallisation and carbon dioxide. In a later patent, Luciani (Fr. Pat. 380963, 1906) proposes a mixture of carnauba wax, bees-wax, and sodium bicarbonate. Edwards (Eng. Pats. 24025, 1907, and 12188, 1908) proposes a similar mixture, in which the sodium bicarbonate may be replaced by the ammonium or magnesium compounds; and Vender (Fr. Pat. 405822, 1909) claims for hydrated magnesium carbonate or manganese peroxide. Sodium resinate and other sodium and potassium salts have been suggested, but these give more smoke on firing. Oxalic acid and its salts have also been tried, but a really suitable ingredient for decreasing the flame of smokeless powders in guns of large calibre has however not yet been found.

Solvents.—The solvents used in the gelatinisation of smokeless powders are usually acetone, ethyl acetate or amyl acetate for guncotton powders, and a mixture of ether and alcohol for the collodion cotton powders.

Powders gelatinised with ether-alcohol are very liable to blister, curl up, and become distorted during drying, owing to the rapid evaporation of the ether, and there is difficulty in driving off the amyl acetate owing to its high boiling-point. The correct proportion of solvent has to be carefully worked out for individual powders. Too much solvent increases the difficulty of drying, and increases the liability to distortion and cracking, whilst too little delays the mixing and renders it imperfect.

The secondary ingredients are usually dissolved in the solvent before it is added to the main ingredients.

Heating with camphor under pressure, instead of treatment with solvents, gelatinises and hardens soluble nitrocellulose powders, but this substance, as it remains as a constituent, causes physical instability owing to its volatility, and its use has been abandoned. The use of phenyl benzoate, or an ester of a homologue of phenol, for the collodion of soluble nitrocellulose has been patented by the Dupont de Nemours Company (U.S. Pat. 1161863, 1915). The solvents used in the gelatinisation do not, as a rule, remain in the finished powders except in very small quantity.

Manufacture.—Only a general outline of the manufacturing processes is given here: the details vary, and some are given under individual powders.

The drying of the nitrocotton.—In this country some 30 p.c. of water is left in the nitrocellulose in its finished condition as a safety measure. The nitrocellulose, either loose or, for convenience in handling and to prevent

dust, lightly compressed into cylinders or slabs, is dried by exposure on tiers of copper- or brass-gauze trays in well-constructed and well-isolated wooden huts or 'stoves' by means of a current of dry air forced in through a series of holes at the top of the stove and leaving through openings near the floor (the moisture-laden air falls as the temperature is lowered by the evaporation of the water), the temperature in the stove being kept at about 40°. The drying takes up to several days according to the degree of compression of the nitrocellulose. This is one of the most dangerous operations in the manufacture of smokeless powder, especially when the last portions of the moisture are being driven off. Any dry dust is very susceptible to ignition by friction or shock, and the dry nitrocotton is readily electrified even by a current of dry air, and special precautions have to be taken to connect the drying trays to earth, the necessity for which was first pointed out by Reid. The nitrocotton must be cooled down before unloading the stove, as it is more susceptible to ignition by friction or percussion whilst hot, and the stoves are specially constructed to avoid the accumulation of dust. The nitrocellulose is sometimes dried by removing part or the whole of the water by treating it with alcohol. This process was used in 1891 in Austria, and was patented in England by Durnford in 1892. To render the nitrocellulose anhydrous, it is first soaked in alcohol that has been previously used, squeezed and pressed, and then treated similarly with fresh alcohol. When ether-alcohol is to be used as the gelatinising agent of the nitrocellulose, displacement of the water by alcohol is now the usual method of eliminating the water, and this method is in general use in the United States and on the Continent. The nitrocotton is packed into the cylinder of a hydraulic press and alcohol forced through it. Water is at first forced out, then a weak alcohol, which is collected and rectified by distillation, and finally only slightly weakened alcohol, which is used again for the preliminary displacement of another cylinder of wet nitrocotton. The nitrocotton is then submitted to a higher pressure, so as to leave only sufficient alcohol in the mass for its gelatinisation on admixture with ether. Dehydration by alcohol is carried out in some factories by spraying the alcohol over the nitrocotton packed to form a layer over the basket of a centrifugal. A further advantage of this process is that unstable impurities are eliminated by this washing with alcohol. Berl and Deply (*Zeitsch. Ges. Scheiss-u. Sprengstoffw.* 1913, 8, &c.) have examined the impurities extracted by the alcohol in the dehydration of nitrocotton, and, besides a small quantity of inorganic impurities derived from the wash waters, find them to consist of a sticky brown mass of lowly-nitrated organic matter of poor stability and low ignition point.

Mixing and incorporating.—The nitrocellulose should be in as fine a condition as possible. The first wetting with the solvent is a difficult matter, and is sometimes effected *in vacuo*. The absence of all dust, when once the solvent is added, makes the manufacture of smokeless powders much safer than that of gunpowder. Even if ignition occurs, the combustion, though

fierce, never leads to explosion, and is usually very local in its effects. The introduction of alcoholising the wet nitrocotton in the manufacture of nitrocellulose powders renders their manufacture a safe one from the beginning, except for fire risk.

The incorporation is usually carried out in kneading machines, but sometimes by rolling. The kneading machine almost exclusively used is that of Werner, Pfeleiderer, and Perkins. It consists of an iron trough, the upper part of which is rectangular. The bottom is in the form of two parallel half-cylinders, in which two heavy screw-shaped paddle-blades revolve in opposite directions, one at about twice the rate of the other. The allowance between the blades and bottom is small and the mixture is thoroughly kneaded and mixed between them and the trough. Some of the solvent is first introduced, then the nitrocellulose and any other ingredients, and finally the remainder of the solvent. The incorporation takes some hours for completion, and at the end the trough is tilted, and the direction of rotation of the blades reversed, the finished 'dough' being thrown out and caught in a suitable box with a lid for transference to the rolling or pressing house. The mass becomes considerably heated during the kneading, and to prevent loss of solvent, the machine is covered and the bottom is surrounded by a cold-water jacket. It is necessary to connect the mixing machines to earth, as in the case of the drying trays.

When the material is to be worked into sheets, the rolling is sometimes effected in two operations, the first to effect incorporation of the materials, and then between closer set rollers to reduce the sheets to the requisite thickness. For powders of the ballistite type, the rollers are hollow and steam heated. The sheets are then dried to drive off greater part of the solvent, and again rolled to eliminate any blisters formed during the drying. Thick sheets are produced by folding the thin sheets over and over and passing them backwards and forwards between the rolls, by which means a homogeneous thick sheet is obtained. In the manufacture of strip and flake powders it is now more usual to incorporate as usual and press the dough through a suitable die to give a ribbon of the required thickness and width, which is subsequently cut into suitable lengths for drying.

Cutting and pressing.—The partially dried sheets are usually cut into small square plates. The machines generally used are similar to those in use at the German Government factory at Spandau, in which two sets of revolving circular cutting knives, slightly overlapping, cut the sheet into strips, which are then fed over a fixed cutting edge, and chopped into plates or cubes by a set of rotating knives. Round flakes and discs are cut from cords. After cutting, the grains are further dried. For the preparation of spherical grains the pasty mixture is cut into small fragments, frequently cylinders cut from cords, dried superficially, and then rolled over a rapidly oscillated heated surface.

Cord and tube powder is usually pressed through dies, as in the manufacture of cordite, the material being sometimes subjected to a preliminary rolling to exclude air bubbles, but

the Austrian rifle powder is stated to be drawn and not pressed. For producing the tubular and multi-perforated powders, one or more pins are arranged so as to project into the holes of the dies. When long perforated tubes are to be manufactured, the pins of the dies are tubular, so as to admit air into the powder perforations, otherwise there is a tendency for the tubes of powder to collapse.

Drying.—The powders are dried slowly in stoves, at a temperature of about 40°. The time of drying depends on the size and shape of the grains, but usually lasts several days. In modern factories, the drying stoves are airtight, and the current of hot air is drawn, by means of fans, through special apparatus for recovering the solvent. In some cases, the solvent is largely eliminated by boiling the shaped powder in water. The Dupont de Nemours Company (Fr. Pat. 477343, 1915) suggest drying smokeless powders by heating the grains in oil at about 100°C., the liberated solvent being condensed and recovered, and the oil subsequently removed from the surface of the grains by washing with acetone.

One of the drawbacks of pure nitrocellulose powders is the difficulty of eliminating the solvent in a reasonable time, especially from the larger sizes, without causing the development of cracks on the surface of the grains. Sometimes a rather large proportion of solvent is left in the powder, but then on storage the solvent evaporates, and cracks may also form and so render it impossible to attain the constancy of ballistics necessary in a military powder. The solvent can be more easily removed from nitroglycerin powders, and the higher the percentage of nitroglycerin the more rapidly and more efficiently can the solvent be eliminated.

The flake small-arm powders are usually graphitised, so that the grains may run freely through the cartridge-loading machines.

Blending.—To ensure uniformity of ballistics, the different batches of powder are thoroughly blended.

Sporting smokeless powders have the advantage over black powder that they give less recoil and less noise. They may be broadly divided into two classes—bulk powders and condensed powders.

The bulk powders have a low density, and are designed so that a charge may have the same bulk as black gunpowder to give the same velocity and pressure, and so that the standard 12-bore paper cartridge, of 2½ inches nominal length and holding 3 drams of gunpowder by measure, needs no alteration. They are used mainly in shot guns, and only to a limited extent in sporting rifles. Relatively to military powders, they are required to be quick-burning, and are consequently not so completely gelatinised. The grains are loose and only surface hardened by means of a solvent. They are usually composed of soluble nitrocellulose, or a mixed nitrocellulose containing about 12.5–12.8 p.c. nitrogen, incorporated in the usual mill with a mixture of barium and potassium nitrates. Usually about 7 parts of barium nitrate are used to 1 part of potassium nitrate, but sometimes barium nitrate is used alone. Barium nitrate has the advantage that it is not hygroscopic and yields very little smoke,

but it has a disadvantage in leaving a residue in the gun that is difficult to remove. A small proportion of vaseline, or paraffin wax, is sometimes added as a moderant. Starch is used occasionally to help in the agglomeration of the grains, and camphor was at one time used to help the gelatinisation. Mononitro- and dinitro-benzenes and toluenes are present in some powders to moderate the action, and assist the gelatinisation. Lamp black, wood meal, various gums, and potassium ferrocyanide have also been used as ingredients, and a small proportion of calcium carbonate has been added for stabilisation. The mixture is usually granulated either by sprinkling with water and rotating in a drum or by spreading out on a rapidly oscillating table, but sometimes the mixture is slightly compressed and afterwards broken up into grains, which are then sifted and dried. In all cases, the solvent is sprinkled over the powder after granulation. The manufacture of these powders is described in detail by Glaser (Eng. Pat. 23105, 1892), and by Jones (Eng. Pat. 1154, 1897).

The bulk powders are graded according to the number of grains weight that are equivalent to the 3 drams measure of black powder. The original standard charge was 42 grains, to-day 33 grains is the most common, but there are also 38-, 36-, and 30-grain powders.

The condensed powders have a high density, and the charge occupies only one-third to one-half that of a gunpowder charge. They are used in cartridges with a false base of coned paper, or in smaller cartridges in specially designed modern weapons. These powders are completely gelatinised, and are made in a similar way to the military flake small-arm powders. The requisite rate of burning is obtained by suitable adjustment of size and shape of the grains. The powder paste is rolled into thin sheets, which are cut up into small flakes, and the grains dried as usual.

Occasionally sporting powders are made by an intermediate process, the grains being thoroughly gelatinised. The powder, wet with solvent, is treated with steam, so that the solvent rapidly evaporates and leaves the grain in a bulky form, but the nitrocellulose is hardened throughout the mass, and waterproofed.

Properties.—Pure nitrocellulose powders are grey to yellow, and nitroglycerin powders yellow to brown in colour. They are sometimes coloured by the secondary ingredients, or dye substances may be added, and the grains, more especially those of smaller size, are frequently coated with graphite, giving them a grey to black colour. The surface is usually smooth, but sometimes matted. The powders usually have the consistency of horn, but those containing nitroglycerin are softer and more readily cut than the pure nitrocellulose powders. The specific gravity of the powders varies with their composition and mode of manufacture, but the gravimetric density of the small flakes or grains is usually between 0.25 and 0.40.

The shape of the grains varies considerably. Sporting powders are usually in grains or very thin flakes; military small-arm powders either in thin squares, rectangular plates or discs, or in small cubes, thin cords, or narrow ribbons. The powders for large guns may be in the form of

ribbons, thick cords, round or square sectioned, large cubes, tubes, or cylinders, the size and shape of the grain being adapted to any particular-sized gun, so that the highest possible muzzle velocities may be obtained without excessive pressures. The larger the grain, the less the initial burning surface per unit weight, and the slower burning the charge. The thicker cords and cylinders are frequently perforated through their length by one or more fine holes. The length of the perforated cords must not be too great, or they break up into fragments under the pressure developed in a gun, and the excessive pressures developed may burst the gun. If very long, tubes will even burst when fired in the open. Sometimes long perforated cords have transverse cuts or perforations made in them at intervals to facilitate the escape of the gases and prevent the bursting.

Irregularity of ignition causes irregular burning and pressures. Flakes, strips, and sheets may ignite and burn irregularly, owing to the grains adhering together. To prevent this irregular ignition and burning, the flakes are frequently cupped, or the edges scalloped or grooved, and the strips and sheets have grooves cut in them, or have ridges or small projections moulded on their surface. Fully gelatinised powders give a surface that is less favourable for ignition than the more porous powders. Rough edges on the grains or strips facilitate ignition, but if not normally present and allowed for, may lead to too rapid ignition and abnormally high pressures. Schmidt (D. R. P. 286784, 1913) proposes to give a hardened rough surface suitable for ignition by first gelatinising the outer layers of the pressed grains in a bath of acetone, and then degelatinising the surface by dipping in a bath of benzene, or light petroleum.

To obtain slow initial burning of the grains and low initial pressures, powders with delayed ignition and progressive rate of burning have been introduced. The grains are sometimes coated with a deterrent, either a non-explosive, such as graphite or a wax, or a semi-explosive like dinitrotoluene. The idea of *delayed ignition* was patented by Jones (Eng. Pat. 15553, 1898), and was a most important step in the development of smokeless rifle powders. He suggested the use of a wax, or a mixture of waxes, a solid hydrocarbon of high melting-point, solid substances, like dinitrotoluene, which have, when melted, a solvent action on the substance of the grain, or of graphite mixed with a small quantity of oleaginous substance. In the *progressive propellants* the grains are built up of layers of different rates of burning, the inner layers having the higher rate. In the Dupont powders this result is attained by regulating the processes of manufacture so as to close the minute pores with the result that the density of the grains is very high in the surface layers, and gradually decreases towards the interior. These powders are very cool burning, and not so hygroscopic as ordinary nitrocellulose powders, and give a marked increase of muzzle velocity without increase in chamber pressure. Progressive powders are made at Röttweil by impregnating the surface layers of the grain with 'centralite,' dimethylphenylurea, as a restrainer, and in other powders of this class the

grains are impregnated by soaking in a weak solution of paraffin wax in benzene.

Stability, physical and chemical, under all conditions of climate, storage, and use, is one of the most desirable qualities in a military explosive. Smokeless powders usually contain small quantities of moisture or residual solvent. This has a considerable influence on the shooting qualities of a powder, and has to be carefully regulated in quantity. The effect of excess of solvent, especially on the nitrocellulose powders, in causing physical instability has been already pointed out. Pure nitrocellulose or nitroglycerin-nitrocellulose powders are not affected by moisture, but all nitrocellulose powders are subject to slight deterioration on storage, the deterioration being a function of the temperature, increasing with rise of temperature. The chemical stability of military powders is tested on manufacture and at frequent intervals (*see Stability tests*). Nitroglycerin powders may exude nitroglycerin on cold storage, but it is usually re-absorbed at normal temperatures.

Smokeless powders require smaller charges and gun chambers to produce equal velocities with black gunpowder, and the pressures are more slowly developed and better sustained whilst the shot is in the bore of the gun. This gradual development of the pressure depends on their colloidal nature; the grains when ignited only burn in successive layers, even under the high pressures developed in a gun. An ideal propellant should have a low maximum pressure, slowly developed and maintained so long as the projectile is in the bore of the gun, and should be completely consumed at the moment the projectile leaves the bore.

The regularity of the shooting of smokeless powders, after regularity of ignition, depends on the purity of the materials and the perfection of the manufacture. All powders are carefully blended, and subjected to analysis and a test for pressures developed and velocities obtained before acceptance.

Smokeless powders are very insensitive to shock and percussion; they are not fired by the passage of a bullet through them. Even those powders with a high percentage of nitroglycerin cannot be detonated by means of a strong detonator, unless there is much unabsorbed nitroglycerin present. They are somewhat difficult to ignite, and sometimes ignite irregularly, owing to their horny nature and smooth surface. Small-arm powders require more powerful caps than black gunpowder, and the larger charges require priming with gunpowder or gun-cotton to make ignition certain. The ignition point of gelatinised nitrocellulose powders is about 175°–180°, and of nitroglycerin-nitrocellulose powders about 180°–185°, when the temperature is raised rather rapidly. The ignition point is lowered by heating up slowly, and even a trace of acid has a considerable effect in lowering the ignition-point.

The solid residue from smokeless powders and its effect on the formation of rust in small arms has been examined by van Pittius (Zeitsch. angew. Chem. 1906, 848). He found that a graphited pure nitrocellulose powder gave about 0.11 p.c. of a faintly alkaline residue. The matter insoluble in water was 0.01 p.c., and contained graphite, oxides of copper and iron, and traces of

antimony sulphide. The soluble residue, 0.1 p.c. on the powder, contained 17 p.c. potassium ferrocyanide, 17 p.c. ammonium carbonate, 13 p.c. ferric chloride, 31 p.c. potassium carbonate, 10 p.c. calcium chloride, 7 p.c. copper sulphate, and 5 p.c. potassium antimoniate. The residue contained no nitrates, nitrites, chlorates, cyanides, or sulphides. A graphited nitrocellulose-nitroglycerin powder, 40 : 60, gave about 2 p.c. of a faintly alkaline residue of which only about $\frac{1}{50}$ th was insoluble in water, and contained graphite and oxides of iron and copper. The soluble residue contained 51 p.c. potassium carbonate, 38 p.c. potassium chloride, 11 p.c. potassium antimoniate, and traces of iron and sulphate. There were no nitrates, nitrites, chlorates, cyanides, ferrocyanides, sulphides, or ammonium salts present. In the residues, the antimony, potassium, sulphate, and chloride, actually come from the cap composition, the iron largely from the gun and the copper from the bullet.

After experimenting with various solutions, Pittius concludes that the residue from the powders are not in themselves rust producers, but become so after a time, as they are hygroscopic. Frequent washing out of the gun and

subsequent oiling with a viscous lubricant will be sufficient to prevent rusting.

The erosion of the bore of the guns caused by smokeless powders is almost entirely conditioned by the temperature developed in their explosion, and not to any corrosive action of the products of combustion. It is greater with the powders containing nitroglycerin than with the pure nitrocellulose powders.

The gaseous products of combustion of smokeless powders are water vapour, carbonic acid gas, carbonic oxide, hydrogen, nitrogen, and a small quantity of marsh gas. Sometimes oxides of nitrogen are formed when the explosion is imperfect. They may be always produced at the moment of explosion and be subsequently reduced by the large volume of carbonic oxide and hydrogen at a high temperature.

The heat of explosion and products of combustion of several commercial varieties of smokeless powder have been determined by the ordinary calorimetric bomb method, by Macnab and Leighton, and the following table showing some of their results is taken from a paper read by them before the Society of Chemical Industry, in March, 1904 (*J. Soc. Chem. Ind.* 1904, 298):—

Powder	Calories per gram	Permanent gas per gram c. and 760 mm.	Water vapour c.c. per gram	Total gas c.c. per gram 0° and 760 mm.	Percentage composition of permanent gas				
					CO ₂	CO	CH ₄	H	N

Under the conditions of the experiments no oxides of nitrogen were formed. The authors call attention to the fact that the quantity of heat developed in the nitrocellulose powders increases with the nitrocellulose content, and that a large increase takes place when nitroglycerin is present. Other conclusions are, that as the heat increases, the quantity of carbon dioxide increases, the carbon monoxide and hydrogen decrease, and a larger quantity of water vapour is formed.

The relative temperatures of explosion of these powders were determined by a thermoelectric pyrometer method described by Macnab and Ristori in 1900 (*Proc. Roy. Soc.* 66, 221). The order of the powders according to the temperature developed was, broadly speaking, the same as that given by the total heat of combustion.

The constants of explosion of several smokeless powders have been exhaustively examined by Noble, showing their relationship to the

density of loading (*see Proc. Roy. Soc.* 1905, 381, 512 and 1906, 453). With the density of charge varying from 0.05 to 0.50, Noble found that, as a general rule, with increase of resulting temperature and pressure, there was at first a slight increase and then a steady decrease in the volume of the permanent gases, also a large increase in the volume of CO₂ and decrease in the volume of CO. The volume of H decreases with increasing pressure, while that of CH₄ rises rapidly. He also found that the amount of erosion depended almost entirely on the heat developed, and was independent of the pressure.

Only a few smokeless powders can be referred to in any detail. With many powders the details of composition and manufacture are desired to be kept secret; and of the details characteristic of any powder, only those are given which have been already published.

The military smokeless powders, especially, are constantly undergoing modifications and

improvements and frequently different compositions, nitrocellulose or nitrocellulose-nitroglycerin powders of different degrees of nitration and proportions, are in use at the same time by a country for military purposes, according to the calibre of the gun in which they are to be used, and according as the powder is required as a propellant or for blank ammunition.

At the present time most countries use nitrocellulose powders, usually of the same composition, but differing in form of grain, for small-arm purposes and for field guns, and in the United States, France, and Russia they are used even for the largest naval guns. England, Italy, and Norway use nitroglycerin powders generally, and most other countries use them for large naval guns.

(1) Nitrocellulose Powders.

Poudre B., or *Vieille powder*, was the pioneer of military smokeless powders. As invented by Vieille, in 1886 (*Mém. des Poudres et Salpêtres*, 1908-9), it was a mixture of soluble and insoluble nitrocellulose, thoroughly gelatinised with a mixture of ether and alcohol, rolled into sheets and then cut into strips. It sometimes contained about 2 p.c. paraffin. It had a nitrogen content of about 12.7 p.c. For a short time a smokeless powder containing metallic nitrates was adopted in France, but eventually a pure nitrocellulose with a little stabiliser was adopted for general use. Amyl alcohol was tried as a stabiliser in proportions of 2 p.c., and later 8 p.c., in the powders B.A.M.₂ and B.A.M.₈, but diphenylamine was afterwards used. The nitrocellulose used in the manufacture contains about 40 p.c. soluble nitrocellulose, and as used is a mixture in the requisite proportions of an insoluble nitrocotton CP₁ (coton poudre), containing about 12.8 to 13.1 p.c. nitrogen, and a soluble nitrocotton CP₂ containing about 12 to 12.5 p.c. nitrogen. These nitrocottons are manufactured alternatively by one of the three usual processes, and after the usual washing, boiling, and pulping are dehydrated by alcohol. In the incorporation per 100 parts of nitrocotton 140 to 150 parts are used of a mixture of 1.9 vols. of ether, 65°B., sp.gr. 0.7264, to 1 vol. of alcohol, 92.5 p.c. by weight, sp.gr. 0.8164, including the alcohol present in the nitrocotton after dehydration. The diphenylamine, 1.5 to 2 p.c. of the nitrocotton, is added with the solvent. The incorporation takes from 1 to 3 hours, and the 'dough' is squirted through a die, over which is a filter of fine wire gauze to remove solid impurities, to form ribbons of from 20 to 150 mm. in width, and a thickness which varies according to the calibre of the gun in which the powder is to be used. The ribbons are cut into lengths, and the strips are hung on rods in the solvent recovery chambers, where they first meet warm air containing a high proportion of vapours of ether and alcohol, and are gradually moved forward against the air current, so that they eventually meet air containing only a small proportion of solvent vapours. This prevents the strips curling up at the edges by too rapid evaporation of the solvent at first. Part of the solvent vapours is removed from the air by condensation at a low temperature, and then, after being heated up, the air passes again into the recovery

chambers. After this preliminary drying the strips, which still contain 15 to 20 p.c. solvent, mostly alcohol, are cut first into narrow ribbons, then into short strips of the requisite size. Irregular grains are picked out by hand from the larger sizes, and sifted out from the small square flakes used for small arms. The sorted grains are then further dried for about 6 hours on trays in stoves at 45°-50°, then soaked, in canvas bags or wire trays, in a tank of hot water, the time of soaking being about 8 hours, and the temperature of the water about 75°, but the time and temperature vary slightly with the size of the strips. By this soaking nearly all the alcohol is eliminated. The grains are then drained and the water finally dried off in a stove. The volatile matter, water, and residual solvent, left in the powder is about 0.8 to 2 p.c. of the powder, according to the size of the grains. If dried too far, the grains are exposed to moist air until of the requisite volatile content. Finally, the grains are thoroughly blended before being made up into cartridges.

The rate of burning of the French *Poudre B* is controlled not only by the size of grain and content of volatile matter, but also by varying to some extent the proportions of CP₁ and CP₂ in the powder. CP₁ is not gelatinised by the solvent, but in the finished powder is coated by the gelatinised CP₂. A higher proportion of CP₁, consequently, gives not only greater power, because of its higher nitrogen content, but also more rapid burning, as it is ungelatinised. The presence of ungelatinised CP₁ renders the powders slightly porous, and consequently the moisture content varies somewhat with the conditions of storage, and the powders are also less stable on storage than the fully gelatinised powders.

E. C. powder, a bulk sporting powder, as originally invented by Reid, was a pure nitrocellulose powder, superficially gelatinised with ether-alcohol and coloured orange with aurine. The *E. C.* powders are now manufactured by the *E. C. Powder Co.* at Dartford, under the patents of Johnson and Borland, already mentioned, and contain a more highly nitrated cotton, with potassium and barium nitrates and sometimes camphor and wood meal.

Walsrode powder, one of the earliest granulated sporting powders, made by Wolff and Co. of Walsrode, is a pure nitrocellulose powder gelatinised with ethyl acetate. The grains were formed, and the solvent eliminated by adding water to the kneaded mass and introducing steam, and subsequent boiling in water; the grains were then centrifugated and dried. The granulation is now effected differently, but the essential treatment is the same. The finished powder contains about 1 p.c. of volatile matter and 98.5 p.c. of nitrocotton.

M. N., or *Maxim-Nordenfelt*, powder is an American guncotton powder gelatinised with ethyl acetate.

Normal powder manufactured by the Swedish Powder Co. of Landskrona, and adopted by the Swiss Government, is a gelatinised guncotton powder made in various forms. Ethyl acetate is the gelatinising solvent. The small-arm powder was at one time in the form of small, light-grey, graphited square tablets of about 1.25 mm. side, but now small cylinders, of about 1 mm. diameter

and length are used. It contains about 1.5 p.c. of residual solvent, and about 95 p.c. guncotton.

Von Förster powder (Fr. Pat. 164792, 1884) and *Troisdorf powder* are gelatinised nitrocellulose flake powders, the former containing a little calcium carbonate.

Wetteren powder, made by Cooppal, and used as the Belgian Service powder, was a guncotton powder, containing a little calcium carbonate, gelatinised with amyl acetate. It was at one time a nitrocellulose-nitroglycerin powder, containing soluble nitrocellulose and about 30 p.c. nitroglycerin, the small-arm powder being made into graphited cubes of about 1.5 mm. side. The Belgian Government eventually adopted a powder similar to 'Poudre B,' containing 40 to 60 p.c. soluble nitro cotton, and gelatinised with ether-alcohol. The paste was rolled into sheets and cut into strips or flakes.

The Russian Government at first used nitrocellulose powders containing various proportions of insoluble and soluble nitro cotton, but, after investigation by Mendeleff, eventually adopted a nitrocellulose powder for both naval and military purposes made from an almost completely soluble nitro cotton containing a high percentage of nitrogen, about 12.4 p.c., termed 'pyrocollodion.' This has the advantage over the mixed nitro cottons used in France, that it is practically completely gelatinised by ether-alcohol, and gives a much more uniform colloidal product of increased stability on storage. The powder is manufactured very much on the lines of 'Poudre B,' and is stabilised with about 1 p.c. diphenylamine.

The United States service powder was at one time the *Maxim-Schupphaus powder*, composed of 80 p.c. insoluble nitrocellulose, 19.5 p.c. soluble nitrocellulose, and 0.5 p.c. urea. Another form contained 80 p.c. guncotton, 9 p.c. nitroglycerin, 10 p.c. collodion cotton, and 1 p.c. urea. These powders were gelatinised with acetone. Nitrocellulose powders with barium and potassium nitrates, and a nitroglycerin powder, were also used for a time as small-arm powders. The modern United States powders, for all purposes, are manufactured from a nitrocellulose containing about 12.5 to 12.7 p.c. nitrogen, about 80 p.c. being soluble nitro cotton, that is practically a 'pyrocollodion.' The nitro cotton, after the nitration and preliminary boiling, is pulped in water made just alkaline with sodium carbonate, and boiled in poachers for several periods, carbonate of soda being added only in the first period. The nitro cotton, after alcohol drying, is thoroughly colloided with ether-alcohol, stabilised with diphenylamine, and pressed into short perforated cylinders, with usually one or, for the larger grains, seven perforations, one central, and the others arranged 'symmetrically,' the multi-perforated cylinders differing in web-thickness according to the use of the powder. The method of solvent elimination and drying the grains is similar to that in use in France.

The powder used in the cartridges for the Mannlicher-Schoenauer (Austro-Hungarian) rifle is in the form of thin cupped discs, of 2 mm. diameter, lightly graphited, composed of soluble nitrocellulose, with about 1 p.c. of residual solvent. That for the Mauser (German and Turkish) rifle is of similar form and composition,

except that a more highly nitrated cotton is used.

* The Japanese use a nitrocellulose powder containing both soluble and insoluble nitro cotton, the proportions of which vary according to the size of the gun in which the powder is to be used; the more rapid powders, used for small arms and guns of low calibre, containing more of the highly nitrated cotton. The Spanish and Dutch powders, both for small arms and large guns, are nitrocellulose powders containing various proportions of collodion cotton and guncotton.

(2) Nitrocellulose Powders with Nitrates.

Schultze powder, invented by Schultze of Potsdam, and now manufactured in England, was one of the earliest sporting smokeless powders. It is manufactured from nitrated wood cellulose, sometimes called 'nitrolignin.'

Hard wood is cut into sheets and punched into grains. The wood grains are purified by boiling with dilute sodium carbonate, by washing with water, and treating with solution of chloride of lime. They are then washed, dried, and immersed in the mixture of strong nitric and sulphuric acids for 2 or 3 hours, with frequent stirring, the acids being kept cool. The nitrated wood is freed from most of the acid in a centrifugal machine, washed with water, boiled with dilute sodium carbonate, and dried. The nitrolignin appears to contain a large quantity of matters soluble in ether-alcohol, and, besides insoluble nitrolignin, some unconverted wood. It is steeped in a solution of potassium and barium nitrates, and dried at a low temperature. It is a fibrous, 42-grain, bulk powder containing approximately 65 p.c. nitrated cellulose, of which 40 p.c. is soluble in ether-alcohol, 30 p.c. metallic nitrates, up to 4 p.c. mineral jelly, and up to 2 p.c. volatile matter.

In later varieties, wood pulp, treated by one of the usual chemical processes to remove material other than wood cellulose, is used for nitration. The nitrated wood cellulose and nitrate mixture is formed into *irregular grains*, which are treated with a solvent to gelatinise and harden them. Another form of the powder, *Imperial Schultze*, consists of about 80 p.c. nitrolignin, 10 p.c. barium nitrate, 8 p.c. vaseline, and 2 p.c. of volatile matter. It is less bulky than the older powder, and is said to be quite free from smoke and to leave no residue. The still more modern *Cube powder*, a gelatinised 30-grain bulk powder, and *Lightning powder*, a fibrous 33-grain bulk powder, contain the same ingredients in different proportions and differently manufactured.

The modern '*E. C. powders*,' manufactured by the E. C. Powder Co., as already explained, belong to this class. No. 1 contains about 2 p.c. resin, No. 2 2 p.c. resin and 1 p.c. camphor, and No. 3 6 p.c. vaseline and 4 p.c. camphor. The different varieties also contain different proportions of metallic nitrates and nitrocellulose of different degrees of nitration. The camphor present in Nos. 2 and 3 is added in accordance with the suggestion of Johnson (Eng. Pat. 8951, 1885) to use a solution of camphor in a volatile solvent to harden the fibrous granules. No. 1 was hardened by ether-alcohol.

Amberite, as originally patented by Curtis

and Andre (Eng. Pat. 11383, 1891), was a mixture of insoluble and soluble nitrocellulose with nitroglycerin. The mixed nitrocelluloses were first granulated, and then treated with ether-alcohol, so that only the soluble nitrocellulose was dissolved, and on drying, cemented the grains together and hardened their surface. A small quantity of linseed oil, paraffin, or shellac, was sometimes added as a moderant.

Amberite, as now manufactured by Curtis's and Harvey at Tonbridge, contains a mixture of potassium and barium nitrates instead of the nitroglycerin, and a little paraffin. An analysis gave: 13 p.c. guncotton, 59.5 p.c. collodion cotton, 19.5 p.c. barium nitrate with a little potassium nitrate, 6 p.c. paraffin, and 2 p.c. volatile matter.

Cannonite, also made by Curtis's and Harvey, is a similar powder to Amberite, containing a higher proportion of nitrocellulose and a smaller proportion of nitrates, together with small quantities of potassium ferrocyanide and lamp-black. Resin was a constituent of the earlier forms.

Empire powder is a 33-grain fibrous, bulk powder, manufactured by Nobel's Explosives Co., containing insoluble and soluble nitro cotton, about 10 p.c. metallic nitrates, and 7 p.c. mineral jelly.

Neonite is a 33-grain sporting rifle powder, manufactured by the New Explosives Co., Stowmarket, containing about 10 p.c. metallic nitrates and 6 p.c. mineral jelly, the nitrocellulose being largely insoluble.

Poudre pyroxylée is a French sporting powder, containing soluble and insoluble nitro cotton mixed with about 35 p.c. barium and potassium nitrates. The mixture is incorporated with water, ether is then added, and the mixture granulated. The grains are then dried and afterwards glazed by means of an ether spray. *Poudre J.* contains about 83 p.c. guncotton and 17 p.c. potassium dichromate. *B. N. powder* was a French military powder, similar to 'Poudre B,' with the addition of barium and potassium nitrate and a little sodium carbonate.

Smokeless diamond, a gelatinised, 33-grain, bulk powder, manufactured by Curtis's and Harvey, consists largely of insoluble nitrocellulose, with about 15 p.c. metallic nitrates, 6 p.c. charcoal, and 3 p.c. mineral jelly.

W. A. powder made by the American Smokeless Powder Co., is a guncotton-nitroglycerin powder with barium and potassium nitrates. It is manufactured in the same way as cordite, but the powder for small arms is cut into short cylinders.

One form of *U.S. Naval powder* is composed of soluble nitrocellulose with barium and potassium nitrates, and a form of *U.S. Army powder* contains insoluble and soluble nitrocellulose, nitroglycerin, metallic nitrates, and a moderant. Some American small-arm powders, besides barium nitrate, contain a small quantity of starch. One form of *Belgian blank ammunition* consisted of small light-coloured grains of soluble and insoluble nitro cotton, with about 25 p.c. of barium nitrate and a little rosin.

(3) Nitrocellulose-Nitroglycerin Powders.

Ballistite, the first nitroglycerin-nitrocellulose powder, as patented by Nobel, was a mixture of equal parts of collodion cotton and nitroglycerin

with about 10 p.c. camphor. The mixture was first made with an excess of nitroglycerin, which was afterwards removed in a press or centrifugal machine, and the mass then thoroughly incorporated by passing between steam-heated rollers—malaxation, as Nobel termed it.

In this way, nitro cotton was dissolved in the nitroglycerin, and horny, colloidal sheets of varying thickness obtained, which were afterwards cut up into thin squares or cubes. At some factories, benzene was added to assist the incorporation, and afterwards removed by drying the finished product.

Camphor, suggested to Nobel by its use in celluloid, was at first used to reduce the rate of burning, and was also found to facilitate solution of the nitrocellulose. Owing to its slow evaporation from the finished explosive, it led to variable ballistic results being obtained from the explosive, and its use was subsequently abandoned. 1 to 2 p.c. of aniline or diphenylamine is now usually added to ballistite for the purposes of stabilisation.

Ballistite is now manufactured by an improved process invented by Lundholm and Sayers (Eng. Pat. 10376, 1889). The nitro cotton, in the form of fine powder, is suspended in water at a temperature of about 60°, the nitroglycerin, in which the diphenylamine is dissolved, is added and the mixture stirred by means of compressed air. The nitroglycerin gradually displaces the water and dissolves the nitro cotton, and, when the solution is complete, the water is partly drained off and the remainder removed in a centrifugal or by pressure, and the mass allowed to ripen. The paste is then rolled under heavy pressure, between rollers, steam heated to 50°–60° to complete the incorporation and remove the last traces of water. The great advantage of this process is that the dangerous and tedious drying of the nitro cotton is done away with.

Ballistite is the Service explosive of Italy, and is used not only in small squares, small perforated cylinders, and larger cubes, but also in cords, '*Filite*,' and round flakes cut from the cords. The powders sometimes contain a little mineral jelly. Ballistite is used for certain military purposes in England, and has been adopted by some other countries specially for large guns.

Ballistite, composed of equal parts of nitroglycerin and soluble nitrocellulose, has considerable erosive effect on the gun, and for the larger guns a modified composition with a lower proportion of nitroglycerin, often 40 p.c., is used. Nitro cotton with a proportion of insoluble nitrocellulose is also sometimes used. The German cannon powders are ballistites of various compositions made into the form of thick flakes or cubes. Some of them approach cordite in composition, that is, they contain a high proportion of insoluble nitro cotton, and the grains are sometimes in the form of tubes.

Ballistite is dark-brown in colour, and has an average density of 1.6. It has the consistency of soft horn, and can easily be cut with a knife. It is but little affected by moisture, but is more susceptible to heat than most smokeless powders, the nitroglycerin tending to exude. The grains are frequently coated with graphite. It burns

slowly in the open, and is almost entirely smokeless.

Cordite, the English Service propellant, is so named because of its usual cord-like form. For special purposes, however, it is made into tubes, with single or several perforations, and is sometimes used in the form of tape, and in flakes made by slicing cords.

Composition.—Cordite is essentially a mixture of nitroglycerin and guncotton, thoroughly incorporated and gelatinised by means of acetone. The guncotton has a nitrogen content of 12·8–13·1 p.c., and contains not more than 12 p.c. soluble nitrocellulose. A small proportion of mineral jelly is the third ingredient.

Mineral jelly was originally added to prevent metallic fouling of the magazine rifles by the bullets, and was also found to diminish erosion by acting as a restrainer or cooling agent, to improve the regularity of the burning, and act as a water-proofing agent.

It was subsequently found that cordite made for blank purposes without mineral jelly was considerably less stable in hot climates than ordinary cordite, and it is now recognised that the mineral jelly contains constituents, olefines and naphthenes, that stabilise the cordite for a prolonged period by combining with the products of decomposition. It also protects the nitroglycerin and nitrocotton from atmospheric influences.

The mineral jelly obtained in a particular stage of the distillation of petroleum, used in the manufacture of cordite, is required to have a flash-point above 204·5°C. (400°F.), and not to be completely melted below 30°. It must be free from acidity and mineral impurities, and have a sp.gr. of not less than 0·87 when melted at 38°.

The guncotton used for the manufacture of cordite usually contains from 10 to 12 p.c. soluble nitrocellulose.

The original cordite, the manufacture of which was commenced at the Royal Gunpowder Factory in 1890, was composed of 58 p.c. nitroglycerin, 37 p.c. guncotton, and 5 p.c. mineral jelly. The composition was the same for small-arms and for the different calibre guns for which it was used, the requisite rate of combustion being obtained by varying the diameter of the cord. Owing to its high nitroglycerin content, this cordite had a high temperature of explosion, and produced considerable erosion in guns of very large calibre, and in 1901 its composition was modified for some purposes. This modified composition, known as '*Cordite M.D.*', contains 30 p.c. nitroglycerin, 65 p.c. guncotton, and 5 p.c. mineral jelly. The older composition is known as '*Cordite Mark I.*'; both varieties are now in use. Cordite contains practically no moisture, but retains about 0·4–0·6 p.c. of acetone, according to the size of the cords. Cordite M.D., owing to its smaller proportion of nitroglycerin, retains more volatile matter, about 0·5 to 1·5 p.c. Other modifications of cordite have also been introduced. In one a mineral jelly containing a higher percentage of unsaturated hydrocarbons is used to increase the stability of the product, and another contains soluble nitrocotton instead of guncotton. The former has the same proportions as M.D., in the latter, in order to obtain similar ballistics

to those of M.D., the proportion of nitroglycerin is raised.

Manufacture: Drying the guncotton.—Formerly the guncotton was dried in a loose condition, but it is now loosely compressed into cylinders 3 inches diameter and 4½ inches high, containing about 40 p.c. moisture. Guncotton dust formed in the drying is the great source of danger, and its formation is obviated by the present method. The guncotton cylinders are dried in a stove on wire-gauze trays, by a current of air heated to about 40°, until they contain about 0·5 p.c. moisture. The drying takes from 90 to 100 hours.

Mixing.—The charge of the cooled dry guncotton, sufficient for one incorporator, is weighed out into a rubber-lined canvas bag, carried to the nitroglycerin filtering house, and the requisite charge of nitroglycerin, which was at one time weighed out, is measured out from a lead burette through a rubber tube on to the guncotton. The bag is then carried to the mixing house and the contents roughly mixed by hand and rubbed through a copper wire sieve of ½-inch mesh, or on lead-lined table perforated at one end with ½-inch holes through which the mixture is rubbed into the bag below. The product at this stage is known as '*Cordite paste*.'

Incorporating.—Part of the acetone charge is first poured into a kneading machine of the usual type, the machine started, and the cordite paste and the remainder of the acetone, about 56 p.c. of the weight of the guncotton in all, gradually added. The mixture is covered to prevent loss of acetone, and the mixture kneaded for 3½ hours. At the end of this time, the charge of mineral jelly is added, and the machine run for another 3½ hours. During the kneading, the acetone gradually dissolves the guncotton and nitroglycerin, and thoroughly incorporates them with the mineral jelly. The product is called '*Cordite dough*.'

Pressing.—The cordite dough is conveyed in barrels to the press house, where it is 'squirited' or pressed by plungers working in cylindrical moulds through a die with one or more holes, according to the diameter of the cord required. A perforated plate, supporting a fine wire gauze diaphragm, is placed above the die to retain mechanical impurities. Three kinds of presses are used at Waltham Abbey—screw presses for the smaller sizes, and hydraulic or combined screw and hydraulic presses for the larger sizes. The smaller-sized cords are wound automatically on to reels as they leave the die, the larger sizes are cut into the required lengths.

The sizes of Service cordite refer to the diameter of the cords in hundredths of an inch. It varies from size 3½ to size 50; that is, from 0·0375 inch diameter used in the '303 Service rifle to 0·5 inch diameter used in heavy guns. The actual diameters are rather less than the nominal sizes, as the cords shrink during drying.

Drying.—The cordite is then placed on the reels, or the larger sizes on trays, on open racks in stoves, heated by steam pipes or by a current of hot air at a temperature of about 40°. For the smallest sizes no heating of the stove is necessary in summer time. The time required for drying varies, according to the diameter of

the cord, from 2 to 15 days. The drying is to remove any moisture and the greater part of the acetone, of which about 15 p.c. remains in the pressed cordite. The residual volatile matter in Mark I. cordite varies with the size of cord from 0.4 to 0.6 p.c. M.D. cordite requires a much longer time for drying than Mark I., several months' heating being necessary for the largest sizes.

A process for the recovery of the acetone has been patented by Robertson and Rintoul (Eng. Pat. 25994, 1901), in which the air, containing only a low percentage of acetone, after being saturated with moisture, is led into a scrubbing tower through which a 30 p.c. solution of sodium bisulphite trickles. The acetone is recovered by distillation at a temperature such that the bisulphite is not decomposed and can be used again.

Blending.—The cordite is finally thoroughly blended in order to obtain average uniformity of composition and ballistics. The small-arm cordite is blended by uniformly winding the cords from 10 reels on to one larger reel, and afterwards from six of these ten-stranded reels on to one sixty-stranded reel. The larger sizes are blended by hand, the sticks from the drying-stove trays being placed in boxes and the contents of these blended by combining a few sticks from each box, the operation being repeated.

Testing : Moisture.—The residual solvent or moisture is determined on the ground sample, precaution being taken to prevent loss of nitroglycerin. 5 grams of siftings of the same size as those used for the Abel heat test, are heated for 2 hours on a water-bath in an aluminium dish covered with a glass cone, both of specified dimensions (see Marshall, J. Soc. Chem. Ind. 1904, 154).

Analysis.—Weigh out 2 grams of very fine siftings into a Soxhlet thimble, and allow to stand covered with ether in the extractor overnight. Extract for 2 hours, then dry the thimble and contents at 50° until the guncotton can be removed to watch glasses. Dry at the same temperature till the *guncotton* is of constant weight. The extracted guncotton may be submitted to the usual tests for guncotton.

Distil off the ether from the extract and dissolve out the nitroglycerin with cold methyl alcohol, filtering the solution. Dissolve any mineral jelly on the filter with ether back into the flask, distil, heat in a water-oven, and suck out any traces of nitroglycerin vapours with an air current. Repeat till the *mineral jelly* is of constant weight. The *nitroglycerin* is usually estimated by difference.

Heat test.—See Abel's stability test.

Firing proof for velocity and pressure in a gun of the standard type for the particular form of cordite (see Ballistics of a Propellant).

Properties.—Cordite varies in colour from light to dark brown, according to the colour of the mineral jelly used. Cordite Mark I. has the consistency of hard indiarubber. It is somewhat elastic, and can be readily cut with a knife. Cordite M. D. is considerably harder, being more like horn and more brittle, and can only be cut with difficulty.

Cordite has a slight odour of acetone, and it is poisonous. It is water repellant, and can be

kept under water, salt or fresh, for some time without its explosive properties being affected. Even when fired wet from a gun, the ballistics only fall off to the extent due to the evaporation of the water. On prolonged cold storage, the nitroglycerin exudes slightly, but is gradually reabsorbed when the temperature rises. The sp.gr. of cordite Mark I. is about 1.56–1.57, that of cordite M. D. being 1.58–1.59.

Cordite does not ignite very readily, but when once ignited it burns slowly with a strong yellowish flame, which is practically smokeless. A stick becomes pointed at the end as it burns, and the flame can be extinguished by blowing strongly on it. A considerable bulk of cordite can be burned away in the open without any explosion. It only burns explosively when strongly confined; if an ignition of the cordite confined in a wooden box takes place, the cordite does not explode, but burns quietly, and the box is only broken open to allow the gases to escape.

Owing to the difficulty of ignition of cordite, a stronger cap of different composition is necessary to ignite the fine cordite in small-arm ammunition than was required for black powder, and to ensure the ignition of the larger sizes the charge of cordite has to be primed with an ordinary black powder or guncotton 'primer,' which passes on the flame of the igniting 'tube' to the charge.

Cordite is very insensitive to shock, and cannot be exploded by the passage of a rifle bullet through it.

Exhaustive trials under very varied climatic conditions have proved that the ballistic stability of cordite is very great.

The ballistic power of cordite is very nearly four times that of black powder, owing to the increased volume of gases liberated per unit of weight and the high temperature of the explosion. It can give a pressure, on explosion, of more than 120 tons per square inch, compared with 43 tons, the maximum obtainable with black powder, but in practice the pressure in a gun does not nearly attain this figure (not above 17 tons per square inch) owing to the relatively large size of the gun chamber compared with the volume of the cordite.

The ballistic results of cordite are more influenced by temperature than was the case with black powder, the pressure developed and velocity of the shot being greater with increased temperature, but not to the extent of seriously modifying the shooting under Service conditions. The smaller the size of cordite, the more rapid the explosion, and cordite burns more quickly under high than under low pressures.

The pressure due to cordite is more gradually developed in the gun than was the case with black powder, and is better sustained. The heat of combustion, products of explosion, and other explosion constants for Mark I. cordite were examined, in 1893, by Deering at Woolwich. He worked with an explosion bomb, made of gun-steel, about 1.27 inches in thickness and 108 c.c. capacity. The following are some of the results obtained with a cordite of the composition: loss, 0.24 p.c.; nitroglycerin, 58.55 p.c.; guncotton, 36.11 p.c.; and mineral jelly, 5.10 p.c.; the figures quoted

being the averages of a large number of experiments :—

Pressure developed, tons per sq. inch (by crusher gauge)	6·4	13	16
Vol. of perm. gases at 0° and 760 mm., c.c. per gm. cordite	663·7	669·3	671·1
Volume of total ditto ditto	880·7	870·7	869·8
Water formed, gram per gram cordite	0·1757	0·1621	0·1599
Quantity of heat developed, gram degrees C. per gram cordite : water, liquid	1225	1239·1	1242·9
Ditto ditto : water, gaseous	1131	1152·2	1157·2
P.c.comp.perm.gases, vols.CO ₂	25·40	—	28·20
CO	37·62	—	33·82
H	17·43	—	18·55
N	19·55	—	19·09
CH ₄	not dtd.	—	0·34

With the explosion gases at 6·4 tons pressure, Deering calculated the specific heat to be about 0·403, and the temperature of the gases about 2830°; and with a pressure of 7·0 tons, a specific heat of about 0·366 and a temperature of 3120°. The explosion constants of cordite Mark I. and cordite M. D. have also been determined by Robertson, at Waltham Abbey. The following results were obtained with a density of loading of 0·2 :—

	Cordite Mark I.	Cordite M. D.
Heat of explosion, calories per gram, at constant vol. : water, gaseous.	1156	965
Total gases, c.c. per gram, at 0° at 760 mm. : water, gaseous .	871	920
Temperature of explosion, °C.	2663	2374

The larger volume of gaseous products and lower temperature explain why the erosive effect of cordite M. D. is so much less than that of cordite Mark I. The experiments of Nobel have already been referred to.

The erosive effects of cordite are less than those of black powder, and of a different character. With black powder, the surface of the gun is pitted by the corrosive action of the products of combustion, whilst with cordite the surface is smoothly washed away, only near the gun chamber, by the passage of the hot gases between the projectile and the bore, before the inertia of the projectile is overcome. Cordite M. D. gives far less flame than cordite Mark I. when used in rifles or machine guns.

Maxim's powder contains both soluble and insoluble nitrocellulose, mainly insoluble, nitroglycerin, castor oil, and originally an alkaline carbonate. Acetone is the solvent used for gelatinisation. It is made in cylindrical grains or in cords of various diameters.

Azite, made by Kynochs, Ltd., is a gun-cotton-nitroglycerin powder with vaseline and olive oil, and sometimes potassium and barium nitrates and oxalates, to reduce the temperature of explosion and decrease metallic fouling, made in the form of a rail-shaped ribbon. Its ballistics are equal to those of cordite, and are said to be less variable with changes of temperature.

Moddite, a sporting rifle powder manufactured by Eley Bros., is a gelatinised mixture of nitrocellot, of which one-third is soluble nitrocellulose, and nitroglycerin with about 4 p.c. mineral jelly.

Solenite is an Italian powder used instead

of ballistite for guns of large calibre, containing 40 p.c. insoluble nitrocellulose, 30 p.c. soluble nitrocellulose, and 30 p.c. nitroglycerin gelatinised with acetone. It is stabilised with 1·3 p.c. mineral jelly, and is in the form of short tubes.

(4) Nitrocellulose-Nitro-Derivative Powders.

Indurite, patented by Munro of the United States (Eng. Pat. 580, 1893), contains 40 p.c. guncotton, freed from lower nitrates by thorough extraction with methyl alcohol, and 60 p.c. mononitrobenzene, with or without oxidising salts. The mixture is rolled into sheets and cut into grains. The grains are treated with hot water or steam, which hardens or indurates them to the consistency of bone : hence the name.

Du Pont powder, patented by Du Pont of the United States (Eng. Pat. 15865, 1893), contains nitrocellulose and nitrobenzene, and sometimes potassium nitrate. The nitrocellulose is agitated in water, the nitrobenzene added, and the mass agitated until the nitrocellulose is dissolved and grains are formed, when the grains are hardened by blowing in steam. In some of the powders, a little nitroresin or nitroturpentine was added as a moderant. Later Du Pont powders contained about 40 p.c. soluble nitrocellulose, 40 p.c. nitroglycerin, and 20 p.c. ammonium picrate, the cylindrical grains being graphited.

Colt's pistol ammunition contains a powder in the form of thin graphited squares, 1 mm. side, consisting of guncotton with about 5 p.c. of dinitrobenzene.

Felixite is a fibrous, 42-grain, bulk powder, manufactured by the New Explosives Co. at Stowmarket, containing both metallic nitrates and nitrohydrocarbon, and about 3 p.c. vaseline. *Red star* and *N. E. powder* are powders of different grade, the former 33 grain, the latter 36 grain, containing the same ingredients in different proportions.

Greener's powder is a nitrocellulose-nitrobenzene powder coloured with lampblack.

Rifleite, manufactured by the Smokeless Powder Co. of Warwick, is a nitrocellulose powder gelatinised by acetone containing a small proportion of dinitrotoluene, and the *S.S. powder*, smokeless shot-gun, of the same company is a similar powder containing a rather large proportion of barium nitrate with a little potassium nitrate and a little wood meal. *S.R.*, a sporting rifle variety of this powder, is thoroughly colloided. It contains mainly soluble, instead of insoluble nitrocellulose, a higher proportion of nitrohydrocarbon, about 20 p.c. metallic nitrates, and 8 p.c. starch. It was introduced in 1890, and was the first practical colloidal smokeless powder considered for military purposes.

Kynoch's smokeless powder is similar in composition to *S.S.* powder.

Plastomenite is a German powder invented by Güttler, made by incorporating one part of nitroglignin with 5 parts of fused dinitrotoluene and granulating the fused mass. It may also contain barium nitrate.

Some forms of *Norwegian ballistite* contain from 5 to 6 p.c. nitronaphthalene.

Ruby powder is a fibrous, 42-grain, bulk sporting powder, manufactured by Curtis's and Harvey, containing about 50 p.c. nitrocellulose,

mainly insoluble, with metallic nitrates, about 8 p.c. nitrohydrocarbon, and 6 p.c. starch.

Smokeless powders containing picrates, usually ammonium picrate, have been frequently tried, both for sporting and military purposes, but they have been practically abandoned at the present time. A recently suggested propellant for small arms and guns by the Powderite Explosives Co., of New South Wales (Eng. Pat. 16505, 1915), is a nitroglycerin powder with 1 p.c. mineral jelly, and 2 p.c. calcium picrate. It is claimed to be more powerful than cordite, and quite stable. Some of the early French military smokeless powders contained picric acid, and at one time a powder containing about 5 p.c. ammonium picrate was tried in the Mauser rifle by Germany.

The American *Peyton powder* was, at one time, a nitrocellulose and nitroglycerin powder containing about 20 p.c. ammonium picrate.

FULMINATES.

Although the fulminates of many heavy metals have been prepared, most of them are exceedingly sensitive and too unstable for use in explosives. The mercury salt is the only one in practical use, though *silver fulminate* has been licensed for use in toy fireworks only. Silver fulminate is prepared in a similar manner to mercury fulminate. It is more sensitive to friction and percussion than the mercury compound, and has a greater explosive power.

Mercury fulminate, discovered by Howard in 1800, is produced by the reaction which ensues on mixing together alcohol and a solution of mercury in excess of nitric acid.

In Liebig's process, and Chevalier's modification of it as used in France, the solution of mercury in nitric acid is used cold; in Chandon's process it is used warm.

Chevalier's process. 3 parts by weight of mercury (300 grams) are dissolved in the cold in 30 parts of nitric acid of 1.34 sp.gr., and the solution is poured into a flask containing 19 parts of alcohol (of 90 p.c. strength). After some minutes an energetic reaction commences, with formation of crystals of mercury fulminate. Towards the end of the operation, two successive additions of 2.38 and 1.58 parts of alcohol are made; the fulminate obtained is thoroughly washed and dried.

The addition of too large a quantity of cold alcohol towards the end of the operation is stated to yield an impure fulminate. The yield by this process varies between 118 and 128 p.c. of the weight of mercury used.

Chandon's process is the one almost universally used, and the original proportions are usually closely adhered to. 1 part by weight of mercury is dissolved in 10 parts of nitric acid (sp.gr. 1.4) at a gentle heat; the solution, at a temperature of about 55°, is poured into a capacious flask or retort (its capacity must be at least equal to six times the volume of the liquid) containing 8.3 parts of alcohol (of sp.gr. 0.83). The flask is connected by a cork and tube with a stoneware condenser, to recover spirit.

In about a quarter of an hour, the reaction commences with a slight formation of gas bubbles; very soon the liquid boils, and the flask becomes filled with voluminous white

vapour. The violence of the action can be checked by adding, as required, a little alcohol; for this purpose the recovered spirit after redistillation with caustic soda can be utilised. If the reaction be too much restrained in this way, the fulminate is likely to contain metallic mercury.

The mercury fulminate is precipitated from the liquid in small greyish-coloured needles. When the action is over, the contents of the retort are cooled down quickly and the mother liquid poured off, the fulminate is filtered and washed, then passed through a fine net filter to remove large crystals, and finally washed on a finer net filter until free from acidity. The nitric acid liquid, after cooling, does not contain any appreciable quantity of mercury. The calculated yield of fulminate is 142 per 100 of mercury; by this process the mean yield is 125 p.c. mercury fulminate.

A process very similar to the above is employed in this country; the yield of fulminate is about 123 parts per 100 of mercury.

Mercury fulminate is usually light brown-grey in colour. *White fulminate* of mercury is manufactured by adding a little copper and hydrochloric acid or potassium chloride to the solution of mercury nitrate, before pouring it into the alcohol. Solonina (Zeitsch. Ges. Schiess-u. Sprengstoffwesen, 1910, 41, 67) finds that other chlorides have a similar effect, but that the use of hydrochloric acid alone leads to the formation of a considerable quantity of oxalic acid which contaminates the fulminate. He finds that the purest fulminate results from the addition of cuprous chloride.

Mercury fulminate is sometimes recrystallised from boiling water or from alcohol, but this is not usually found necessary. The best method of purification is to dissolve in pyridine, filter the solution, and precipitate by adding an excess of water. Traces of free mercury can be removed from fulminate by placing it for a few days in a vacuum desiccator.

Angelico (Chem. Zentr. 1901, ii. 404) prepares mercury fulminate by treating a solution of mercury in an excess of dilute nitric acid with a strong aqueous solution of malonic acid and a little sodium nitrite solution. A considerable rise of temperature takes place, with copious evolution of carbonic acid gas, and crystals of fulminate separate out. So far as is known, this process has not been used on the manufacturing scale.

Fulminate is usually stored in linen bags immersed in water. The explosive power of samples is unaffected even by prolonged storage under these conditions at normal temperatures. Before use it is usually washed through a 40-mesh sieve. If dry fulminate is required, it is spread out on linen or paper, supported in wooden frames with string-net bottoms, and dried in a current of dry air, or it is spread out on cloths on copper tables, varnished with copal to prevent attack by the wet fulminate, heated either by hot water or steam, at a temperature of about 40°, the temperature not being allowed to rise above 45°. Passburg of Breslau has devised an apparatus for drying fulminate of mercury in a vacuum. The drying chamber is heated by steam, which can be replaced by cold water when the fulminate is dry. Explosives

only burn with difficulty in a vacuum, and there is sufficient vacuous space, with the aid of safety valves, to prevent any damage, should an ignition take place of the quantity of fulminate dried at one time. When dry, the fulminate is allowed to cool, any lumps are broken down by a soft pad, and the fulminate passed through a muslin cloth. The dry fulminate is stored in papier-mache cylinders with lids.

Properties.—Commercial mercury fulminate is in the form of small crystals, of white or pale-brown colour. The crystals of most commercial samples all pass an 80-mesh sieve, 80 p.c. or so pass a 120-mesh, and about 60 p.c. pass a 200-mesh. Some very fine crystal dust is usually present. It crystallises in well-defined octahedra, which frequently twin along the major axis, and repeated twinning to form ladder-like crystals is common. The larger crystals are usually truncated to such an extent that they form plates.

In a state of purity it crystallises in white silky needles. It is almost insoluble in cold water, but soluble in 130 times its weight of boiling water. It is decomposed slowly by boiling water, and even at lower temperatures on prolonged digestion. The brown colour of some commercial samples, attributed to the presence of resinous impurities, is usually evenly distributed throughout the crystals, but in some samples it occurs mainly along the edges of the crystals, or in spots. The larger crystals generally have the darker colour. It is soluble in pyridine and alcohol. Fulminate may be dissolved to a clear solution in ammonia, and in solutions of potassium cyanide or sodium thiosulphate. The primary reaction for the solution in thiosulphate is represented by the equation

A small residue is left from commercial samples, which consists largely of free mercury, but also contains mercury compounds, containing carbon and hydrogen, of uncertain composition. It has a sweetish metallic taste, and is usually stated to be very poisonous. However, fungi frequently grow on organic matter, the linen bags and wooden barrels in which fulminate is stored, in contact with its dilute solution in water, and workmen engaged in handling wet fulminate do not show signs of mercury poisoning. A non-poisonous property would accord more with the fact that an aqueous solution of fulminate does not give the ordinary reactions for mercury ions.

Its sp.gr. is 4.42 (Berthelot and Vieille). The bulk density of different samples varies considerably, and mainly according to the size of the crystals. It is difficult to get very concordant results, as much depends on the amount of tapping, but comparative figures for fine and coarse fulminates were 1.35 and 1.55 respectively. This variation is of importance in charging fulminate detonators by measurement. In the dry state it explodes violently by a moderate blow or by slight friction; its sensitiveness is lessened when it is moistened with water. Large crystals and complex crystals and clusters are more sensitive than small crystals. Thus Berthelot states that the presence of 30 p.c. of water prevents the decomposition of the ful-

minate in fine powder by friction or shock, that with 10 p.c. of water it decomposes without detonation, that with 5 p.c. water only the portion struck detonates. These results were, however, obtained with small quantities of fulminate, and should not be presumed on in manipulating the substance. In small quantities it will burn fiercely without explosion when ignited, and large quantities may be safely destroyed by burning it in a train after mixing with oil. Mercury fulminate, when heated with a large volume of water under pressure, decomposes into metallic mercury and non-explosive mercury compounds of unknown composition. Small quantities may be destroyed by warming with ammonium sulphide or sodium thiosulphate, care being taken that the sulphide or thiosulphate is in sufficient excess.

When only slightly confined, even between sheets of paper, mercury fulminate explodes violently when ignited.

It is detonated by heat; the temperature of explosion is variously stated as 187°, 200°, and 149°. The firing-point, as usual, depends on the form of apparatus and the rapidity of heating up; ignition takes place at a lower temperature if the explosive be slowly heated than when heating up is rapid, and with increased quantity of material, when this is small, up to a limiting weight. The results are, no doubt, influenced by the heat of decomposition of the material decomposing before ignition. Wöhler found that with 0.02 gram of fulminate detonation took place after 5 seconds at a temperature of 215°.

It can also be exploded by a spark from an induction coil or by contact with strong sulphuric acid. Fulminate can be exploded by contact with a wire heated to incandescence by means of an electric current, but *in vacuo* only the part actually in contact fires.

The products of its detonation are carbonic oxide, nitrogen, and metallic mercury. Berthelot and Vieille examined them—the fulminate being detonated in an atmosphere of nitrogen—and obtained in five experiments per 1 gram fulminate 234.2 c.c. of gases, consisting of CO₂ 0.15 vol., CO 65.70 vols., N 32.26 vols., H 1.89 vols. per 100 vols. gas. This agrees with

requiring 235.6 c.c. From these results and from an estimation of the mercury, they obtain for the composition by weight of mercury fulminate, C 8.35 p.c., Hg 71.30 p.c., N 9.60 p.c., O 11.05 p.c., H 0.04 p.c., total 100.34, every constituent having been estimated. This confirms the accepted formula $\text{HgC}_2\text{N}_2\text{O}_2$, requiring C 8.45 p.c., Hg 70.42 p.c., N 9.86 p.c., O 11.27 p.c. The fulminate analysed contained a trace of metallic mercury.

The decomposition $\text{HgC}_2\text{N}_2\text{O}_2$ into

disengages +114.5 Calories (kgm.-degrees) of heat at constant pressure per 284 grams fulminate, the mercury supposed liquid; for mercury gaseous, +99.1 Cals.; or per 1 kgm. fulminate, 403 Cals. and 349 Cals. respectively. Mercury fulminate is an endothermic substance; in its formation from its elements there is absorption of heat, -62.9 Cals. per 284 grams, or -221.5 Cals. per 1 kgm.

The pressure produced by the detonation of mercury fulminate in a space entirely filled by it has been estimated by Berthelot and Vieille in the crusher-gauge apparatus of the former; they find it to be more than twice that of nitroglycerin, and about three times that of gun-cotton, detonated in spaces filled by them (but including the interstitial air of the gun-cotton). They attribute the power of mercury fulminate in effecting detonation to the greatness of this pressure, coupled with its sudden development (Berthelot and Vieille, *Annalen*, [21] 569, 1880).

The main factor causing the detonative character of the explosion of mercury fulminate, is, perhaps, the extreme rapidity of the explosion, which is further helped by the high density of the explosive. The effects of the detonation of fulminate and fulminate compositions are always quite local. The sharpness of the explosion is also no doubt connected with the fact that the products of detonation do not undergo dissociation, and so the explosive reaction is not prolonged by this phenomenon, as is usually the case.

The larger the crystals of fulminate, the more easily can it be detonated and the greater the explosive effect: for this reason, brown or grey fulminate is slightly more powerful than white.

Testing: Microscope.—The crystals should be well defined, of uniform size, and free from visible impurities. Metallic mercury can sometimes be detected.

Total mercury is estimated by dissolving the sample in strong ammonia or a solution of potassium cyanide, precipitating with ammonium sulphide, and weighing the mercury sulphide as usual. It may also be estimated by electrolytic deposition on copper. The sample should preferably be dried in an atmosphere saturated with mercury vapour to prevent loss of free mercury. Commercial samples generally contain about 70.5 p.c. Hg.

Fulminate is determined by the method described by Philip (*Zeitsch. Ges. Schiess-u. Sprengstoffwesen*, 1912, 180, &c.). 0.3 gram of the fulminate is dissolved in 50 c.c. N/10-thio-sulphate containing 3 grams of potassium iodide. The following reactions take place:

The free alkali is determined by N/10 sulphuric acid, and the excess of thio- may also be determined by titration with N/10 iodine solution and starch. Pure fulminate should give identical results by the two titrations. Supplies give from 98.5 to 99.5 p.c. mercury fulminate by this method of estimation.

Free mercury is determined by dissolving the sample in 0.880 ammonia or other solvent, filtering and washing the residue, and determining the mercury in it as usual. As already mentioned, this residue also contains some mercury compounds; an idea of the quantity of free mercury can be got by examining the residue on the paper microscopically before dissolving in acid.

Oxalate is determined in the filtrate from the mercury sulphide in the total mercury estimation, by adding NH_4Cl and CaCl_2 .

VOL. III.—T.

Carbon and nitrogen may be estimated by a careful combustion, if the fulminate is mixed with a large excess of copper oxide. The mercury is absorbed by gold leaf placed in the calcium chloride tube.

Explosive power is found by firing in lead blocks. 20 grains are fired, electrically, in a cylindrical lead block 6 inches high and 4 inches in diameter, with an axial cylindrical hole 0.25 inch in diameter and 3 inches deep. The enlargement of the cavity formed, measured by running in water from a burette, is an index of the explosive power, as compared with that of standard samples.

FULMINATE COMPOSITIONS.

Mercury fulminate is used in detonators, and is the active ingredient in igniting and detonating mixtures, its value depending on its extreme sensitiveness to friction and percussion.

Igniting mixtures. Mercury fulminate is too rapid in its action to be used alone. On firing a train of fulminate covered with gunpowder or cordite, the latter are simply dispersed without being ignited. If the fulminate be mixed with a little potassium chlorate, the rate of burning is decreased, and the temperature and flame increased by the combustion of the carbonic oxide, and the powders are ignited. The explosion with potassium chlorate may be represented by:

A mixture of 22.3 p.c. potassium chlorate and 77.7 p.c. mercury fulminate, i.e. in the proportion required for the oxidation of the carbon to carbon dioxide, gives by its explosion 706 cals. (mercury, liquid) or 663 cals. (mercury, gaseous) per 1 kgm. of mixture. The volume of gases (at 0° and 760 mm.) produced is 183 litres per 1 kgm.—less than with the fulminate alone; the theoretical pressure is very near that of pure fulminate. The chlorate renders the mixture very sensitive (Berthelot).

Percussion caps were invented by Egg in 1815, Forsyth having suggested the percussion system of ignition in 1807. The cap shells are small closed cylinders usually of pure copper. In the early caps, pure fulminate was used agglomerated by means of wax or an aqueous solution of gum.

In later igniting compositions, mercury fulminate and potassium chlorate were mixed with other combustible substances, such as antimony sulphide, sulphur, and meal powder, to increase the size of the flame and ensure ignition of the powder. Powdered glass is frequently added to increase the frictional surfaces and sensitiveness of the composition. The best igniting composition for any particular composition and form of propellant has largely to be found by experiment.

A cap composition must not be too slow nor too rapid in its rate of burning. If too slow, much of the heat of combustion may be conveyed to the metal parts and irregular ignition of the propellant or even miss-fires may occur; and, on the other hand, if too rapid the charge of propellant is disturbed and uneven ignition and irregular firing results are obtained. There should be a certain proportion of solid ingredients of high specific heat in the combustion

products, in order to make ignition certain. To secure regularity of ignition, the ingredients of the composition should be of even size and well mixed.

Aluminium powder has been suggested by Brownsdon (Eng. Pat. 23366, 1904) as an addition to increase the strength of cap composition, the metal being either mixed with the other ingredients or pressed in a layer on the surface. Zieger (Eng. Pat. 14583, 1900) suggests barium nitrate, with a little barium carbonate, as a substitute for the potassium chlorate: the products are said to act less corrosively on the gun-barrel, and the carbonate is said to give stability to the mixture.

For black gunpowder, the English Service cap composition was a mixture of 37.5 p.c. mercury fulminate, 37.5 p.c. potassium chlorate, and 25 p.c. antimony sulphide, with in some cases 12.5 p.c. ground glass, the charge being 0.22 to 0.25 grain per cap. A mixture of similar composition was used by most other countries.

For smokeless powders, which are more difficult of ignition, a slower mixture with a longer flame is necessary. The Service composition for cordite small-arm ammunition is composed of 19.05 p.c. mercury fulminate, 33.33 p.c. potassium chlorate, 42.86 p.c. antimony sulphide, and 2.38 p.c. each sulphur and meal powder. The charge per cap is 0.6 grain. Barium nitrate now replaces a large proportion of the potassium chlorate in many commercial cap compositions, a suitable composition being 40 p.c. mercury fulminate, 39 p.c. barium nitrate, 7 p.c. potassium chlorate, and 14 p.c. antimony sulphide. The ingredients, other than fulminate, are usually ground so that they pass a 120-mesh sieve, but it is desirable also that they should not contain much dust, or the sensitiveness of the composition may be seriously lowered. The presence of grit, such as is frequently present in commercial samples of antimony sulphide, has a marked effect in increasing the sensitiveness of these compositions.

Mixing cap compositions.—The ingredients of cap compositions were formerly mixed in a wooden mortar for some hours, after wetting with an aqueous solution of gum arabic or an alcoholic solution of gum benzoin, or were mixed by hand on paper and afterwards sifted. The ingredients are now usually mixed dry. In England and France, a so-called 'jelly bag' is used; this is a conical silk bag with rows of indiarubber rings strung on cords passing from top to bottom. The contents are mixed together by working the bag up and down by means of a cord fastened to the apex of the bag. The mixing only takes a few minutes. In Germany, a similar principle is used, but the mixer is saucer-shaped and contains indiarubber balls.

Charging the caps.—At one time the caps were charged with the wet composition by hand, but now the charging is always done by a machine. The composition in the cap shells is compressed by a pressure of about 1000 lbs. per square inch, and then covered with shellac varnish or a tinfoil disc, or sometimes both.

Proof.—The usual proof of caps comprises the microscopic and analytical examination of the composition, photographing the flash,

detonating in a cavity in a lead bar and measuring the enlargement of the cavity and noting the comminution of the cap shell, and a firing proof when made up into cartridges. In special examinations, determinations are made of the total heat of combustion, temperature, and duration of the flash, the volume of gaseous products and their relation to the solid product of combustion, &c. (For details, see papers by Brownsdon, J. Soc. Chem. Ind. 1905, 381; and Borland, *ibid.* 1906, 241.)

Detonators may be fired electrically or by the flame from a fuse, and the construction varies accordingly, but the detonating composition is contained in what are practically long percussion caps made generally of copper.

The charge, as in the case of caps, was at one time pure fulminate, and is at the present time in many Service detonators, but a mixture of fulminate with potassium chlorate, and sometimes other ingredients, such as gun-cotton, is now usually used in industrial detonators. The mixtures contain 80 to 90 p.c. mercury fulminate; 80 p.c. fulminate is common in England, 90 p.c. in the United States.

Hagen (Zeitsch. Ges. Schiess- u. Sprengstoffwesen, 1912, 201, &c.) states that the addition of potassium chlorate increases the detonative efficiency of mercury fulminate, owing to the increased heat and gas pressure produced; but Wöhler (Zeitsch. angew. Chem. 1911, 209) is of the opinion that the increase of total energy resulting from the addition of the chlorate is more than counterbalanced by the decrease in the velocity of detonation. Storm and Cope (U.S. Bureau of Mines, Tech. Paper 125, 1916), by practical experiments in their sand bomb apparatus, found that 80 : 20 fulminate-chlorate mixture had greater detonative power than the 90 : 10 mixture, and that the latter in turn is superior to mercury fulminate alone. For example, for complete detonation of 0.4 gram of 'tetryl,' 0.35 gram of mercury fulminate, 0.30 gram of 90 : 10, or 0.275 gram of 80 : 20, fulminate-chlorate mixture is required. If the detonating composition be compressed very highly in detonators it simply burns on contact with flame, but within the limits of compression used in commercial detonators the degree of compression has little or no effect on the detonative power. The presence of 0.75 p.c. moisture in the charge of a detonator filled with 90 : 10 composition was found to have practically no effect on its detonating efficiency. Tests by Taylor and Cope (U.S. Bureau of Mines, Tech. Paper 162, 1917), carried out with mixtures of mercury fulminate with various oxygen carriers, did not show any relationship between the priming efficiency of the mixtures and any property of the oxidising salt; they all gave equally efficient mixtures. They found mercury fulminate to be more efficient as a detonating agent when uncompressed than when compressed, whereas the efficiency of detonators containing lead azide increased with the loading pressure. They conclude that the detonating efficiency of an explosive depends on two factors, an intensity or quickness factor, depending on the acceleration of the explosive reaction, and a capacity factor, the 'strength' of the explosive as measured by the sand bomb apparatus, the intensity factor being the more

important. Silver acetylide has low detonating power, but increases the efficiency of mercury fulminate, probably due to the low 'strength' but great 'quickness' of its explosion.

The property of detonating another explosive does not depend merely on the violence of an explosive, for Abel found that 0.32 gram of mercury fulminate would detonate guncotton, whereas ten times the weight of the more violent nitrogen chloride was required. To explain the value of an explosive in initiating detonation in other explosives, Abel (Compt. rend. 1874, 1228) advanced his theory of wave synchronism or sympathetic vibration. Wöhler and Matter (Zeitsch. Ges. Schiess- u. Sprengstoffwesen, 1907, 181, &c.), in the case of mercury fulminate, attributed its value as a detonant to the pressure produced by the kinetic energy of the molecules, that is, that it is due primarily to the rate of detonation and density of the fulminate, and secondarily to the gas volume and heat evolved. Nobel attributed this property of fulminate to the very intense shock or pressure instantaneously set up on its explosion, and Berthelot, as mentioned when considering the properties of mercury fulminate, adopted the same view, but also called attention to the contributing fact that the products of explosion undergo little, if any, dissociation. It is certain that velocity of detonation and power, or total energy, alone do not determine the value of an explosive as a detonant, otherwise nitroglycerin and blasting gelatin would have greater, instead of far less, detonating value than mercury fulminate, and mercury fulminate would have greater value than its admixtures with an oxidising salt. It is probable that all these factors are contributory to the property of initiating detonation, and considering the high value of this property of silver, mercury, and lead compounds, fulminates, azides, picrates, and acetylides, it still seems that Abel's original theory, or something analogous to it, is not entirely to be neglected.

The detonators are charged and the charge compressed as with caps, except that detonators are usually compressed singly, owing to the strength of the charge. A pressure of about 4000 lbs. per square inch is used, giving the fulminate or mixture a density of 2.8. The ingredients should be even in size and well mixed to act efficiently.

The following detonators are used:—

Description No.	1	2	3	4	5	6	7	8
Charge, grams	0.3	0.4	0.54	0.65	0.8	1.0	1.5	2

They vary in length, from 16 to 45 mm., and in diameter from 5.5 to 6.8 mm.

To obtain the full effect from a detonating explosive, a detonator of sufficient power is necessary. A No. 3 detonator is sufficient for ordinary dynamite, but for the modern safety explosives, such as those of the ammonium nitrate class, at least a No. 6 detonator is necessary for effective detonation of the explosive.

As a detonating composition for high explosives, which can be fired with safety in shells, Maxim (Eng. Pat. 18682, 1894) proposes a mixture of 75 to 85 p.c. of mercury fulminate with 15 to 25 p.c. of a blasting gelatin composed of 75 to 85 p.c. of nitroglycerin and 15–25 p.c. of

collodion cotton. The admixture is aided by the use of acetone, and to decrease the sensitivity the mixture is sometimes made of a spongy nature by blowing air through it whilst it is in a syrupy condition, or nitrobenzene may be added.

Other igniting and detonating compositions.

Many mixtures, frequently not containing mercury fulminate, have been from time to time suggested. The drawback to fulminate cap compositions is that the mercury in the combustion products attacks the metal of the cartridge cases, causing them to crack and be unfit for further recharging. Early mixtures containing guncotton and potassium chlorate, lead picrate, &c., were not very successful. Mixtures of mercury or lead thiocyanate with potassium chlorate, and of mercury or lead chromate, mercury fulminate, antimony sulphide, and powdered glass have been proved efficient with certain sporting powders. A mixture of 82.8 p.c. of mercury fulminate and 17.2 p.c. of ammonium perchlorate was suggested by Alvisi (U.S. Pat. 707493, 1902). It was proposed by Bielefeldt (Eng. Pat. 20133, 1900) to substitute all or part of the mercury fulminate in detonating composition by picric acid, nitronaphthalene, nitrocellulose, &c. With safety explosives, he also suggested the addition of aluminium nitrate. Wöhler (Eng. Pat. 21065, 1900) proposed the use of high nitro derivatives, such as trinitrotoluene; and Gehre (Eng. Pat. 19402, 1905) suggested di- or tri-nitromesitylene, and di- or tri-nitropseudocumene. A little fulminate is necessary to ensure detonation, but with trinitrotoluene not more than one-tenth of the usual quantity. Trinitrotoluene detonators are very largely used in Germany, and the Rheinisch-Westfälische Gesellschaft have patented the use of tetranitromethylaniline, or 'Tetryl' (Eng. Pat. 13340, 1905). Swope (U.S. Pat. 1194095, 1916) suggests a compressed mixture of nitrocellulose, or other nitrocarbohydrate, a thiocyanate, and a chlorate as a priming or detonating composition.

As substitutes for mercury fulminate, Angeli (Fr. Pat. 327892, 1902) proposed the barium, strontium, or calcium salts of the hydroxamic acids; Wöhler (Ger. Pat. 196824, 1907) proposed the azides of silver, mercury, or other heavy metal; it is claimed that a smaller quantity of these substances is necessary. Hyronimus (Eng. Pat. 1819, 1908) suggested the use of lead azide. The azides are coming into increasing use for igniting and detonating compositions. The Winchester Repeating Arms Co. (U.S. Pat. 1174669, 1916) suggest a mixture of lead azide, a nitro compound, such as nitrocellulose, and a substance such as an alkaline azide, which leaves an alkaline residue on ignition; and Buell (U.S. Pat. 1184316, 1916) suggests sodium azide, with or without potassium chlorate, and antimony sulphide as an igniting charge. Herz proposed nitrodiazobenzene perchlorate (Fr. Pat. 450897, 1913), and Von Girssewald (J. Soc. Chem. Ind. 1912, 1058) suggested hexamethylenetriperoxidodiamine as detonating agents. They both have great efficiency, being decidedly superior to mercury fulminate or lead azide, but they are gradually and progressively decomposed by the moisture in the atmosphere on storage. Buckard (Eng.

Pat. 16405, 1914) suggests their use in composite detonators, in which these substances are primed and further protected by an igniting charge of cap composition. The tetranitrate of pentaerythritol is suggested by Stettbacher (Zeitsch. Gess. Schiess- u. Sprengstoffwesen, 1916, 11) as suitable for use in primers and detonators.

Mixtures, without fulminate, containing aluminium, have been proposed by Führer (Eng. Pat. 2755, 1901, and 24812, 1902), Bielefeldt (Eng. Pat. 7148, 1901), and von Dahmen (U.S. Pat. 702357, 1902), but these mixtures require very strong confinement to be effective; the Westfälisch-Anhaltische Sprengstoff Actien-Gesellschaft have patented mixtures without fulminate, containing potassium chlorate with mono-, di-, or tri-nitrocresol, &c.; and Bielefeldt (Eng. Pat. 23889, 1901) suggests a mixture of potassium chlorate with trinitronaphthalene.

Composite detonators, in which the main base charge is tetryl, trinitrotoluene, or other nitro-body or organic nitrate, primed by mercury fulminate, a fulminate-chlorate mixture, or lead azide, are now used very largely instead of a heavy charge of mercury fulminate. For example, a base charge of 0.32 gram of tetryl primed with about 0.32 gram of a 9 to 1 fulminate-chlorate mixture will make a detonator of about No. 6 power, and so effect considerable saving of the expensive mercury fulminate. In *reinforced detonators* an inner perforated metal shell is pressed down over the charge.

Efficiency.—Detonants have, by their effect when detonated on a lead plate, been placed in the following order of efficiency as regards their value as initial detonants for other explosives, by Wöhler and Mauer (Zeitsch. Ges. Schiess- u. Sprengstoffwesen, 1907, 265): silver azoimide, mercury fulminate, trimercuraldehyde and a perchlorate, trimercuraldehyde and a chlorate, diazobenzene nitrate, nitrogen sulphide, sodium fulminate, and mercury nitromethane. Wöhler and Matter (Zeitsch. Ges. Schiess- u. Sprengstoffwesen, 1907, 245) found that the detonative power of a detonating charge depends on the conditions of use, especially on the area of contact surface between the detonator and the explosive. By trial with a No. 8 detonator, the 2-gram charge of which was compressed at pressures from 100 to 2000 kgms. per square cm., they found at first a decrease in the size of the cavity in the lead block test, with increased loading density, but still higher densities of loading give no difference in result.

The sand bomb test (*see p. 95*) is an excellent method for comparing the efficiency of detonators.

OTHER EXPLOSIVE COMPOUNDS.

Nitrostarch. Braconnot and Pelouze first nitrated starch at the same time as cellulose, the explosive product, like nitrocellulose, being originally called 'xyloidin.' Attempts to use nitrostarch, from time to time, for explosive work failed, partly owing to the instability of the product, and partly because, owing to the difficulty in nitration, the product had a considerably smaller nitrogen content than nitrocellulose.

Braconnot and Pelouze carried out the nitration with nitric acid alone. Uchatius first

used a mixture of nitric and sulphuric acids. In his process the starch was not added directly to the acid mixture, as it clotted together and resisted nitration, but was dissolved in 8 parts of cooled fuming nitric acid and the syrupy solution poured, with stirring, into 16 parts of concentrated sulphuric acid. The mixture was allowed to stand for 12 hours, washed, boiled with a solution of sodium carbonate, and dried at 60°.

The product was a white powder insoluble in water and alcohol, but soluble in ether. It was very hygroscopic and readily decomposed spontaneously, doubtless because of insufficient purification. It ignited at about 175°, and was very explosive.

Later, in America, Volney succeeded in nitrating starch directly in cold mixed acids by using a special stirring apparatus.

The Actien-Gesellschaft Dynamit Nobel, in 1891, patented the use of nitrostarch in smokeless powders (Eng. Pat. 6129, 1891), and prepared it on the manufacturing scale. The method of preparation is similar to that of Uchatius. The well-dried starch is first dissolved in 10 parts of nitric acid, of 1.5 sp.gr., in a special apparatus of lead, in which the mixture is well circulated by means of a paddle stirrer, and kept well cooled by means of inner and outer water-jackets. When all the starch is dissolved, the solution is introduced as a spray from an 'atomiser' into five times its weight of mixed acids, as a rule waste acids from nitro-glycerin manufacture, containing 70 p.c. H_2SO_4 , 10 p.c. HNO_3 , and 20 p.c. H_2O . The nitrostarch is precipitated as a fine powder, and is retained on a filter of guncotton between two perforated plates, when the waste acids are run off from the bottom of the vessel. The acid is pressed out, and the cake of nitrostarch stirred in water until neutral. The product is treated for 24 hours with a 5 p.c. solution of sodium carbonate, and finally stabilised by soaking in a solution of aniline. The finished cake contains about 23 p.c. water and 1 p.c. aniline. The nitrostarch so obtained is a mixture of mono-, di-, and tetra-nitrates, when related to $\text{C}_{12}\text{H}_{20}\text{O}_{10}$ as the molecule of starch—that is, up to and mainly $\text{C}_{12}\text{H}_{16}\text{O}_6(\text{NO}_3)_4$, containing 11.1 p.c. nitrogen. It is readily soluble in nitroglycerin, even in the cold, and forms gelatinous to waxy solids when sufficient of the nitrostarch is added.

The penta- and hexa-nitrostarches, on the same basis, have been prepared by Mühlhausen (Dingl. poly. J. 1892, 137). *Pentanitrostarch* $\text{C}_{12}\text{H}_{15}\text{O}_5(\text{NO}_3)_5$, containing 12.75 p.c. nitrogen, was prepared by adding dry starch to twenty times its weight of a mixture of 1 part of nitric acid, sp.gr. 1.5, and 3 parts of sulphuric acid, sp.gr. 1.8. The product, stabilised in the usual way, was freed from the tetranitrate by dissolving in ether-alcohol and distilling off the ether. The tetranitrate remained in solution in the alcohol, and the pentanitrate was precipitated. *Hexanitrostarch* $\text{C}_{12}\text{H}_{14}\text{O}_4(\text{NO}_3)_6$, containing 14.14 p.c. nitrogen, was prepared, mixed with the tetranitrate, by dissolving dry starch in ten times its weight of nitric acid, sp.gr. 1.5, standing 24 hours, and pouring the solution into five times its weight of sulphuric acid, sp.gr. 1.77.

A nitrostarch containing 16.5 p.c. nitrogen, corresponding to an *octonitrate* of the composition $\text{C}_{12}\text{H}_{12}\text{O}_2(\text{NO}_3)_8$, was prepared by Hough in the

United States in 1904 (U.S. Pat. 751076, 1904) by injecting dried maize starch below the surface of an acid mixture consisting of 3 parts of strong nitric acid, 2 parts of strong sulphuric acid, and sufficient Nordhausen sulphuric acid, containing 40 p.c. SO_3 , to give an excess of 2 to 3 p.c. of unhydrated SO_3 . The temperature is kept at 7° to 10° , and Nordhausen acid is added during the nitration to keep up the strength of the mixture. The nitrated starch is filtered off, washed, and treated with hot dilute ammonia to dissolve out lower nitrates and stabilise the product. The final product is an orange-coloured powder, soluble in ether-alcohol. Subsequently, Holmes (U.S. Pat. 779422, 1905) stabilised the product by dissolving in a mixture of alcohol and acetone, and then evaporating off the acetone. The impurities and lower nitrates remain in solution in the alcohol.

This nitrostarch is used in several American smokeless powders, and was also for a time tried as a constituent in a U.S. Service powder.

The production of so highly nitrated a starch as claimed by Hough has been questioned by Berl and Butler (Zeitsch. ges. Schiess- u. Sprengstoffw. 1910, 82). Using Hough's method, they failed to obtain a product with a higher nitrogen content than 13.44 p.c. A stable nitrostarch containing 14 p.c. nitrogen was prepared by Will and Lenze (Ber. 1898, 68) by dissolving dried starch in cold nitric acid of sp.gr. 1.52, standing for 24 hours, and gradually adding sulphuric acid. The product was washed with water, then cold alcohol, and finally hot alcohol, and further purified by dissolving in a mixture of acetone and alcohol, and precipitating by evaporating off the acetone. The ignition-point of the product, 194° , was considerably higher than those of the earlier products of the Nobel Co., and of Hough, which ranged from 120° to 175° .

Properties.—Nitrostarch is a white powder, readily soluble in acetone and ethyl acetate, but all preparations are not soluble in ether-alcohol. It is soluble in nitroglycerin, but does not gelatinise it as collodion cotton does. Berl and Butler (*loc. cit.*), by comparing the viscosities of the solutions in acetone, showed that the molecular complexity of nitrostarch is very small as compared with that of nitrocellulose, which explains the non-gelatinisation of nitroglycerin. Saposhnikoff (J. Russ. Phys. Chem. Soc. 1903, 126), by boiling-point determinations of solutions in acetone, concluded that the molecular weight of nitrostarch containing 13.4 p.c. nitrogen corresponds to a C_{36} formula.

Besides being more difficult to manufacture and less stable than nitrocellulose, nitrostarch is decidedly more hygroscopic, but its manufacture has been improved, and many suggestions have been made for its use in explosives, especially in the United States. A more stable product, for example, is stated by Sadtler (U.S. Pat. 1211761, 1917) to be obtained by preliminary treatment of the starch with a solution of caustic soda, and then with nascent oxygen, to swell the grains and remove impurities. After nitration, the first stabilisation is carried out, as has been found best with nitrocellulose, by boiling the product in the presence of a small amount of residual acid. Some mixtures that have been suggested are:

Pieters (U.S. Pat. 1048578, 1912), a blasting explosive containing 20 p.c. nitrostarch, 75 p.c. ammonium nitrate, 4 p.c. nitrobenzene, and 1 p.c. asphalt; Bronstein and Waller (U.S. Pat. 1188244, &c., 1916), several explosives consisting of mixtures of nitrostarch with ammonium nitrate, barium nitrate, trinitrotoluene, and sulphur; and Trese (U.S. Pat. 1265975, 1918), a blasting explosive containing 26 p.c. nitrostarch, 11 p.c. potassium nitrate, 22 p.c. potassium chlorate, 13 p.c. yellow wax, 7 p.c. soap stock, and 21 p.c. sulphur.

Nitrodeextrin, prepared similarly to nitrostarch, has been proposed for use with ammonium nitrate in safety explosives, mixed with a little resin.

Nitromannite or *Nitromannitol*, a nitric ester $\text{C}_6\text{H}_8(\text{NO}_3)_6$, prepared by the action of the usual mixed acids on the hexahydric alcohol mannitol, extracted from manna, the dried sap of the manna ash (*Fraxinus Ornus*) (Linn.). The nitrated product, after being well washed, and dried at 40° , crystallises from ether or alcohol in needle-shaped crystals, which are insoluble in water. It is a very sensitive and highly explosive compound, exploding at about 300° , and has been suggested as a substitute for mercury fulminate. It is more sensitive to friction and shock than nitroglycerin, and nearly as powerful and local in its effects as fulminate. It is stable when thoroughly purified, but this purification is difficult to obtain on the large scale, and the product is usually very liable to spontaneous decomposition.

Nitrosugars. *Nitrosaccharose*, nitro-cane sugar, or 'fulminating sugar,' was first obtained by Schönbein, by nitrating cane sugar with a mixture of 1 part of strong nitric acid and 2 parts of strong sulphuric acid at 12° , washing, and drying. It is a white, amorphous powder, soluble in water, alcohol, and ether. On gently heating, it softens, and can be kneaded, but on strongly heating, it explodes violently. It is very sensitive and has been proposed for use in percussion caps. It is, however, deliquescent, and, as prepared up to the present, very unstable. Cocking and Kynoch Expl. Co. (Eng. Pat. 2836, 1911) suggest the nitration of a solution of 20 parts of cane sugar, or invert sugar, in 80 parts glycerol, with an anhydrous mixture of 54 parts of sulphuric acid, and 46 parts of nitric acid. The manufacture is carried out as with nitroglycerin, but more thorough washing is necessary for complete stabilisation. The product is given successively 2 washings with water, 6 with a 2 p.c. solution of sodium carbonate, and 2 final washings with a 0.2 p.c. solution of sodium carbonate, all at 40° . The nitrated mixture is suggested for replacing nitroglycerin in blasting gelatin, gelatin dynamite, and gelignite. *Nitrolactose* is similar to nitrosaccharose, but can be crystallised from its solution in alcohol or ether. It has similar violently explosive properties, and is equally sensitive and unstable. *Nitroglucose*, with vegetable fibre and potassium chlorate and nitrate, is a constituent of *Keil's explosive*, and solid and liquid nitro products, obtained from molasses, have also been proposed.

Other nitro explosives, prepared by the nitration of a great variety of organic substances, such as wood, flax, hemp, jute, gelatin, resin,

coal, &c., have been prepared, and several have been already mentioned as constituents of various explosive mixtures.

Amino, and amino-nitro explosive compounds. Ammonium nitrate may be considered as the simplest of the amino-nitro compounds. Glyccoil nitrate, the nitrate of aminoacetic acid, has been used in a propellant, and good results obtained. Its explosion may be represented by:

and its explosion constants have been compared with those of picric acid by de la Roque (Rev. de Chem. indus. 11, 5). The Westfälisch-Anhalt-Sprengstoff. A. G. (Ger. Pat. 203190, 1907) suggested the dinitrodialkylamides for use in explosives. The nitrates of the aromatic amines, like aniline nitrate, are used as constituents (for example, Ceipek (Fr. Pat. 341021, 1904) mixes the latter with ammonium nitrate), but they do not contain sufficient oxygen to form explosives by themselves. Hermann (Ger. Pat. 176072, 1905) proposes condensation products of formaldehyde and the aromatic amines.

Picramic acid and the picramates, and the corresponding reduction products of trinitro-cresol, were proposed by Turpin in potassium nitrate mixtures (Fr. Pat. 185034, 1887). Claessen (Fr. Pat. 355695, 1905) proposed tetranitromethylamine and the ethyl compound, as detonating explosives, and Will (U.S. Pat. 827768, 1906) uses the same compound mixed with mercury fulminate. Nitramines of the anthraquinone series of various degrees of nitration and explosibility have been suggested by Scholl (Ber. 1904, 4427), and von Schroetter (Eng. Pat. 8156, 1907) proposed hexanitrodiphenylamine and its salts, alone or in mixtures. Nitro derivatives of the condensation products obtained by heating primary aromatic amines with oxalic acid, and the nitro derivatives of aromatic diamines, such as pentanitrodiphenylmetaphenylenediamine, have been claimed by the Soc. Anon. d'Explosifs, &c. (Fr. Pat. 391106 and 391107, 1907).

The nitration of aniline directly gives only poor yields of nitro derivatives, owing to secondary reactions, and the nitranilines have not been much used in commercial explosives. Ortho- and para-nitraniline can be prepared by the nitration of acetanilide, and then removing the acetyl groups (Holleman, Hartog, and v. d. Linden, Ber. 1911, 704), and metanitraniline by the partial reduction of metadinitrobenzene. The mononitranilines can be readily further nitrated. 2,4,6-trinitraniline, or *picramide*, is a powerful explosive, readily obtained by the further nitration of orthonitraniline, or by the action of ammonia on trinitrochlorbenzene.

Tetranitraniline, the four nitro groups being in the 2,3,4,6-positions, was obtained by Flürscheim (8th Int. Cong. App. Chem. 1912) by the reduction of metadinitrobenzene with aqueous sodium bisulphide, the product being readily nitrated by mixed acids at a temperature not higher than 70°. Its direct production from aniline is described by van Duin and van Lennep (Rec. trav. chim. 1917, 37, &c.). They dissolved 26 grams of aniline in 700 c.c. of conc. sulphuric acid, then cooled to -5°, and added a mixture of 16 c.c. of nitric acid of sp.gr. 1.49

with 80 c.c. of conc. sulphuric acid. The mixture was kept in the cooling mixture for 2 hours, and then 117 grams of potassium nitrate were added, the temperature being kept below 50°. The mixture, after standing for a day, was then heated to 50° for 1½ hours, and again allowed to stand for a day. The crystals of tetranitraniline were then filtered off, and washed first with 50 p.c. sulphuric acid, and finally with water, and dried.

The product, melting at about 207°, is best crystallised from acetic acid. It gives yellow crystals, melting at about 216°, but it does not melt without some decomposition. It is stated to be stable, but on boiling with water, or if recrystallised from acetone containing water, it is converted into trinitroaminophenol, and it is doubtful, even when pure, whether it will stand prolonged storage. Flürscheim states that it has an explosive power, as measured by the lead block test, greater than that of any other solid compound, but inferior to that of nitroglycerin. It is detonated by a weight of 5 kilos falling 35 cms. It is readily detonated, when loose or compressed, either alone or when mixed with nitrates.

Tetryl, or *Tetralite*, is an explosive compound of this class used in large quantities in detonators, and as a 'priming' or intermediary detonating agent for the less sensitive high explosives. It is made by nitrating methyl- or more usually dimethyl-aniline, and its commercial name was given on the supposition that it was tetranitromethylamine. It is actually trinitrophenylmethylnitramine

one of the nitro groups being in the side chain, the other three being symmetrically placed in the nucleus. A specially purified form of the explosive is known in the British Service as 'Composition exploding,' or 'C. E.'

Manufacture.—The explosive is liable to be of inferior stability, and it is very necessary that the materials used in its manufacture should be as free as possible from foreign matter. The following method of manufacture is given by Langenscheidt (Zeitsch. Ges. Schiess- u. Sprengstoffw. 1912, 445): the nitration is carried out in one stage in a jacketed enamelled-iron pot, fitted with an enamelled stirrer and a thermometer. 100 kg. of dimethylaniline, boiling very closely at 190°, is very slowly run into 1000 kg. of pure lead-free 97 to 98 p.c. sulphuric acid, the mixture being kept stirred and cooled. This solution, which should be of a clear light-brown colour, is without standing run slowly into 430 kg. of nitric acid of 47°B. strength, sp.gr. 1.483, kept stirred, and at a temperature of 40°. The reaction is violent, and the temperature is carefully kept below 44°, whilst two-thirds of the sulphuric acid solution are run in, after which it is allowed to gradually rise to 55°. The time taken for addition of the charge is 8 to 9 hours, after which the nitration is completed by further stirring for 2 hours at a temperature of 53°–55°. The nitric acid must not be stronger than stated, or large and less pure crystals are produced. The mixture is allowed to cool overnight, and the waste acids are run off. The crystals are washed on a vacuum filter, first with

dilute sulphuric acid, and then with water until quite free from acidity, and rapidly dried. The crude product melts at about 126°-127°.

Purification.—It is necessary to further purify the product. This is done by recrystallisation from a suitable solvent, frequently benzene of a high degree of purity. The crude tetryl is dissolved in the boiling benzene, the solution filtered, and allowed to crystallise rapidly in a cooled pan, the mother liquor run off, the crystals washed with benzene, and dried in the washing vessel. The benzene is recovered by distillation under precautions, as the contained impurities are of an unstable and explosive character. It is also purified by crystallising from its solution in acetone, and an inferior grade from nitric acid. The last traces of acid can be removed by boiling with water, but prolonged boiling causes appreciable decomposition with the formation of picric acid.

Properties.—The purified tetryl is in the form of very fine pale-yellow crystalline powder. It is practically insoluble in water, but readily soluble in acetone, ether, and benzene, the best solvent being benzene. The melting-point of pure tetryl is 129°. It is distinctly more sensitive to blow than picric acid, being detonated on an anvil by a blow from a hammer, and is also more powerful. According to Langenscheidt, it can be exploded by a 5 kg. weight falling 30 cms. When strongly heated it burns fiercely with a very hot but smokeless flame, and 'puffs off' when projected on to a red-hot iron plate. It is readily detonated by a small charge of fulminate. It is not only a very powerful explosive, but has great shattering power, its velocity of detonation being of the order of 7000 metres per second. When compressed to a density of 1.6 its detonation velocity is 7200 metres per second, being slightly higher than that of picric acid at a density of 1.5. It is an excellent initiator of detonation in less sensitive explosives, being used for this purpose either as crystalline powder, granulated or 'corned,' or compressed into pellets. It is characterised by its high nitrogen content, 25.5 p.c., as compared with the 18.5 p.c. of trinitrotoluene, and is endothermic. It has been used to some extent in explosive mixtures, for example, in the ammonium nitrate explosive 'Fortex.' It is non-poisonous, but it has an extremely irritant action on the skin and mucous membranes, some persons being more susceptible than others. In some cases a most painful rash is produced, for which one of the best remedies is boro-calamine lotion.

Hexanitrodiphenylamine

has been used to some extent as a high explosive for bombs by the Germans, usually with the addition of a little trinitrotoluene. It is a stable light-yellow powder, melting at 238°. It is insoluble in water, and not at all readily soluble in the usual organic solvents. It can be recrystallised from boiling glacial acetic acid. It has about the same power and sensitiveness as picric acid, and has the same drawback: that it is acid and readily forms sensitive salts with metals. It has an extremely irritant action on the skin.

Diazo explosive compounds. All the diazo

derivatives are very sensitive explosive compounds. '*Chromate de benzine diazotée*', $\text{C}_6\text{H}_5\text{N}_3\text{HCrO}_4$ is one of a class of explosive compounds proposed as detonants by Caro and Griess (Eng. Pat. 1956, 1866). The diazo compounds generally are too sensitive and highly dangerous to be used in practical explosives.

Azo compounds. The azo compounds are more stable than the diazo compounds. They do not form explosives in themselves, but have been proposed in mixtures. For example, Girard (Fr. Pat. 349635, 1904) uses azobenzene mixed with dinitrotoluene or picric acid in chlorate and ammonium nitrate mixtures, in order to lower the melting-point of the nitro compound, and effect incorporation at a lower temperature.

Hydrazines. Hydrazine chlorate and perchlorate have been prepared by Salvadori (Gazz. chim. ital. 1907, ii. 32); they are highly explosive and sensitive compounds, the perchlorate being the more stable.

Hydrazoic acid, or azoimide HN_3 , is one of the most explosive substances known. It is a volatile liquid, the vapour of which detonates on contact with a flame. The aqueous solution of the acid forms metallic salts; those of the heavy metals being extremely explosive. With ammonia it forms a white crystalline solid $\text{HN}_3 \cdot \text{NH}_3$, which is less explosive. It burns away rapidly but not explosively, unless confined.

Azides. The heavy metal salts of hydrazoic acid, such as lead and silver azide, are sensitive explosives, and have considerable detonative power. The lead salt has greater power than mercury fulminate in initiating the explosion of many nitro explosives, and has been increasingly used in recent years in composite detonators, especially in Germany. Nickel azide is also particularly sensitive to friction, and is violently explosive. The azides have been prepared, and their explosive properties studied by Wöhler. The insoluble azides are prepared by double decomposition from sodium azide, which is manufactured either by the sodamide or hydrazine process, and the soluble azides by the action of hydrazoic acid on the carbonates or basic oxides of the metals in the presence of ether (Ber. 1917, 586). The soluble azides are readily hydrolysed in solution giving basic precipitates. The sensitiveness of the azides to heat and percussion has been determined by Wöhler and Martin (Zeitsch. angew. Chem. 1917, 33). They found that the azides of metals of low atomic weight are more hygroscopic, and have generally lower temperatures of ignition than those of high atomic weight, and that the azides of the alkaline metals exploded without true detonation. Some of the explosion temperatures found were: calcium azide, 158°; nickel azide, 200°; mercury azide, 281°; silver azide, 297°; lead azide, 327°. As usual, the results depended on the conditions of experiment, and the ignition temperatures quoted were the temperatures at which 0.02 gram of the salt detonated after an interval of 5 seconds. The azides of lithium, sodium, and potassium could not be exploded by percussion, the azides of barium, strontium, and calcium only exploded with flame, but the azides of the heavier metals gave true detonation with sufficient blow. In

thin layers the sensitiveness of the azides to percussion was in the same direction as the sensitiveness to friction, the azides of the heavy metals being the more sensitive. Contrary to the results obtained with most explosives, the azides of lead and mercury were found to be more sensitive in thick than in thin layers, a result which accords with the property stated to be shown by their large crystals of spontaneous detonation.

Lead azide PbN_6 is manufactured on the large scale from the sodium salt by double decomposition with a soluble lead salt, such as lead nitrate or acetate. The solutions of the two salts are kept strongly agitated so that the lead azide is precipitated in the form of fine crystals. The precipitated crystals are well washed with water till free from impurities, and dried in a current of dry air at about 50° .

Lead azide is less sensitive to friction or blow than mercury fulminate, the large crystals being more sensitive than the small, and it has a considerably higher ignition point. It is not rendered less sensitive by wetting with water. It is quite stable, except in the presence of acid fumes. Stettbacher (*Zeitsch. ges. Schiess- u. Sprengstoffw.* 1914, 341) gives the heat of decomposition of lead azide as 364 calories per gram, and the temperature of explosion as 3483° . It is practically the only explosive in actual use that is not an instance of oxidation.

The explosive properties of the *nitrogen halogen compounds* are well known, but these compounds are unsuitable for practical explosives.

Acetylene compounds. Many of the compounds formed by the action of acetylene on metallic oxides and salts are violent explosives, and have been proposed as detonating explosives. The white solid obtained by passing acetylene into an acid solution of silver nitrate has been claimed by the Société Anon. Dynam. Nobel (Fr. Pat. 321285, 1902) as a substitute for mercury fulminate in chlorate detonating mixtures, and that obtained from an ammoniacal solution of mercury nitrate has been proposed by Venier (Fr. Pat. 364461, 1906) for a similar purpose. The explosive properties of these two varieties of silver acetylides have been examined by Eggert (*Chem. Zeit.* 1918, 199). He attributes the difference in their explosive properties to the presence of occluded impurities, silver nitrate and oxide in the acid and ammonia products respectively, and the gas they yield on detonation. He found the acid product gave more gaseous product and greater explosive effect, and also that the 'acid' silver acetylide has greater disruptive power than silver fulminate, but less than silver azide, and attributes the differences to differences in velocity of detonation.

SAFETY EXPLOSIVES.

Prior to about 1880, black gunpowder and dynamite were almost the only explosives used in mines and quarries; the former for mining soft coal or obtaining large blocks of rock, the latter for the harder materials and where shattering effects were desired. At the present time, although gunpowder is used in this country to the extent of more than half the total weight of mining explosives, kieselguhr

dynamite has been largely displaced by blasting gelatin, and a large variety of other explosives have come into use, more especially the so-called 'safety explosives' used in 'fiery' coal-mines. The use of gunpowder in these mines is everywhere prohibited.

The following table, taken from the 39th Annual Report of H.M. Inspector of Explosives, gives the amount of different explosives used in mines and quarries in Great Britain in 1913:—

Explosive	Quantity used, lbs.	P.c. of total
Permitted explosives	11,051,231	33.0
Gunpowder	17,060,874	50.1
Gelignite	3,960,173	12.0
Gelatine Dynamite	474,922	1.4
Blasting Gelatine	297,907	0.9
Roslin Giant Powder	247,871	0.7
Cheddite	187,226	0.6
Nobel Polarite	149,593	0.5
Blastine	122,590	0.4
Saxonite	85,606	0.3
Dynamite, Stonax, and Matagnite Gelatine	23,947	0.1

Of the 'permitted explosives,' those most used, in order of quantity, were: Bobbinit, Samsonite, Arkite, Ammonite, Bellite, Monobel Powder, Rippite, Roburite, Stow-ite, Ammonal, Westfalite, Swalite, Faversham Powder, Carbonite, Excellite, Rexite, Cornish Powder, Kentite, Abbeite, Permonite, Dynobel, St. Helens Powder, Fracturite, Negro Powder, Fortex, Stomonal, Dreadnought Powder, Cambrite, Britonite, Dominite, Minite, Superite, and as many other varieties used in smaller quantities.

Owing to an ever-increasing number of coal-mine explosions, due to the ignition of fire damp or dust by the firing of shots, the British Government appointed a Commission, which recommended that the explosive should be surrounded by a jacket of water, but no attempt was made to devise a safety explosive. Subsequent to the English Commission, several of the Governments on the Continent also appointed Commissions, but the factors which render an explosive safe to use in contact with inflammable mixtures were not definitely settled, and even now they are not known with certainty. It has been found impossible to devise an explosive that is absolutely safe under all conditions, and at the present time there is, in this country, no special definition of a 'safety explosive,' except that it must pass the Home Office tests and be placed on the 'permitted list.'

According to the French Commission, in 1888, the factors determining the ignition of inflammable mixtures are the temperature of explosion of the explosive and the duration of the flash. They found that a mixture of marsh gas and air ignited at 650° , but that at this temperature the ignition was delayed ten seconds, and a much higher temperature was permissible, if of short duration. A safety explosive had to fulfil the conditions that the products of explosion were free from inflammable substances, and that the calculated temperature of explosion should be below 1500° . Explosives having a high temperature of explosion, such as nitroglycerin 3200° , gun cotton 2600° , and collodion cotton 2060° , should be mixed with a material having

a low temperature of explosion, such as ammonium nitrate, 1130° , so that the mixture comes within the prescribed limit. Three classes of safety explosives were introduced, the 'Grisounites' containing nitroglycerin and ammonium nitrate, 'Blasting Powder P' containing colloidal cotton and ammonium nitrate, and the 'Grisounites' containing nitrohydrocarbons and ammonium nitrate.

This temperature limit cannot, however, be rigidly applied; for 'carbonite,' the first safety explosive, invented in 1885, and at the present time one of the safest, had a temperature of explosion well above this limit. According to Bichel, the inventor of carbonite, the calculated temperature of the explosion is of no value in determining safety, but the maximum temperature of the products of combustion, the length and duration of the flame, and the velocity of detonation, are the determining factors. The amount of the explosive used and the physical and chemical nature of the products of combustion, for example, the proportion of incandescent solid particles, are of great importance (Glückauf, 1904, 35).

The Prussian Commission came to the conclusion that the quicker the explosion, the greater the safety; consequently, that kieselguhr dynamite and guncotton were safe, and that fulminate detonators could not ignite pit gas. But this view is no longer held to be true in all cases; for 'bobbinit,' a slow black powder mixture, is one of the safest and most extensively used safety explosives, whilst blasting gelatin is not safe.

The Austrian Committee defined a safety explosive as one that gives a short, but not bright, flame, and one that passes the usual gallery tests. Von Lauer, in Austria, stated that bore-hole shots that have done their work never ignite pit gas, and that the risk arises from blown-out shots and fissured coal, but this contention has not held good in all cases. Guttman considered that the risk of a blown-out shot is frequently due to the rapidity of the explosion being sufficient to ignite the gas mixture, owing to the heat produced by the compression and friction set up in the atmosphere by the explosion gases.

Testing galleries.—The question as to whether explosives are suitable for use in fiery mines is now chiefly decided by submitting them to a practical test, which is intended to simulate, more or less, the conditions of use in these mines. The exact nature of the test varies in different countries, and the severity of the test has, from time to time, been increased as the factors determining safety have become better understood, and the manufacture of safety explosives consequently become more perfected. Explosives at one time 'permitted' are occasionally removed from the list, as the conditions of test are made more stringent.

The test consists in firing a number of shots under definite conditions into an explosive mixture contained in a long gallery, the explosive passing the test when no explosion occurs. Most countries have one or more official testing stations, and many manufacturers of explosives have their own testing galleries.

A testing gallery, based on a private one at Hebburn Colliery belonging to some north-

country private manufacturers, was established at Woolwich in consequence of the Coal Mines Regulation Act, 1896, to test explosives proposed for use in coal-mines. This was amended by the Coal Mines Order of August, 1905, and by a later Memo. in May, 1912, in which the tests for 'permitted' explosives were revised, with the result that the testing station was removed from Woolwich to Rotherham. Those that pass this test are put on the list of '*permitted explosives*,' which indicates, not that they are absolutely safe under all conditions of use, but that they are safer than those not on the list. It is, indeed, recognised that all explosives, used under certain conditions and in sufficient quantity, will ignite mixtures of pit gas or coal-dust and air.

In testing, a given weight of the explosive is fired from a gun into a mixture of 85 p.c. air and 15 p.c. coal gas. The shot is 'stemmed' with a definite length of dried pottery clay. These conditions at Woolwich are not intended to exactly imitate the actual conditions obtaining in a fiery mine, but rather to give a severe test which can be uniformly reproduced at any time. It is for this reason that coal-dust is not employed in the Woolwich test.

The Woolwich testing gallery is an iron tube 2 feet 6 inches in diameter and 28 feet in length, with seven safety-valve orifices at equal intervals along the top of the tube, to allow the escape of the gas following an explosion. The shot is fired from a gun at a definite angle with the roof. Such a weight of the explosive is fired as is equivalent in strength to 4 ozs. of dynamite No. 1. The charge was determined previous to 1900 by finding the weights necessary to give equal enlargements in the lead-block test, but since that time the relative strengths of the various explosives has been measured by a ballistic pendulum test, which has been found to give more accurate results. One of the guns is charged with the explosive and fired from a fixed distance into the muzzle of a 5-ton mortar of 13-inch calibre suspended in an iron framework from an overhead beam. The swing of the mortar gives a measure of the strength of the explosive.

If the gas mixture does not fire in 20 shots, 10 shots with 12 inches' stemming and 10 shots with 9 inches' stemming, no explosive being left unconsumed, the explosive is considered safe. The size of detonator and nature of the wrapping to be used with the explosive are defined, as these are found to materially affect the results. For instance, explosives containing sulphur are much less safe in a lead alloy case than in a paper wrapper.

Any explosive, if fired in sufficient quantity and unstemmed into a mixture of coal gas and air, would cause the ignition of the mixture, and as early as 1903, Watteyne, of the Belgian testing station at Frameries, suggested that the highest charge which in a given number of shots failed to ignite the mixture used in the testing gallery, called the '*charge-limite*,' should be taken as a measure of safety of the explosive, and some idea of the order of safety of different explosives obtained. This idea was generally adopted except in England, and this and other differences in the conditions of testing led to the English and Continental systems giving

very different results, and many explosives passed by the one were condemned by the other. The present system of testing in England conforms more closely to Continental practice.

In 1912 the conditions of testing in England were altered, and a more modern station was erected at Rotherham, the old station at Woolwich being closed in February, 1911. The Rotherham gallery is an iron tube, 5 feet in diameter, and 50 feet long. The bore of the cannon is 4 feet long and 2 inches in diameter. The capacity of the gallery is 354 cubic feet, and the proportion of coal gas used in the mixture is 13.5 p.c. Coal-dust is also used, 40 ozs. being spread on a board in the first 10 feet in front of the cannon, and a further 80 ozs. placed in heaps along the remaining 40 feet of the gallery. The coal used is of a particular quality, giving 2.4 p.c. moisture, 29.6 volatile matter, 65.4 p.c. fixed carbon, and 3.94 p.c. ash, and is ground to pass a 150-mesh sieve. No tamping is used in this test, the charge being fired directly into the explosive mixture of coal gas, coal-dust, and air. The largest charge which fails to fire the mixture in one of five shots is known as the 'maximum' charge, and this must not be less than 8 ozs. The explosives are made up into cartridges of $1\frac{1}{8}$ inch diameter, so that they occupy only half the sectional area of the bore.

The ballistic pendulum at Rotherham weighs 5 tons 1 cwt., and has a bore of 13 inches; the radius of swing is 7 feet 8 inches, and the bearings are made as frictionless as possible. A charge of 4 ozs. of the explosive is loaded into a cannon, stemmed with clay, and fired close up into the mouth of the pendulum, the back swing of which is recorded in inches.

On the Continent, similar testing stations exist, the first testing station being built by the Prussian Government at Neunkirchen. The galleries are long wooden or iron tubes, round or oval in section, but usually considerably larger in section than the Woolwich gallery. At first the explosives were suspended in the gas mixture for firing, but the mixture under these conditions always fired, and the method of firing into the mixture from a small cannon, was adopted. The galleries vary in sensitiveness according to their diameter, material, and situation; and the results obtained at one gallery are not directly comparable with those obtained at others. A particular gallery will also give irregular results on certain days, for reasons that have not been explained, but atmospheric pressure is probably a considerable factor, and results obtained on these days have to be neglected. The explosive mixture generally used is prepared with natural pit gas, but occasionally artificially prepared methane, coal gas, or even benzene vapour is used, and usually coal-dust is suspended in the explosion mixture. Coal-dust is said not to increase the sensitiveness of the mixtures, but causes the ignition to be more violent and therefore more visible. Beyling showed experimentally (Glückauf, 1908, 1717) that all explosives ignite either coal-dust or a gas mixture more readily than a combination of the two, and in Germany safety explosives are not now tested, as formerly, in a gas mixture containing coal-dust, but in fire-damp (8 to 9 p.c.) and coal-dust mixtures separately. The cannons used vary in bore, and it has been found

that the narrower the bore of the cannon, the easier the ignition. At the United States testing station at Pittsburgh, the gallery is a steel cylinder, 100 feet long, and $6\frac{1}{2}$ feet diameter. The gallery is filled with either coal gas and air, coal-dust and air, or coal gas, coal-dust and air. The Belgian gallery at Frameries is a wooden cylinder, 30 metres long, and 2 square metres in sectional area. The bore of the cannon is 46 cm. long and 5.5 cm. diameter. A mixture of coal gas, coal-dust, and air is used.

The general method in use is to find the *charge-limité*, or maximum charge of the explosive which, in a series of 10 shots, just fails to fire the explosive mixture, the charge being unstemmed. The conditions for use of 'permitted' explosives are frequently defined. They must be used with a certain No. detonator, an explosive ceases to be 'permitted' if it is frozen, and the nature of the wrapping and stemming, combustible or otherwise, may be laid down.

Composition.—By far the greater number of safety explosives are either nitroglycerin mixtures or ammonium nitrate mixtures. Sometimes the mixtures contain both ammonium nitrate and nitroglycerin, so as to combine the advantages of the two types. Some black powder and chlorate and perchlorate mixtures are also used. The proportion of oxygen is frequently kept low so as to reduce the temperature of combustion by burning the carbon to monoxide only, but the objection to this is the poisonous and combustible nature of this product.

The nitroglycerin explosives, containing a little nitrocotton to gelatinise them, have a high charging density, are readily detonated, and are waterproof. The latter quality enables them to be used in damp or wet bore holes. They are plastic and can be well rammed into the bore holes, thus assuring a maximum effect. They are specially useful in blasting the harder materials. The safety of these explosives varies inversely with the proportion of nitroglycerin, and the maximum permissible is about 30 p.c. The nitroglycerin explosives are not so safe against percussion, such as an accidental blow, or too hard ramming, as the ammonium nitrate explosives; and when so ignited not only does the whole cartridge explode, but the explosion may be communicated to the adjacent cartridges. Another drawback is their liability to freeze.

The ammonium nitrate explosives, which give a large volume of gas at a comparatively low temperature, are very safe, because of the large amount of water contained in the products of explosion, but they are difficult to detonate completely, and usually their hygroscopic nature necessitates the use of a waterproof wrapper. They are so difficult to ignite and so insensitive to percussion, that their transport is quite safe, but their charging density is low and their effect less than that of the nitroglycerin explosives. When ammonium nitrate explosives do fire by percussion, only that portion actually struck is ignited. They necessitate the use of large bore holes, and are consequently best adapted for blasting soft materials. Ammonium nitrate itself is quite safe in any quantity, and the safety of mixtures prepared with it depends on the nature and proportion of the combustible material.

Ammonium nitrate explosives containing a small percentage of nitrocellulose, have been thought, especially in Austria, to be amongst the safest, but they are not permitted in this country. The reason for this is that they are liable to slowly decompose and become acid, and the liberated acid and ammonia attack and decompose the nitrocellulose.

Both Dautriche and Taffanel have established that, by the addition of potassium nitrate to safety explosives, the factor of safety in pit gas mixtures is considerably increased, whether the temperature of explosion be high or low. The heat of combustion is considerably lowered, whilst the explosive force is not appreciably diminished (Taffanel, *Zeitsch. Ges. Schiess-u. Sprengstoffw.* 1910, 305, &c.).

Safety ingredients.—In safety explosives, the ingredients are so proportioned that the carbon is mainly converted into carbon monoxide. This reduces the temperature of the explosion without sensibly diminishing the explosive force, owing to the increased volume of gases produced. The principle of safety explosives is, further, so to arrange the nature and proportion of the ingredients that a sufficient volume of non-inflammable gas, such as water vapour, carbon dioxide, nitrogen, ammonia, &c., is produced to dilute the carbon monoxide and prevent its contact with the air until its temperature has fallen below the ignition-point.

As already mentioned, the first suggested remedy for the prevention of the ignition of fire-damp was to surround the cartridge with a water-jacket. Subsequently it was found that tamping the explosive with wet moss, sawdust saturated with a solution of alum or ammonium chloride, sand, or clay added considerably to the safety; tamping even with only 1 inch of dry sand was shown by Guttman to double the safety.

The use of wet tamping materials led to the use of salts containing large quantities of water of crystallisation, such as sodium carbonate and magnesium sulphate, or salts which liberate much water at the temperature of explosion, such as ammonium oxalate.

A large percentage of sodium carbonate is used in 'wetter dynamite' and 'Grisoutine,' and ammonium oxalate in 'securite.' Magnesium sulphate has not been much used because of its effect on the miners.

Another class of additions is salts which dissociate and absorb heat at the temperature of explosion. Examples of this class are the potassium dichromate in 'dahmenite,' potassium permanganate in 'roburite,' and ammonium chloride in 'antigrison.' The use of ammonium chloride led to the production of hydrochloric acid in the mine gases, and it was consequently mixed with an equivalent quantity of sodium or potassium nitrate; or better, the alkali chlorides are themselves used (Richel, *Fr. Pat.* 327868, 1902).

Modern German safety explosives contain large proportions of potassium or sodium chloride, and these explosives are very safe, especially in coal-dust mixtures, but are not so powerful as the older explosives.

The use of materials which absorb heat on decomposition, such as wood pulp and rye flour, has been found to confer great safety on explo-

sive mixtures containing them, such as 'carbonite' and 'gelignite.'

The good effect of wood meal led to the manufacture of those safety black powders, like Argus powder and earthquake powder, containing a high percentage of volatile matter (*see* Curtis and others, *Eng. Pat.* 17878, 1898, and 6523, 1899). Some of the good effect of these slack-burnt charcoals has also been attributed to their reduced content of solid matter. Curtis and others (*Eng. Pat.* 6756, 1898) claimed the use of a layer of sodium bicarbonate in front of an ordinary gunpowder charge, the safety action depending on the liberation of carbon dioxide. The Westfälisch-Anhalt. Sprengstoff. Actien-Gesells. (*Eng. Pat.* 3334, 1902) compound an explosive mixture so as to produce a large volume of ammonia on detonation; Reschke (*Eng. Pat.* 25780, 1905) suggests copper oxalate; von Dahman (*Eng. Pat.* 7562, 1898) suggests the use of acetic, citric, or tartaric acid and their salts with such explosives as roburite; Callenberg (*Fr. Pat.* 322946, 1902) proposes to add turpentine chloride; Macnab proposed to insert a glass tube containing aqueous ammonia into the gunpowder cartridge.

TESTING EXPLOSIVES.

The explosive characteristics of a powder depend primarily on its chemical nature. The analysis of explosives is consequently of great importance. As far as space would permit, an outline of the analysis has already been given under the individual explosives.

The purity of the ingredients, size of the grain, intimacy of the admixture and density, also largely influence the character of the explosive. A microscopic examination of a mechanical mixture, as with the cap composition, is of value.

An eye inspection of explosives that have been in store should be made for any sign of efflorescence and deliquescence or exudation, if a nitroglycerin explosive; and for signs of cracking or breaking down, in nitrocellulose powders; or local patches of discoloration in nitro powders generally. The development of acidity, as shown by the reddening of blue litmus paper, often indicates decomposition.

Stability Tests for Nitro Explosives.

One of the most desirable properties in explosives, whether for use as propellants or disruptives, is that they shall be chemically stable under all the conditions of climate, storage, and transport that they may have to withstand. All nitro explosives undergo decomposition at temperatures below, in some cases considerably below, their exploding-points, even when pure, and many of them are liable to contain traces of acids and impurities that are much less stable. The decomposition of these impurities leads to the production of higher oxides of nitrogen which act catalytically on the explosive itself, and may lead to the spontaneous ignition of the latter.

The extensive use of guncotton, dynamites, smokeless powders, and other nitro explosives necessitates the use of tests that will not only determine the stability of the ingredients themselves, but also detect the presence of any unstable impurities. The test should also be

simple and reliable, and only take a short time to carry out. No single test has been devised that is universally applicable and will satisfy all these requirements, and it is usual to employ two, three, or more of the numerous tests that have been worked out and to form a definite conclusion on the combined results.

Vieille concluded from his results with the French 'Poudre B,' that the life of a propellant could be calculated from the rule that a life of 1 hour at $100^{\circ}=1$ day at $75^{\circ}=1$ month at $40^{\circ}=1$ year at 17.5° . This rule is expressed by the formula $L_t=L_T \cdot 10^{T-T'}$, where L_t is the life at the storage temperature t° , and L_T the life at the temperature T° of the stability test. The rule is approximately true with the reservation that the coefficient 1.10 varies slightly with the nature of the propellant, its composition, and method of manufacture.

Unless otherwise mentioned, the tests apply only to nitrocellulose or nitrocellulose powders.

Deflagration test.—One of the earliest tests was that devised by Hess. The explosive was heated at a fixed high temperature, and the time of evolution of coloured fumes and also of firing was noted. In a modified test, the explosive was heated under pressure at 75° till explosion took place. This test, which is, at best, only a very rough indication of stability, is not much used at the present time, but is the basis of several other tests.

Fume test.—The test, devised by Thomas, consists in heating a definite weight of the explosive at a definite elevated temperature until brown fumes appear, the stability of the explosive being judged by the time taken. The method of carrying out the test with guncotton is as follows: 2.5 grams are weighed out into a well-cleaned glass tube, 32 cm. \times 1.6 cm., and pressed down to a height of 4 cm. The tube is closed by a well-fitting glass stopper and placed to a depth of 10 cm. in an oil-bath, heated to 135° . At the end of 10 minutes, any moisture condensed on the upper part of the tube is wiped out. A standard tint for fixing the end of test is made by filling a tube with a solution containing 8 mgms. of potassium dichromate and 0.4 gram of cobalt sulphate per litre. The test is an official one in France and Holland, and is frequently used in combination with other tests; the temperature of the test being varied.

An objection to it is the length of time it takes for completion; for example, as used in Holland, guncotton heated for 10 hours a day at 95° requires 21 days before red fumes are developed.

Abel heat test is the English official heat test applied to nitro explosives generally, and is defined by the Explosives Act, 1875. The principle of the test is to note the time required to produce a standard discoloration of a test potassium iodide-starch paper, when the explosive is heated under specified conditions. The explosive is weighed out into test-tubes, about $5\frac{1}{2}$ to $5\frac{1}{2}$ inches long, and holding 20 to 22 c.c. when filled to a height of 5 inches, which are closed by an indiarubber stopper, fitted with a glass rod terminating in a platinum wire hook. On the hook is suspended a test paper, about 10×20 mm., the upper half of which is moistened

with a mixture of equal parts of glycerol and water. The test papers, on the correct preparation and sensitiveness of which the test depends, are now made by the Home Office and by the War Office, and supplied to manufacturers of explosives. The test-tubes are placed to a depth of 3 inches below the cover, in a water-bath, the temperature of which is carefully regulated, at usually 160° or 180°F . The water-bath is a spherical copper vessel, about 8 inches in diameter, fitted with a cover having a number, usually six, of circular holes, fitted on the under side with clips to take the tubes. The bath is fitted with a thermometer, the bulb dipping $2\frac{3}{4}$ inches into the bath, and usually some form of temperature regulator. The test is complete when the faint brown line which appears at the junction of the wet and dry parts of the test paper, which is adjusted to be $\frac{5}{8}$ inch above the cover, is equal in tint to the brown line on a standard-tint paper. This standard tint is a line drawn on paper of similar make to unprepared test papers, with a solution of caramel in water of defined strength.

The English Government specifications require that nitroglycerin displaced by water from dynamite, shall stand for 15 minutes at 160°F . (71°C .); blasting gelatin and gelatin dynamite 10 minutes at 160°F .; cordite and ballistite, 15 minutes at 180°F . (82°C .); guncotton and tonite, 10 minutes at 170°F . (76.6°C .); and gelatinised guncotton preparations for 15 minutes at 180°F . Smokeless powders are ground in a mill and sifted, and the portion retained between two sieves having holes equal to 14 and 21 B.W.G. respectively is used for the test.

In the United States, the first appearance of a brown line is taken as the end of the test, and the specified times are nitroglycerin, 15 minutes at 160°F .; blasting gelatin dynamite, 10 minutes at 160°F .; nitrocellulose for the Army 40 minutes, for the Navy 30 minutes, at 150°F . (65.5°C .); guncotton from compressed blocks, 10 minutes at 150°F .; nitrocellulose powders, 10 minutes at 100°F . and nitroglycerin-nitrocellulose powders, 20 minutes at 150°F .

In Germany, zinc iodide is used instead of potassium iodide in the preparation of the test papers, which are more sensitive than those prepared with potassium iodide.

This test is perhaps the most generally applicable and most frequently used. Objections that have been raised to it are that it is purely empirical, and depends largely on the conditions of its application, and further that it is really a test for traces of unstable impurities, and not of the absolute stability of the explosive itself.

Guttmann, in 1897, pointed out that the Abel test could be masked and falsified. With an explosive containing residual solvent, such as acetone, the test depends on decomposition of the nitro compounds, combined with the retarding influence of the solvent. In a similar way, the small quantities of stabilisers added to nitro explosives influence the time of test.

This is of little importance so long as these masking agents are recognised constituents of the explosive and present in their normal amount, or are extracted before the test is taken, as the limits of the test are fixed accordingly.

Mercuric chloride, which has a very strong masking influence on the heat test (as little as one part in 50,000 appreciably lengthens the heat test of cordite) is, in some countries, a recognised constituent of certain gun-cotton explosives, with the idea of sterilising them, but its use is not permitted in this country.

Modifications of the Abel test have been suggested, principally with a view of obviating the influence of masking agents. Guttman (J. Soc. Chem. Ind. 1897, 287), for example, proposed a test paper treated with diphenylamine dissolved in sulphuric acid, which gives an intense blue colour with traces of nitrous acid; and Hoitsema (Zeitsch. angew. Chem. 1899, 705) proposed the same reagent used in a different manner. This indicator works well with gun-cotton explosives, but with nitroglycerin explosives the results are erratic, and they can also be readily masked.

Metaphenylenediamine was suggested as the best reagent by Spica, in 1899, but this again does not seem to work well with nitrocellulose-nitroglycerin explosives, and neither of the proposed modifications has been adopted.

Silvered-vessel test.—This test was devised at the Royal Gunpowder Factory, Waltham Abbey, to give an idea of the amount of deterioration that a sample of cordite had suffered, and from this to judge the further length of time it would be safe to store the cordite at any given temperature.

A silvered vacuum-jacketed flask is filled with the ground sample of cordite and exposed in a bath heated to a constant temperature of 80°. Readings of a thermometer, the bulb of which is in the centre of the cordite, are taken at intervals until the temperature rises 2° above that of the bath. The time taken for this rise of temperature of 2° is a measure of the stability of the cordite. The flask is fitted with a side tube in the neck, and the appearance of brown fumes in this tube indicates the active decomposition of the cordite, and serves as a warning that the test is near completion.

From the time of the test in hours, using a factor that has been established connecting rate of increase of deterioration of cordite with rise in temperature, the length of serviceable life of the cordite at any particular temperature can be calculated.

A newly made Mark I. cordite has a S.V. test of from 500 to 600 hours.

German test.—In this test, which is largely used on the Continent and is one of the American Service tests, 2.5 grams of the air-dry explosive are heated in a glass tube loosely closed with a perforated cork at a fixed temperature, until a folded piece of litmus paper, fixed at 0.5 inch above the explosive, is completely reddened. The temperature of the test is 135°. The time limits are fixed by tests with standard samples of the particular explosive. Besides the time of complete reddening of the litmus, the time of the appearance of brown fumes and the time before the sample explodes, are also noted.

The American limits for this test are: for nitrocellulose and nitroglycerin powders, complete reddening over 30 minutes, brown fumes over 45 minutes, explosion over 5 hours; and for colloided nitrocellulose, complete reddening

over 75 minutes, brown fumes over 2 hours, and explosion over 5 hours.

Vieille test.—This test is the French Service test. 10 grams of the explosive are weighed out, and a piece of standard blue litmus paper is also introduced into a glass tube which is closed as tightly as possible by means of a clamped well-fitting stopper. The tube is heated in a bath maintained at 110°. When the litmus paper is completely reddened, the time is noted and the tube cooled. The sample with a fresh piece of litmus paper is introduced into a second tube and the heating continued. This process is repeated until a period of less than an hour is taken to completely redden the litmus paper. The sum of the number of hours of the previous heatings is then taken as the time of the test.

Vieille found that, as the temperature of the test was raised, the time is reduced in arithmetical progression, and concluded that 110° is the best temperature for giving reliable results within a reasonable time.

'Poudre B' has a Vieille test of approximately 50 hours.

There is a gradual loss of nitrogen from the powder during the test which Vieille found to be approximately 0.009 p.c. nitrogen per hour, during a test of 100 hours (Mém. des Poudres et Salpêtres, 1909, 71). The decrease in the nitrogen content, and the time taken to first redden the test paper, are both considered in conjunction with the total time of the test in sentencing a powder.

Will test.—This test gives a quantitative idea of the stability of a nitrocellulose, and is very largely used in conjunction with such tests as the Abel test. The test, which is fully described by Will in the Mitt. aus der Centralstelle f. Wissensch. Tech. Untersuchungen, 1900, [2] 5, and 1902, [3] 34, is based on the measurement of the nitrogen evolved from gun-cotton when heated at a temperature of 135°. 2½ grams of the dry nitrocellulose, or 3½ grams of moist nitrocellulose as it leaves the centrifugal machines, are weighed out into a glass decomposition tube and compressed to a given volume. This tube is connected at one end with a pre-heating glass coil, and is fitted at the other end with a well ground-in exit tube. The tube is placed in an oil-bath fitted with a stirrer, the temperature of which is carefully regulated to 135°. To remove the products of decomposition as fast as they are formed, a uniform current of purified, air-free, carbon dioxide is passed over the heated nitrocellulose at a rate of about 25 c.c. per minute. The gases after passing over heated copper gauze, contained in a heated copper U-tube, to reduce the oxides of nitrogen, are collected over caustic potash in a gas burette, with a special zigzag arrangement to give thorough absorption of the carbon dioxide. The column of the nitrogen collected is read off first after 30 minutes, then after every 15 minutes for a period of about 4 hours, the caustic soda being frequently renewed. Explosions may occur, and the oil-bath is surrounded by a strong screen. The results are plotted on a curve. The gas from a stable nitrocellulose should be evolved at a uniform rate, and, if this is so, Will considers that the sample is normal, or has attained a 'limit state' of purification.

With unstable samples, the gas evolution is much greater at first than later in the test.

To interpret the results given by any nitrocellulose explosive, a set of standard curves must be obtained from well-purified samples for purposes of comparison. English Service gun-cottons average an evolution of 7.5 mgms. \pm 1 mgm. of nitrogen per 4 hours (Robertson).

Reiss test.—This is a modification of the Will test, in which the decomposition is effected at 135° *in vacuo*.

This modification is the one usually applied to high explosives of the nitro class, the temperature of the bath and time of heating varying with the explosive. The decomposition tube is connected by means of a well-fitting stopper, having a mercury lute with a long mercury manometer tube in which the gas volumes are read off at intervals for some days, and the results, corrected to N.P.T., plotted and interpreted by reference to curves obtained from standard samples.

Obermüller test.—This test is similar to the last, except that the gas volumes are not calculated, but the pressures exerted by the evolved gas, the volume of which is kept constant, are recorded. The rate at which the pressure increases is taken as a measure of the decomposition, and so of the instability of the explosive. For nitrocellulose, the temperature of the test is 140° . Mittasch (Zeitsch. angew. Chem. 1903, 929) describes a similar test in which the gas evolution is automatically recorded.

Bergmann and Junk test.—This test gives very reliable results, and has been largely used, especially in Germany. 2 grams of the dry nitrocellulose are weighed out into a tube 35 cm. long and 2 cm. wide, and pressed down. The decomposition tube is connected with a ground-glass stopper connected with an absorption bulb containing water. The explosive is heated for 2 hours in a bath, kept at a constant temperature of 132° by boiling amyl alcohol. The decomposition tube is then allowed to cool, and the water to flow back on the explosive. The contents of the tube and apparatus are washed and filtered, the filtrate oxidised with permanganate, and the nitrogen estimated as nitric oxide by the Schulze-Tiemann method. The limits of gas evolution fixed are 2.5 c.c. of NO per gram gun-cotton, or 2 c.c. per gram collodion cotton. This test is considerably influenced by the amount of moisture present in the sample.

Sy test.—This is a U.S. Service test (J. Amer. Chem. Soc. 1905, 549). 1 to 4 grams of the explosive are weighed out on a covered watch glass and heated in an air-bath, maintained at a constant temperature of 115° by a boiling mixture of xylene and toluene. After 8 hours' heating, the watch glass is cooled and weighed, and the process repeated daily for some six days or more. The daily loss in weight, mgms. per 1-gram sample, is plotted out, and comparison made with standard curves. The advantages claimed for this test are that whole pieces of the powder are tested, and that all volatile products of decomposition are determined.

Jacqué test is a modification of the above, made in order to reduce the time of the test (Zeitsch. Ges. Schiess- u. Sprengstoffwesen, 1906,

395). The sample is heated at 130° – 140° , and weighed after successive 2 hours' heating.

Intensity of Action of Explosives.

The intensity of action of an explosive depends on the volume of gases produced, on their temperature, and on the velocity of explosion or detonation of the substance.

Closed-vessel experiments.—The 'strength' of an explosive may be calculated by Berthelot's 'characteristic product,' QV_0 , where Q is the heat of explosion of unit weight, and V_0 the calculated volume of the gaseous products of explosion at 0° and 760 mm. pressure. The results so obtained are generally in the same direction as the results experimentally obtained for 'strength' by the lead block test. The volume of permanent gases and the quantity of heat evolved have been determined for many of the more important explosives; but the gases collected and examined are those remaining after cooling down to atmospheric temperatures, not those existing at the period of maximum temperature. The uncertainty as to the nature and the specific heat of the products of explosion at the high temperatures produced, renders the calculation of quantity of heat into temperature hazardous. The experiments are carried out with different densities of charge in some form of steel bomb, similar to Berthelot's calorimetric bomb, as used in the experiments of Abel, Noble, Deering, Macnab, and others already mentioned, details of which are given in the papers referred to.

The pressures developed in the bomb are usually measured by a *crusher gauge*. This consists of a small steel cylinder, closed at one end, into which a collar screws gas-tight. A piston working through the collar fits against a small cylinder of copper resting on the bottom of the cylinder chamber. On firing the explosive, the gas pressure acting on the end of the piston compresses and shortens the copper cylinder. The pressure in tons per square inch corresponding to the reduction in length of the cylinder, accurately measured on a micrometer scale, is obtained from tables compiled from the compressions produced by various statical pressures. Other methods of measuring the pressure are used. Deering checked the results obtained with the crusher gauge by closing an orifice of the bomb with a steel ball held in position by heavy lead cylinders. The weight was gradually reduced until the pressure was sufficient to lift the load. Several pressure gauges have been invented for directly measuring the pressure. For example, Bichel (Eng. Pat. 18273, 1898) has designed a gauge, fitted into the explosion vessel, which records the pressure developed by means of a pencil working on a drum, rotating by clockwork. Some knowledge of the rapidity of the explosive is also obtained by the steepness of the curve recorded, and the pressure of the cooled gases is indicated when the curve becomes horizontal. From the latter and the volume of the chamber, the volume of permanent gases can be calculated. Petavel (Proc. Roy. Soc. 1905, 492) describes a method of measuring the pressure developed by explosives by means of a specially constructed manometer which records photographically on a revolving cylinder.

The attempts of Macnab and Ristori to experimentally measure the temperature of explosion have been already referred to. Bichel has attempted to obtain an idea of the temperature of explosion by taking spectrum photographs of the flames produced on detonation.

Information of value, concerning the intensity of action of explosives, may be obtained by detonating a charge (a pound or so in weight) buried in earth, and observing the size of the crater; or by noting the reaction effects (the dimensions of the crater) produced on undisturbed earth, or the bulge or hole produced in wrought-iron plates, by the detonation on them of the explosive; comparison being made with an equal weight of guncotton or other known explosive, the charges having the same area and shape (most conveniently cylindrical).

Lead cylinder method: Trauzl test.—In this method the enlargement of the cavity in a lead block of given dimensions gives a measure of the power of the explosive. Abel's results, quoted in this article, were obtained by this method, using cylinders of soft, pure lead, 12 inches high and 12 inches in diameter, with a central cylindrical hole 7 inches deep and 1.3 inches in diameter, in which 1 oz. of explosive is detonated. With cylinders of these dimensions, no cracking through of the bottom is to be anticipated; the diameter of the bore hole just takes a service 1 oz. dry guncotton primer, which is used as a standard of reference. The lead cylinder is placed on a stout iron plate, the weighed explosive (cast or compressed into a cake, or rammed to a known volume in the bore hole, according to circumstances) with a mercury fulminate detonator (or suitable priming such as will produce a maximum effect on detonation) inserted into it is placed at the bottom of the bore hole, the latter filled with fine sand poured into it without pressure, and the detonator fired electrically or by safety fuse. The volume of the cavity produced is ascertained by means of water and a graduated vessel, and the volume of the bore hole being deducted gives the enlargement. With an unknown explosive, several experiments are necessary to ascertain the best conditions of detonation. This test is only reliable for the comparison of explosives of the same type, and the results obtained with slow-acting explosives are of little value. The higher the velocity of detonation, the greater the expansive effect.

Standard conditions for carrying out this test were suggested by the 5th Inter. Congress of Applied Chemistry, Berlin, 1903. The standard dimensions of the lead cylinder are, height 200 mm., diameter 200 mm., with an axial bore hole 125 mm. deep and 25 mm. diameter. The lead must be pure and soft and the cylinders used in a series of tests must be cast from the same melt. The temperature of the cylinder must be uniform throughout and between 15° and 20°. 10 grams of the explosive are formed into a cartridge 25 mm. in diameter by wrapping in tinfoil, weighing 80–100 grams per square metre. An electric detonator with a charge of 2 grams is placed in the midst of the explosive. The charge is gently pressed to the bottom of the bore hole by means of a wooden stick and the bore hole filled up with dry quartz sand.

After firing, the cavity is brushed out and finally measured.

Sand bomb method.—This method of testing the explosive power was developed for detonating explosives by Storm and Cope (U.S. Bureau of Mines, Tech. Paper 125). A detonator charged with the explosive under examination is fired, by means of a length of safety fuse or electrically, in the centre of 100 grams of sand contained in a cylindrical steel bomb, 21 cm. × 9 cm., cavity 15 cm. × 3.1 cm., fitted with a loose cover perforated for the firing fuse or wires. The sand used is a pure quartz sand, passing a 20-mesh sieve, and retained on a 30-mesh sieve. After the detonator has been fired the sand is sieved through a nest of five sieves of 30-, 40-, 60-, 80-, and 100-mesh to the linear inch, and the strength of the detonating charge determined by the comminution. It was found that the total weight of sand that passes the 30-mesh sieve after the test is a measure of the strength of the explosive. Storm and Cope found that the quantities of pulverised sand are directly proportional to the weight of explosive charge in the detonator, and also showed, for instance, that the strength of mercury fulminate and fulminate-chlorate mixtures of different proportions as indicated by this test, was in the same direction as their relative efficiencies in initiating detonation in other explosives.

Abbot's ring apparatus.—Many of the earlier values for the intensity of action of explosives were obtained by Abbot in the ring apparatus described in his classical report upon 'experiments and investigations to develop a system of submarine mines' (Washington, 1881). The explosive was contained in a suitable case fixed in the centre of a wrought-iron ring 4 feet in diameter into which six lead crusher gauges were fixed at equal intervals. The apparatus was submerged in deep water, and the explosive fired electrically. The explosive force was obtained as usual from the shortening of the lead cylinders.

McRoberts has described a method of comparing explosives by the reaction effect their detonation produces on a pendulum-hung mortar weighing about 600 lbs. The distance from the centre of suspension to centre of trunnions is exactly 10 feet; the mortar is set with its axis horizontal. 10 grams of explosive are placed in a small recess behind the chamber for the projectile; the latter weighs about 40 lbs. and fits the bore gas-tight. The explosive is fired by means of a fuse and detonator; the angle of recoil of the mortar is marked on a graduated index by a pencil which the former carries. The work done by the explosive is twice that done in raising the mortar through the versed sine of the angle of recoil; this is expressed in foot-pounds.

Detonative power and sensitiveness to detonation. The sand bomb apparatus used for detonating the explosive power is adapted for determining the detonative power or sensitiveness to detonation of explosives, as worked out by Taylor and Cope (U.S. Bureau of Mines, Tech. Paper 145). In this method a composite detonator, containing a fixed base charge of some nitro explosive, say trinitrotoluene or 'tetryl', is primed with diminishing quantities of the detonating explosive, whose detonating

power is to be tested, and fired in the bomb, the minimum quantity of the priming explosive necessary to give certain and complete detonation determined. The relative sensitiveness of various explosives to the initiation of the same detonant may also be determined in the same way, by using them as base charges in a parallel series of trials. 0.4 gram of the explosive is weighed out into a copper detonator shell, say 5 mm. diameter, and lightly compressed by means of a glass rod. The priming charge is then introduced, covered with a thin perforated copper reinforcing cap, 9 mm. long with 2.3 mm. perforations, and pressed down with a loading pressure of 200 atmospheres per square inch. Incomplete detonation is indicated by a small comminuting effect on the sand, and the presence of part of the unaltered base charge in the sand. For example, by this method it was found that trinitrotoluene is less sensitive to detonation than tetryl, the minimum charge of a priming composition of 9 : 1 fulminate-chlorate required for certain and complete detonation was for trinitrotoluene 0.25 gram, and for 'tetryl' 0.19 gram. The sensitiveness of trinitrotoluene was found to be increased by admixture with 'tetryl' in proportion to the amount added. Lead azide was found to be a particularly good detonant for tetryl.

The 'Esop test' is another method of determining the detonating power of explosives, the principle of which is to determine that mixture of picric acid with olive oil containing the highest proportion of oil that the detonator will just detonate.

Velocity of detonation. The old method of determining the rate of detonation was to place a number of cartridges end to end, pressed well in contact with one another, so as to form a continuous length of the explosive. This cord of explosive was fired at one end by some efficient detonating agent, and the time of explosion was taken by a Boulengé electro-ballistic chronograph, as described under 'Ballistics of a propellant,' the two electric currents being successively interrupted by the firing of the two ends of the cord.

The results of numerous experimenters showed that the velocity of detonation increased, up to a certain point, with the diameter of the train of explosive. These experiments required a large bulk of explosive, the train of explosive being usually about 3 cms. in diameter and 35 metres in length, so that they were both costly and dangerous to carry out.

Mettegang's recorder.—An improved, purely electrical method of determining the velocity of detonation was described by Mettegang, at the 5th Inter. Congress of Applied Chemistry, Berlin, 1903. It is a modification of Siemens' apparatus for measuring small intervals of time. The method depends on the consecutive interruption of two wires, carrying a divided current, running through two ends of a long cartridge and connected with a sparking induction coil. The main current passes through a resistance of electric lamps, and to ensure a high potential, no iron core is used in the primary. Any change in the tension of the current passing through the primary coil sets up an induced current in the secondary coil. One terminal of the secondary coil is connected to the bearing of a revolving

drum coated with lampblack, the other terminal ending in a fine platinum point. The induced currents cause sparks from the platinum point which are recorded as tiny specks on the blackened surface of the drum. From the space between these specks and the speed of the drum, the time of detonation of the explosion train is found. The cartridges of the explosive are 3 cms. in diameter, and a total length of 3 to 4 metres is used, the cartridges being enclosed in an iron pipe and buried in sand.

The highest rate of detonation recorded in experiments with numerous explosives is about 8000 metres per second. A 4-metre length of explosive would therefore detonate in $\frac{1}{8000}$ of a second, and with a rotary speed of 25 metres per second the markings on the drum would be 12.5 mm. apart.

The velocity of detonation of explosives has been determined by Dautriche (Compt. rend. 1906, 143, 641), by a method depending on the use of detonating filaments, which had a constant and determined velocity of detonation of 6500 metres per second.

Two equal lengths of the filament are detonated, one of which is cut, and a tube filled with the explosive is interposed. One end of each filament is fixed to a detonating charge of fulminate, the other ends are bound together and fixed on a lead plate. The retardation of the velocity of detonation of the filament with the length of explosive introduced, causes the displacement of a depression mark on a sheet of lead from the position given when two equal uncut filaments are used. This displacement with the known velocity of detonation of the filaments give the time of detonation of the given length of the explosive.

Sensitiveness to percussion. The relative sensitiveness of explosives to direct blow is usually determined by finding the height at which a falling weight just fails to fire or explode them in one of several trials, and is frequently expressed in terms of the sensitiveness of an explosive of the same type taken as a standard, say picric acid for high explosives. Weights of different mass are used for explosives of different type, a 5-kilo weight being common for high explosives, in the form of a cylinder, with a plane striking face, and fitted at the sides with pulley wheels which run down vertical guiding rails. The explosive is spread evenly on the face of a heavy steel anvil, sometimes being covered with a steel disc, or the layer may be spread between two discs. With the less sensitive explosives a partial explosion or ignition occurs with a considerably less blow than that required to give complete detonation, and it is frequently difficult to say with certainty whether any decomposition has taken place or not. In these cases the limiting blow has to be fixed by a spark or faint flash, by smoke, or a stain on the anvil, or even the odour of decomposition products rather than by noise of explosion, and the results at the best are only approximate.

A sharper result is obtained with detonating explosives, and a more quantitative result can be obtained by the following method: the explosive in a very thin but continuous layer is placed on a dead-hardened and surfaced steel block and covered with a small steel cylindrical

striker enlarged at the head and tapered at the base to give a circular striking surface, say, 0.2 inch in diameter, which is again dead-hardened and truly planed. This striker, which is pressed well down on the explosive, is held in a vertical position by means of a steel collar, in which the fit is good without offering any noticeable friction. The blow communicated through the striker is obtained by dropping a steel ball, falling freely and electrically released from a pointed magnet of just sufficient strength to support it, on to the centre of the top surface of the striker. The fall of the ball, the weight of which is selected according to the sensitiveness of the explosive, is determined by adjusting the electro-magnet fixed in a clamp working on a rod graduated in tenths of a foot. The shortest fall is determined, to one-tenth of a foot, which does cause ignition or explosion in at least one out of five attempts, and also the longest fall which does not cause ignition or explosion in each out of five successive attempts. From these falls the blows in foot-pounds per square inch are calculated, and a mean in round figures is recorded as the sensitiveness of the explosive. This method eliminates such influencing factors as friction of the pulley-wheels on the guides, the resistance of burred edges on the discs, and the blow of the falling weight not being truly given by the full striking surface, and it is only necessary to carefully adjust the layer of explosive to not only obtain concordant results, but also a quantitative idea of the blow required for ignition or explosion under the conditions of the test.

Detonator caps are tested by the fall, to a limiting height, of a small weight with a striking steel pointer.

Sensitiveness to friction. No satisfactory quantitative method of testing the sensitiveness of explosives to pure friction has been devised. One qualitative method is to rub the explosive between two surfaces of sand-paper fixed to a board and a sliding block of wood respectively, the latter being suitably weighted. This method is far from satisfactory; mercury fulminate, for instance, may frequently be reduced to fine powder by this means without firing.

The *sensitiveness to a glancing blow* is more usually taken as a measure of the comparative sensitiveness of explosives to friction, but this, again, can only be determined approximately. The method usually adopted, in which the personal factor is considerable, is to determine the number of ignitions or explosions obtained in a series of hard glancing blows with a box-wood mallet or steel hammer of given weight on a thin layer of the explosive spread out on a wooden floor, and on a stone and steel anvil alternatively.

As with sensitiveness to direct impact, the explosive must be at approximately normal temperature when tested, as the sensitiveness is increased with rise of temperature.

Sensitiveness to heat. The temperature of ignition of an explosive is very dependent on the conditions of the test. When slowly heated the ignition-point is lower than when the heat is suddenly applied, the heat of decomposition of the explosive causing its temperature to rise locally above the recorded temperature to the ignition-point. The ignition-point should be

taken as the temperature at which a not too small quantity, not less than 0.02 gram, ignites after it can reasonably be expected to have reached the recorded temperature, kept constant, say, after not longer than 5 seconds. The explosive is usually placed in a lightly covered thick glass tube immersed in a bath of air, oil, or fusible metal. Another useful form of apparatus is a long copper bar of square section in which two holes are drilled symmetrically with respect to the end of the bar, into which respectively a thermometer and small glass tube fit closely, so that the centre of the thermometer bulb and the bottom of the explosion tube are on a level with the axis of the bar. The temperature can be readily controlled by adjusting the size of the heating flame and its distance from the thermometer and explosion tube. The approximate temperature of ignition is first determined by gradually heating up the bath or bar until the explosive fires, and then the firing-point determined by trials with fresh quantities of explosive heated at definite temperatures, noting the lowest temperature at which explosion occurs under the conditions given.

Character and duration of flame. The photographing of the flame of explosives was first attempted by Schoeneweg, the inventor of *securite*, and is now very largely used in determining the character of the flames of mining explosives, propellants, and cap compositions.

In testing the flame of explosives, they are fired at night from a vertical steel cannon with a graduated scale placed behind it. The flame is photographed upon a drum covered with a sensitised film, rotating between screw pivots in a guide bracket, contained inside a box provided with a quartz camera lens for focussing the ultra-violet rays attending extreme heat. With the drum at rest, the length of the flame is obtained. To obtain the duration of the flame, the drum, which is motor-driven, is set in motion, and as soon as the required speed is obtained, the shot is fired electrically. From the speed of the drum and the lateral extension of the blurred image of the flame, the duration of the flame is obtained. According to Bichel, the limit values for the length of flame of a safety explosive lie between 0.4 and 2.24 metres, and the limit values for the duration of flame between $\frac{0.23}{1000}$ and $\frac{10}{1000}$ of a second. Coal carbonite and blasting gelatin were taken as representing the two extremes.

Bichel compares the '*after-flame ratio*' of different explosives, that is, the ratio of the velocity of detonation, taken as unity, to the duration of the flame, as an indication of their safety. This ratio for coal carbonite is 1:8.7, and for blasting gelatin 1:883, so that Bichel concludes that the former is 100 times as safe as the latter. The flame of all explosives outlasts the time of detonation, but that of the safer explosives does so in much less degree than those of the less safe.

Ballistics of a propellant. So far as explosives are concerned, only the internal ballistics are meant when ballistics are referred to, that is, the phenomena which take place from the time ignition is brought about until the projectile is clear of the influence of the explosion gases. The ballistics concern principally the pressures

developed in the gun and the muzzle velocity of the projectile. They can be calculated with some degree of accuracy for any particular gun, with any special nature and form of propellant, knowing the gravimetric density of loading, that is, the ratio of the volume of the powder to the capacity of the gun chamber, and the chemical composition and rate of burning of the powder. When explosion first takes place, the gun chamber may be looked upon as a closed vessel, so that the intensity of the initial chamber pressure and the rapidity with which it develops, depend directly on the loading density. The pressures obtained in a closed vessel are, however, never attained, owing to the motion of the projectile enlarging the chamber and lowering the gravimetric density.

In practice, the pressures attained in the bore of a gun are measured experimentally by means of crusher gauges, which are screwed into the bore of the gun at regular intervals, but in the ordinary proof testing of a propellant only the maximum chamber pressures are determined by means of a crusher gauge placed in the chamber. These crusher gauges have already been described in connection with the measurement of closed-vessel pressures.

In proving propellants, the velocity that a given charge will impart to a projectile in a particular gun, is determined by means of a Boulengé chronograph or some modification of this apparatus. The time taken by the projectile to pass over a known distance is determined in terms of the space passed through by a freely falling body in the same time. The projectile cuts through wires stretched on two frames a known distance apart. The cutting of the wire on the first frame liberates a rod suspended by an electro-magnet. The cutting of the wire on the second frame puts into action, by means of a second dropping rod falling through a shorter distance, a knife edge, which makes a nick in the first falling rod. From the space fallen through by the marked rod, the time for the projectile to pass over the distance between the two screens can be calculated.

In testing the ballistics of nitro propellants, they are heated to a definite temperature for some time before firing.

Bibliography.—A chronological bibliography on explosives up to the year 1895 will be found in the second volume of Guttman's *The Manufacture of Explosives*.

G. H. P.

EXTRACTION APPARATUS. The object of extraction is to dissolve out some constituent or constituents from a substance by treating it with a solvent. When the substance is a solid it may be allowed to soak in the solvent at ordinary temperatures (*maceration*) or at higher temperatures (*digestion*), the solution being after a time poured off, both methods being included under the term *infusion*; a third method is to boil the substance with the solvent (*decoction*); and a fourth is to allow the solvent to descend through a column of the substance placed in a suitable vessel (*percolation* or *displacement*). The treatment when the substance is a liquid will be considered further on.

Solids.

Processes of extraction are involved in many of the large industries; for instance, in brewing; in the 'diffusion' process of obtaining sugar from sugar beet or sugar cane; in the 'lixivation' employed in the manufacture of various inorganic salts, &c., &c.; and descriptions of them will be found elsewhere. Besides these, extraction apparatuses are employed in the laboratory of a small size for quantitative work, and on a larger scale for making various preparations; in the manufactory they are used for preparing medicinal extracts, alkaloids, dyestuffs, tanning materials, and volatile oils, and in removing oil from seeds and fat from bones. A mathematical discussion of the processes of extraction of solids, including cases of the *counter current* system, is given by Hawley in *J. Ind. Eng. Chem.* 1917, 9, 866; 1920, 12, 493. See also Lewis, on p. 110.

When water is the solvent employed, the operation may be conducted in a large pan made of copper or nickel or enamelled iron fixed in an outer jacket of iron, so that a space is left between the pan and the jacket through which steam can be made to circulate and heat the contents of the pan. Such pans are either fixed and have a pipe and tap at the bottom to draw off the solution, as shown in section (Fig. 1), or else they are movable about

FIG. 1.

FIG. 2.

an axis (Fig. 2), so that the pan can be tilted and the solution poured off; in these, the axes on which the pan rotates are tubular to permit steam to enter and escape from the space between the pan and its iron jacket. When the infusion has been continued for a suitable time, and the liquid has been drained off, the residue

is placed in a canvas bag and subjected to strong pressure in a screw press, in order to squeeze out as far as possible the last portions of the solution. A common form of press consists of a base to which two uprights with a cross bar at top are fixed; in a thread cut through the centre of the cross bar works a powerful vertical screw. Between the uprights is a strong metal or wooden cylinder perforated with a number of holes; in this the bag of residue is placed, and on top is placed a thick plate which transfers the pressure exerted by the screw to the bag and its contents. The cylinder rests in a tray of a somewhat wider diameter, and provided with a spout; this tray collects and conducts off the expressed liquid to a vessel placed beneath the spout. Instead of pressing the residue, it may be infused several times more with water until it is completely exhausted of the desired constituents, but this method involves a large amount of subsequent evaporation. The solutions obtained by the above processes are next strained through conical bags of linen or flannel, and then evaporated down in jacketed pans like those previously described, the liquid being kept in motion by a mechanical stirrer.

FIG. 3.

In many cases, evaporation at temperatures near 100° has an injurious effect on the substances in solution, and some arrangement for evaporation in a partial vacuum is adopted; this enables the evaporation to be conducted at a lower temperature than when the liquid is subjected to the pressure of the atmosphere.

In the process of *percolation* or *displacement*, the powdered substance is placed in a long cylindrical or conical vessel (Fig. 3), and rests on a perforated disc placed near the bottom and which can be covered with a piece of linen or flannel. A conical vessel is preferable to a cylindrical one, as the mass adjusts itself more readily to the vessel when any change of volume occurs; in a cylinder, if the mass swells on absorbing the solvent, it is apt to become so tightly packed that the liquid cannot pass, or, if it contracts owing to the removal of soluble constituents, it is more liable to form cracks and channels. A second perforated disc of linen or of paper pierced with holes is laid on top of the substance to distribute the solvent uniformly. It is often advisable to damp the powder with about half its volume of the solvent before packing it into the percolator, otherwise some portions may be found to have escaped getting wet during the whole operation. Care must be taken in packing that the substance is throughout in as uniform state of compression as possible, or else the solvent will pass more freely through the loosely packed portions. Different substances require to be packed with different degrees of tightness; and when alcohol or ether are the solvents employed, the packing may be tighter than in the case of water, as they do not cause such a swelling of the substance as water does. The conical vessel is supported in a circular hole cut in a table or wooden stand, a

vessel is placed underneath to receive the solution, and the solvent is poured from time to time on the top. A row of such percolators can be arranged so that the solution from the first is poured on to the next and so on along the row, by which plan the liquid from the last will be a strong solution, and the percolators that are more nearly exhausted will receive the weaker and therefore more active liquids. This is a typical case of the *counter-current* system.

Glass percolators are also used consisting of an upper vessel to hold the substance and of a lower vessel to catch the solution. The upper vessel is stoppered to prevent loss of alcohol or ether vapour, but there must be a small aperture to allow air to enter in order to prevent a partial vacuum being formed. In extracting some plant materials cold percolation is found preferable to hot extraction as the desired constituent is obtained with less troublesome and undesired substances accompanying it and so is easier to purify.

For some purposes, more elaborate forms of aqueous extraction apparatus are preferable. Of these the following is an example:—

Hänig and Reinhard's apparatus (Fig. 4).—This is designed for extracting dyewoods, &c., by the action of steam and water. A and B are two similar vessels (A is shown in section) which can be made to revolve about the axes *xy*, *xy*, by means of the gearing *c*, *c*, so as to facilitate filling and emptying. The axes are tubular and serve for conducting steam and water. In communication with the axis *x* are two pipes having taps *a'* and *a*; one ascends and leads into the upper part of the vessel, and the other descends, and, passing through the bottom of the vessel, leads to a perforated pipe, *g*, which forms a ring underneath a perforated false bottom, *h*. Communicating with the axis *y* is a pipe which descends and, following the dotted lines, joins on to the back of the three-way tap *b*. This tap *b* communicates with the space beneath the false bottom and also with the air. Another three-way tap, *c*, affords means of communication between the two axes *y*, *y*, and also with a pipe at the back indicated by the circle of dots. The covers of A and B can readily be taken off and fastened on again by the row of screws *s*, *s*, *s*. These covers form the condensing apparatus; inside they possess one or more flat horizontal coils *w*, *w*, to which water enters through the tube *m*, and escapes through *n*, and then flows over the whole lid, forming a layer on the top, and is thence conducted away. *e* and *f* are openings for air and safety valves, and *d*, *d*, *d* are taps for ascertaining the level of the liquid inside the vessel.

To work the apparatus A and B are filled with the substance to be extracted, and the covers are fastened on. A suitable quantity of hot water is introduced into A through the tap *c*, placed in such a position that it passes down the pipe *t* and through the tap *b* into A. Steam is now passed in through the axis *x*, and through the valve corresponding to *a*, and escapes through the perforations of the pipe *g*, heating the water and the substance and ascending to the top, where it is condensed and flows as liquid back to the bottom again. The action is further accelerated by opening the valve corresponding to *a'*, and passing steam in at the top of the apparatus.

The first few solutions, which are strong, are drawn off by the tap *b*, then the later and weaker ones are forced by the pressure of the steam into the vessel *B*, the taps *b* and *c* being placed so as to lead to that vessel. *A* is then emptied and refilled with fresh material, and *B* is now worked in the same way that *A* was. By proceeding in this way alternately with *A* and *B*, the later and weaker solutions from one vessel come into contact with fresh material in the other and become strong, and thus economy in evaporation is effected (D. R. P. 18922, 1881; and Dingl. poly. J. 1882, 246, 22, a later form of that in D. R. P. 10771, 1880; and Dingl. poly. J. 1880, 238, 332).

In the laboratory most extractions are made with non-aqueous solvents, but those of tanning materials are made with water. For descrip-

tions of the methods, see the article on LEATHER; and see Procter's Leather Industries Lab. Book of Anal. and Exp. Methods, 1908. Other references are: Wöllny (Zeitsch. anal. Chem. 1885, 24, 50); Koch (Dingl. Poly. J. 1888, 267, 515); von Schroeder (Zeitsch. anal. Chem. 1886, 25, 132); Boegh (J. Soc. Chem. Ind. 1899, 18, 303), comparative results with various apparatuses; Veitch (J. Amer. Chem. Soc. 1905, 27, 724; and 1906, 28, 505), recommends using water in adaptations of Zulkowski's or Soxhlet's apparatus; Rogers (*ibid.* 1906, 28, 194); Wilson (J. Soc. Chem. Ind. 1912, 31, 97) describes a form in which non-volatile solvents can be made to circulate over the material by means of a vacuum pump; Benson and Thompson (J. Ind. Eng. Chem. 1915, 7, 915).

FIG. 4.

SOLVENTS OTHER THAN WATER.

When solvents other than water are used it becomes desirable to avoid the loss that would be involved in pouring off the solvent and pressing the residue, and also to make a minimum of solvent do a maximum of dissolving; various forms of apparatus have been devised to attain these ends, the principle involved being to distil off the solvent from the solution and use it over and over again, and most of the forms are arranged so as to work automatically and to require but little attention. In general, they consist of a receiver in which the solvent is boiled, and to which the solution of the extracted constituents returns, of an extraction vessel in which the substance is placed, and of a tube or space to conduct the vapour to a condenser, which cools and returns the liquefied solvent to the extraction vessel. If this tube is made to pass outside the extraction vessel, the extraction goes on in the cold, or nearly so; but if the vapour encircles the extraction vessel, or if the tube passes through the material, the solvent action is increased by heat which may or may not be desirable.

There are three main plans on which they are constructed, namely:—

A. Percolation.

B. Continuous infusion. In this plan the substance is always immersed in the solvent and

in most forms the solution leaves the extraction vessel at the bottom, rises, and overflows back to the receiver.

C. Intermittent infusion. This plan has the advantage of removing one lot of solution and bringing quite fresh solvent into contact with the substance from time to time; since 1879 it has been brought to a high degree of perfection by exchanging the overflow tube of the second plan for a siphon, which makes the action an automatic one, the improvement being due to Soxhlet and Szombathy.

The number of forms for laboratory use that have been described in chemical journals, taking those for solids and liquids together, amounts to over 200. Some of them are triumphs of glass-blowing, but promise to be very fragile and difficult to clean, especially those designed for extracting liquids. Difficulties have been met in various ways. If corks are used for making junctions, there is the possibility of their yielding matter to the solvent, and a previous extraction with solvents may be required, which does not improve their qualities; if large, they have pores which allow the escape of some of the vapour. A covering of tinfoil is one remedy proposed, another is the use of chrome-gelatin recommended by Neumann (Ber. 1885, 18, 3064). The cork is smeared with a preparation made by dissolving 4 parts of gelatin

in 52 parts of boiling water, filtering, and adding 1 part of ammonium dichromate, and is then exposed to light for 2 days, which renders the mixture insoluble in water, ether, and benzene. Another alternative is to use ground glass stoppers and joints, as in the apparatuses of Sanders, Jerwitz, von der Heide, and others; these are apt to jam and break. A third plan is to employ mercury seals, as in Schwarz's apparatus, and in Knorr's. It is much in favour in the United States. A simple way of making a mercury joint is given by Leather (J. Soc. Chem. Ind. 1889, 8, 81). When mercury is used, all minute globules of it must be carefully removed before weighing a vessel, as their weight is considerable.

To prevent portions of the substance being washed into the receiver, it is often necessary to enclose it in a cartridge of filter paper, or in a holder of filter paper shaped like a thimble; such thimbles are now manufactured for the purpose. Boeck (J. Ind. Eng. Chem. 1912, 4, 303) recommends a thimble made of alundum (that is bauxite fused in an electric furnace) fired with some suitable ceramic bonding material, it can be made as porous as desired. Forbes (*ibid.* 544) finds that alundum vessels alter a little in weight by varying treatment. Aluminium cups perforated at the bottom to hold the thimble or the substance directly, have been described (Richardson and Scherubel, *ibid.* 220; and Bersch, J. Soc. Chem. Ind. 1901, 20, 389).

Various accessory devices have been added to the Soxhlet and other forms; the object of some being to divert at will the stream of condensed solvent from returning to the receiver and to collect it apart. In this way, at the end of an extraction, the solvent can be distilled off and recovered without disconnecting the apparatus. Such are those of Shenstone (Chem. Soc. Trans. 1883, 43, 123); Wollny (Zeitsch. anal. Chem. 1885, 24, 49); Fresenius-Offenbach (Zeitsch. angew. Chem. 1896, 485); Chatelan (Chem. Zeit. 1901, 25, 612); van Leeuwen (*ibid.* 1907, 31, 350); R. von der Heide (*ibid.* 1911, 35, 531); Friedrichs (J. Amer. Chem. Soc. 1912, 34, 1509; and Zeitsch. angew. Chem. 1912, 25, 2208). Further, a tap can be attached either to the bottom of the extraction vessel, or somewhere on the tubes, so that some of the solution can be drawn off for testing, as described by Lewkowitsch (Chem. Soc. Trans. 1889, 55, 359); Landsiedl (Chem. Zeit. 1902, 26, 274); Stein (*ibid.* 1909, 33, 1115); Taurke (*ibid.* 1912, 36, 214); Schmid (*ibid.* 1249). In order to lead ether down from the end of the condenser to the substance, Bain (J. Ind. Eng. Chem. 1910, 2, 455) employs a silk cord with a glass bob at the end; sealed in this bob is a piece of iron wire, so that by means of a magnet it can be drawn to the side to wash particles down. It is sometimes advantageous to attach a calcium chloride drying tube at the top of the condenser to prevent the ether absorbing water.

Below are given descriptions of well-known or typical apparatuses, and also references to other forms that have been described. Apparatuses suitable for the laboratory are taken first, and are, for the most part, grouped on the classification given above, then follow some examples of manufacturing plant.

A. Percolation Forms.

Zulkowski's apparatus (Fig. 5).—The substance is placed in the extraction vessel *E*, and is supported by a plug of cotton wool, *p*. The vapour of the solvent, as it boils off from the flask *R*, passes upwards through the side tube *t*, which is fused on to *E*, and then passes through the adaptor *c* to a condenser. The condensed liquid flows back and percolates through the substance in *E*, and drops again into *R* (Zeitsch. anal. Chem. 1873, 12, 303).

Maly (Annalen, 1875, 175, 80), Wolfbauer (Ber. der Versuchsstationen, Wien, 1878, 1), Weigelt (Repertorium der anal. Chem. 1881, 1, 7), and Flückiger (Zeitsch. anal. Chem. 1882, 21, 467) have described apparatuses which resemble or else are modifications of that of Zulkowski.

Drechsel's apparatus (Fig. 6).—A folded filter, having double the usual number of folds, so that it may fit well to the sides of the vessel, is placed

FIG. 5.

FIG. 6.

FIG. 7.

in the glass globe *E*, and on this paper the substance to be extracted is put. The solvent is placed in the flask *R*, which has a tube *t* fused into its side; on warming *R* the vapour ascending through *t* and through the tube *m*, which is held in contact with *t* by a cork and is fused on to the glass apparatus *c*, passes on to a reflux condenser connected with *c* by the tube *r*. The condensed liquid flows back into *c*, and is led by the tube *n* into the globe *E* where it falls on the substance, and after having percolated through it returns to *R* again (J. pr. Chem. 1877, 123, 350).

Weyl's apparatus (Zeitschrift für Instrumenten-technik, 1885, 5, 126) is an arrangement like Drechsel's, but by the employment of mercury joints an ordinary funnel can be used instead of the glass globe *E*.

Gwiggner's apparatus (Zeitsch. angew. Chem. 1902, 15, 882) consists of a vessel in which a funnel with the filter paper in position can be placed and the substance on the filter extracted by a volatile solvent. The vapour of the solvent rises between the funnel and the outer vessel, and when condensed drops from a ring of points on to the edge of the filter paper. It is useful for extracting sulphur from precipitates and in other analytical operations.

Tollens's apparatus (Fig. 7).—This is an improvement on an earlier form which was described by Tollens (Zeitsch. anal. Chem. 1875, 14, 82).

The substance is placed in the inner tube *i*, which is slightly contracted at the bottom *f*, and then spread out into a rim over which a piece of filter paper is tied. This tube *i* is placed in a wider tube *e*, and rests on a bit of bent glass rod at *f*, which prevents it from closing the aperture into the narrower part *t*. The neck *t* is fitted by means of a cork into a flask containing the solvent, the vapour of which ascends through the space between *i* and *e*, and then through *c* to the condenser. The condensed liquid drops into *i*, and after percolating through the substance passes through the filter paper and back into the flask again (Zeitsch. anal. Chem. 1878, 17, 320). A form, having an extraction tube with a pointed lower extremity, is described by Dunstan and Short (Pharm. J. 1883, [3] 13, 663).

Schulze and von Rampach's apparatus resembles Tollens', with the exception that the inner tube *i*, in which the substance is placed, passes through and is held in its place by the cork at the top of the outer tube *e*. The inner tube *i* is connected with a condenser, and is perforated just below the cork with one or more holes through which the vapour passes up to the condenser (Zeitsch. anal. Chem. 1878, 17, 171).

Scheibler's 1st apparatus (D. R. P. 3573, 1878, and 7453, 1879; Dingl. poly. J. 1879, 234, 128), and also those of West-Knights (The Analyst, 1883, 8, 65) and of Bensemann (Reperitorium der analytischen Chemie, 1886, 6, 390) differ but little from Schulze and von Rampach's.

Knorr's apparatus (Fig. 8).—This is much used in the United States, and was published by the Association of Official Agricultural Chemists. It avoids the use of corks and ground glass joints. *R* is a little flask made by softening the glass round about the neck of an ordinary flask and pressing the neck in so as to form a little depression. Resting on this neck by small projections *p*, there is placed either a tube *e*, with an internal siphon, or a simple percolating tube, ending below in a point, and having a perforated platinum disc sealed in near the point to support the substance. A long covering tube *c* (shown on half the scale of *e* and *R*) comes down over the percolator or siphon tube and fits into the depression in *R* the junction being made tight by a little mercury. *R* is held in position by an indiarubber band passing underneath it, and attached to the two projections *q, q*, on the covering tube. The latter is attached by fusion to the condenser, and the indiarubber stopper of the condenser is either put on before the fusion, or else is slit half way through, so that it can be put on later. *s* is a little siphon to remove any solvent that may collect between the cover and the flask neck. At the end of the extraction by means of an adapter fitting into the mercury joint the solvent can be distilled off and recovered (U.S.A. Dept. Agric. Chem. Division Bull. 28, 1890, 96; and Wiley's Princs. and Prac. of Agric. Anal. Vol. 3).

Variations of Knorr's form are given by Carr (J. Amer. Chem. Soc. 1894, 16, 868), Wheeler and Hartwell (*ibid.* 1901, 23, 338), Fraps (Amer. Chem. J. 1907, 37, 85), Dubois and Robison (J. Amer. Chem. Soc. 1908, 30, 797), Sy (J. Ind. Eng. Chem. 1909, 1, 314), Ames and Bowser (J. Amer. Chem. Soc. 1909, 31, 947), Francis (J. Ind. Eng. Chem. 1911, 3, 673).

Wiley's apparatus (Fig. 9).—This is a compact apparatus used in the United States, it avoids all corks and joints. It consists of a

FIG. 8.

FIG. 9.

large test-tube closed by the brass plate *P*, which has a ground undersurface resting on the ground edge of the test tube. Attached to *P* is the metallic condenser *C*, made of four sections, each formed of two cones fastened base to base; the cross plates shown are circular and direct the current of water against the sides. The substance resting on asbestos is contained in the crucible *E*, which has a removable perforated bottom, and hangs from hooks at the bottom of the condenser. The extract can either be collected and weighed in the test tube; or a little flask *R*, with a funnel *f* above it, can be used; in the latter case a little mercury is put in to fill the space between *R* and the test tube. The solvent is introduced by means of a small funnel through the tube *g*, which is closed when the solvent has boiled for a short time and has driven out the air (J. Anal. and App. Chem. 1893, 7, 65). The apparatus, and a way of arranging it in batteries, is given in Wiley's Princs. and Prac. of Agric. Anal. 1914, 3, 70.

The following are some other small apparatuses: West-Knights (Analyst, 1883, 8, 65); Thomas and Dugan (J. Amer. Chem. Soc. 1905, 27, 293), for removing bitumen from asphaltic mixtures; Jackson and Zanetti (Amer. Chem. J. 1907, 38, 461), a little percolating tube is placed in the flask of solvent and under the end of the condenser; Clacher (Analyst, 1910, 35, 349); Ford (J. Amer. Chem. Soc. 1912, 34, 552); Richardson and Scherubel (J. Ind. Eng. Chem. 1912, 4, 220); Cary-Curr and Cottle (*ibid.* 535 and 856), for testing rubber compounds used on wires; Walker and Bailey (*ibid.* 1914, 6, 497); Stokes (Analyst, 1914, 39, 295); Besson (Chem. Zeit. 1915, 39, 860).

One disadvantage in the percolation apparatus is that the drops from the condenser always fall on nearly the same spot of the surface of the substance, so that some portions do not get such a good chance of being extracted as others. To remedy this, Barbier (J. Pharm. Chim. 1878,

[4] 27, 200) employed an apparatus in which a siphon in a vessel above the percolator pours a considerable volume of the solvent from time to time on the substance, so that the surface of the latter becomes covered with a layer of liquid. The apparatuses of Guérin (*J. Pharm. Chim.* 1879, [4] 30, 511), Stockbridge (*Chem. Centr.* 1885, [3] 16, 280), and of Wollny are others that adopt this plan, and that of the last-mentioned is given below as a type of the class.

Wollny's apparatus (Fig. 10).—This consists of a receiving flask *R* to contain the solvent, and two other pieces shown in section in the figure. These bits are united together by the mercury joints *a*, *b*, *c*, *d*, which are provided with small tubes to permit of their being emptied without tilting the apparatus. The top joint *d* connects the apparatus with the condenser. The substance to be extracted is placed in the tube *E*; it should be contained in a cartridge of filter-paper so as to allow the vapour of the solvent to pass. The vapour ascends the tube *p*, and then passes downwards through *E*, heating the substance on its way, into the space *F*, whence it escapes up the tube *t* to the condenser. The condensed liquid collects in the vessel *V*, and is siphoned off from time to time by the tube *s*, thus ensuring the complete extraction of the substance. The solution returns through *r* and the long tube *q* to the flask again. In cases where boiling the solution injures the dissolved constituents, vapour of the solvent can be introduced through the side tube *r* from another vessel of solvent heated separately, and the flask *R* can be left cold (*Zeitsch. anal. Chem.* 1885, 24, 48). Selecter (*J. Ind. Eng. Chem.* 1915, 7, 871) describes a modernised form on the same plan and less complicated than the above.

Von Bibra (von Gorup-Besanez's *Anleitung zur zoo-chem. Analyse*, 1850, 353) and Hoffmann (*Zeitsch. anal. Chem.* 1867, 6, 370), by alternately heating and cooling the receiving flask, make the solvent pass through the substance. Gawalowski (*Zeitsch. anal. Chem.* 1883, 22, 528) provides a tap on the side tube up which the vapour ascends, in a form like Zulkowski's; if this is closed from time to time, and the source of heat is removed, the contraction in the flask sucks the liquid back through the substance. He also employs underneath an arrangement like Drechsel's, whereby perfect filtration is attained.

Mohr's apparatus (Mohr's *Lehrbuch der Pharm. Technik*, 1847, 108) is an early form often referred to in older chemical literature; it employs a Woulfe's bottle with metal vessels above. Other old forms are those of Payen (*Ann. Chim.* 1845, [3] 13, 59); Schloesing (*ibid.* 1847, [3] 19, 239); Kopp (*Comptes rendus des Travaux de Chimie par Laurent et Gerhardt*, 1849, 5, 305); Arnaudon (*Il Nuovo Cimento*, 1858, 8, 260); Jacobi (*Dingl. poly. J.* 1862, 164, 343); and Storch (*Zeitsch. anal. Chem.* 1868, 7, 68), who constructs a simple form by placing the substance in a broken retort beak and embedding a tube in it through which the vapour of the solvent ascends to the condenser.

References to other authors who have described forms of percolation apparatus are: Vohl (*Dingl. poly. J.* 1871, 200, 236), for oil seeds; Gerber (*Ber.* 1876, 9, 656), for milk analysis; Cazeneuve and Caillol (*J. Pharm.*

Chim. 1877, [4] 25, 265); Tschlapowitz (*Zeitsch. anal. Chem.* 1879, 18, 441); Biechle (*Correspondenz-Blatt des Vereins analytischer Chemiker*, 2, 70); Wolff (*ibid.* 91); Guichard and Damoiseau (*Répertoire de Pharmacie*, 1880, 8, 97); Gantter (*Dingl. poly. J.* 1880, 236, 221); Medicus (*Zeitsch. anal. Chem.* 1880, 19, 163); Thorn (*D. R. P.* 14523, 1880, and *Dingl. poly. J.* 1882, 243, 248; and with later improvements, *D. R. P.* 18850, 1881, and *Dingl. poly. J.* 1882, 246, 374); Dunstan and Short (*Pharm. J.* 1883, [3] 13, 663); Kreusler (*Chem. Zeit.* 1884, 8, 1323); Thresh (*Pharm. J.* 1884, [3] 15, 281); Will (*ibid.* 363); Waite (*ibid.* 376); Johnson (*Chem. News*, 1885, 52, 39 and 82); Foerster (*Zeitsch. Anal. Chem.* 1888, 27, 30 and 173); Neubauer (*Dingl. poly. J.* 1888, 267, 513); Berntrop (*Zeitsch. angew. Chem.* 1902, 15, 121), for bread analysis; Lohmann (*Chem. Zeit.* 1905,

FIG. 10.

FIG. 11.

29, 365); Pescheck (*Zeitsch. angew. Chem.* 1906, 19, 1513); Record (*Chem. News*, 1908, 97, 280); Gebhard and Thompson (*ibid.* 1909, 99, 124); Prager (*Zeitsch. öffentl. Chem.* 1909, 15, 396); Koch and Carr (*J. Amer. Chem. Soc.* 1909, 31, 1341); Lenz (*Arbeiten Pharm. Inst. Univ. Berlin*, 1909, 7, 289); Bornemann (*Chem. Zeit.* 1914, 38, 833), for fine powders, such as asphalt meal; Griffiths-Jones (*Analyst*, 1919, 44, 45), the tube up which the vapour ascends passes from the cork of the receiver up above the condenser, then bends over and passes down inside the condenser to the level of the water intake, the extraction thimble is attached to the condenser and is inside the receiver.

B. Continuous Infusion Forms.

Scheibler's 2nd apparatus (Fig. 11).—As the first apparatus could not be constructed wider to hold large quantities without danger of the solvent percolating in one channel through the substance, and leaving part unextracted, Scheibler designed a modification involving continuous infusion with an overflow. The apparatus (shown in section in the figure) is made of metal, and the substance is placed in the innermost tube *E*, which is closed at the bottom with a piece of wire gauze with a layer of cotton

wool, *p*, above it. This tube slightly widens at the top and is ground into the top of the outer vessel so as to be removable. The outer vessel is composed of two tubes which are permanently united at the neck *a*; the outside one ends below in a funnel which fits into the vessel of solvent; the inner one is closed below, the bottom being bent up as shown; it has two rows of perforations in it near the top. The innermost tube has one row of perforations just below the neck. The vapour passes up the outer space and through the perforations to a condenser fitted to the neck of the innermost tube, the condensed liquid drops on to the substance, descends through it, then passes up the space between *e* and the next tube, and overflows through the lower row of perforations and so back into the vessel of solvent again (D. R. P. 9481, 1879).

Rempel's apparatus (Chem. Zeit. 1887, 11, 936) is also an overflow apparatus, but is so arranged that the substance is placed in the outside vessel and the liquid rises and overflows, and the vapour ascends through tubes in the centre.

Budde (J. Soc. Chem. Ind. 1914, 33, 184) found that when using heavy solvents to extract waxes or fats the solution is lighter than the solvent, and floats on the latter. He got over the difficulty by means of a tube something like *e'* in Yoder's apparatus (Fig. 28), but in which the narrow side tube extends right up to the condenser and ends there in a funnel. In this way the column of heavy solvent in the side tube forces the light solution to overflow from the top of the wide part of *e'* in which the substance is put. Caspari (*ibid.* 1913, 32, 1042) describes an apparatus for separating the pectous part of indiarubber by petroleum-ether; it would also meet Budde's difficulty.

Scheibler's 3rd apparatus (Fig. 12).—This

FIG. 12.

was used in isolating vanillin from raw beetroot sugar. The substance to be extracted is placed in the vessel *e* (an elutriating vessel such as is used in the mechanical analysis of soils) and rests on a plug of cotton wool *b*. The solvent is poured on to it, until some escapes from the tube *t* into the flask *R* which is placed on a water-bath. The vapour of the solvent is conducted by the tube *p* back into *e*, whence it passes through *c* to a reflux condenser. The condensed liquid flows back through *c* on to the substance in *e*, thus causing a constant overflow

of liquid from the end of *t*, carrying with it the soluble constituents of the substance, which thus accumulate in *R* (Ber. 1880, 13, 338a).

References to other continuous infusion apparatuses are: Wynter Blyth (Chem. Soc. Trans. 1880, 37, 140); Johnstone (The Analyst, 1885, 10, 81); Stoddart (*ibid.* 108); Schmidt and Hänisch (D. R. P. 42753, 1887; and Dingl. poly. J. 1888, 268, 564); Göckel (Zeitsch. angew. Chem. 1897, 683); Landsiedl (Chem. Zeit. 1902, 26, 274) for use with solvents of either high or low boiling-point; Warren (Chem. News, 1906, 93, 228), used in indiarubber works; Hahn (Chem. Zeit. 1913, 37, 880); Pinkus (Biochem. Zeitsch. 1914, 60, 311).

C. Intermittent Infusion Forms.

Auld and Pickle's apparatus (Fig. 13).—The substance to be extracted is placed, together with the solvent, in the large bolt-head flask *E*, which is heated in a water-bath. The vapour passes up the wide tube *p*, which is provided with a wide bore tap *c*, and is cooled by a reflux condenser attached to the top. *s* is a long tube ending in *E* in a small thistle funnel packed with cotton wool and covered with fine muslin or cotton cloth; the other end of *s* passes into the receiving flask *R*. A fairly wide tube, *t*, passes from the tube *p* at a point above the tap *c* down into the receiving flask *R*. When the solvent has become saturated, the tap *c* is closed for a

FIG. 13.

FIG. 14.

moment, the pressure of the vapour then drives the solution through the cotton wool, and fills the tube *s*, which now acts as a siphon. The solvent is now boiled off from *R*, and passing up *t* is condensed and returned to *E*. The operation is repeated until the extraction is complete. With some solvents, a joint of wide indiarubber tubing can be used instead of the tap *c*, the tubing being pinched when it is desired to fill the siphon (Chem. News, 1909, 99, 242). The authors find that if the tube *p* is continued down into the flask *E* to a level a little above the thistle funnel, and is given a somewhat flanged termination, the apparatus will work automatically. When vapour is boiled off from *R*, it collects in *D*, forming a small column, which, when it has reached a certain height, forces the liquid into the siphon, which then empties *E*, and the process is repeated.

Schwaerzler (J. Pharm. Chim. 1853, [3] 24, 134), Schiel (Annalen, 1858, 105, 257), and Simon (Zeitsch. anal. Chem. 1873, 12, 179) have also described apparatuses in which the pressure of heated vapour is used to force the solution from one vessel to another.

References to other apparatuses of the intermittent infusion group are: Daubrawa (Vierteljahrsschrift für praktische Pharmacie, 1859, 8, 36); Fleury (J. Pharm. Chim. 1862, [3] 41, 282); Barlow (Chem. News, 1888, 57, 56).

Soxhlet and Szombathy's apparatus (Fig. 14).—This was the first apparatus to introduce the use of the siphon to effect automatic intermittent infusion. The substance to be extracted, contained in a cartridge of filter paper, is placed in the wide tube E, at the bottom of which a tube, s, bent so as to form a siphon, is fused on. Another tube, N, not quite so wide as E, is fused on to the bottom of the latter, without, however, opening into it. The down tube of the siphon s passes through the side of N, and is sealed in by fusion. A reflux condenser is fitted to the top of E, and the tube N is fixed by a cork into a vessel of the solvent. On boiling the solvent, the vapour ascends through N and through the side tube t, which is sealed into both N and E, and reaches the condenser, whence the condensed liquid drops back into E and accumulates until it rises to the level of the top of the siphon s, when the siphon flows and empties the liquid contents of E into the vessel beneath; E then fills again, and its liquid contents are siphoned off every time the level reaches the top of the siphon tube. The top of the cartridge should be below the level of the top of the siphon, so that it may be completely immersed in the solvent, and it should rest on a plug of glass wool or strip of metal bent into a ring so that the opening to the siphon may not be closed (Dingl. poly. J. 1879, 232, 461).

Soxhlet and Szombathy's plan is now very widely adopted, and many variations of it have been devised. Lewkowitsch (Chem. Soc. Trans. 1889, 55, 359) attaches a tap to the siphon just before it enters the tube N in Fig. 14, so that a little of the solution can be drawn off to test the progress of the extraction. The siphon may be placed between the extraction vessel E and an outer vessel or inside the extraction vessel; the risk of breakage is thus diminished, and the material and solvent are warmed by the ascending vapour. The following are references and descriptions of various forms having the siphon all, or mostly, in the air: Wollny (Zeitsch. anal. Chem. 1885, 24, 51); Boessneck's 2nd apparatus (Chem. Zeit. 1890, 14, 870); Christ Kob & Co. (*ibid.* 1901, 25, 379), a form having a perforated glass plate fused in position just above the place where the siphon is attached to E in Fig. 14; Landsiedl (Chem. Zeit. 1902, 26, 274) forms with movable interior vessels; Silberrad (Chem. News, 1911, 104, 54), like Fig. 14, but the main tube E rises very high and contains a pendent condenser; Kardos and Schiller (Chem. Zeit. 1913, 37, 920), for powdery materials, the solvent drops into a central tube full of holes and covered with cloth and embedded in the powder, whence it passes into the powder; Freund (*ibid.* 1914, 38, 802), a clever form easily made from common apparatus.

Clausnizer and Wollny's apparatus (Fig. 15).—In this, the bottom of the inner tube E is drawn out, and to it a siphon tube is sealed on, as shown in the figure. The tube E and its siphon fit loosely into an outer tube, T, which is fitted into a vessel of the solvent below and leads to a condenser above. The substance to be extracted is placed in E, and the mode of working is similar to that of the previous apparatus. The vapour passing up in the space between E and T maintains the substance and the solvent at a temperature approaching the boiling-point of the latter (Zeitsch. anal. Chem. 1881, 20, 81).

An objection to this form raised by Wollny is that as the siphon is in the hot vapour the

FIG. 15.

FIG. 16.

FIG. 17.

solvent in it may boil and hinder the siphoning action, and he describes forms in which the substance is heated yet the siphon is cool (Zeitsch. anal. Chem. 1885, 24, 48). When the solvent is a mixture of liquids of different boiling-points, such as petroleum-ether, the more volatile portions tend to collect and boil in the extraction vessel, while the siphon is superheated by the vapours of the high boiling portions and does not act (Ford, J. Amer. Chem. Soc. 1912, 34, 552).

Fröhling's apparatus (Fig. 16).—A cylindrical tube, E, resembling a tube for drying filters, is open at the bottom, but a little above the bottom it is closed by a conical diaphragm, through the apex of which passes the longer leg of a little siphon, which is thus held in position in E; it lies close to the side. This tube contains the material to be extracted, held in filter paper. The end of the siphon does not quite reach to the bottom of E, so that E can be placed upright on the balance pan, and weighed; it can be closed with a ground-in stopper during weighing. E is slipped into the outer tube T, which is closed by a light hollow glass stopper through which runs the tube of the condenser. The vapour of the solvent passes up the side tube t, is condensed, and the liquid when siphoned from E returns down the narrow tube in the interior of N (Zeitsch. angew. Chem. 1889, 242). Somewhat similar is an arrangement of Bain (J. Ind. Eng. Chem. 1910, 2, 455), he uses as a

percolator a little weighing bottle which can be closed by ground-on caps at each end; in one end is a short movable glass inset carrying a stretched filter-paper on which the substance rests.

The feature of having the siphon inside the apparatus is adopted in the following forms: Blount (Analyst, 1888, 13, 126); Fresenius-Offenbach (Zeitsch. angew. Chem. 1896, 485); Sinnhold (Chem. Zeit. 1901, 25, 423); in this the vapour passes up a tube in the centre of a globular extraction vessel terminating below in a wide tube. The inner tube is ground into the wide tube, and has the siphon fused into it with the long leg passing down the centre, the bend and short leg being in the globular vessel. The apparatus is less fragile than other forms, and the inner tube and siphon can be removed in one piece for cleaning. Chatelan (Chem. Zeit. 1901, 25, 612) bends the delivery tube of the condenser slightly to one side, so that by twisting the condenser round, the solvent can be made to fall either on the material or into the orifice of a tube passing through the side of the extraction vessel near the top. When in the latter position, the solvent is run off through a tap on the side tube, and the necessity is avoided of disconnecting the receiving flask and distilling off the solvent in a separate apparatus. Landsiedl (Chem. Zeit. 1902, 26, 275) describes forms with movable interior vessels for hot extraction. Radermacher (*ibid.* 1177). Hesse (*ibid.* 1904, 28, 18) uses a cork in a tubulure at the bottom of the inner tube to hold the siphon in its place, thus making a very cheap form; the cork can be coated with chromogelatin. Pescheck (Zeitsch. angew. Chem. 1906, 19, 1513), a form with movable interior vessels for percolation or intermittent infusion. Vigreux (Bull. Soc. Chim. 1909, [4] 5, 699). Walpole (Chem. News, 1910, 102, 129), a form somewhat resembling Knorr's (Fig. 8). Aron (Biochem. Zeitsch. 1913, 50, 386). Beadle and Stevens (Analyst, 1913, 38, 143), a compact form made out of an Erlenmeyer flask with a long neck holding a pendent condenser. Thar (Biochem. Zeitsch. 1914, 58, 503). Twiss and McCowan (J. Soc. Chem. Ind. 1917, 36, 692), a form much like Blount's.

King's apparatus (Fig. 17).—In this the siphon is differently constructed. Into the bottom of the wide tube *E* there is fused the long narrow tube *t*, which is ground off at an angle at its upper end. A tube, *s*, slightly wider than *t*, and closed at one end, is inverted over *t*, and rests on the upper end of the latter: it does not quite reach to the bottom of *E*. The tube *E* slips into a still wider one, *F*, which is dented in several places at *d*, in order that the dents may support *E* and prevent it closing the narrower part of *F*. The substance to be extracted is placed in *E*, and rests on a plug of glass wool at the bottom. It is fitted up as in the two previous apparatuses, and when the liquid in *E* rises to the top of *s*, *s* and *t* form a siphon and draw off the liquid into the vessel below (Chem. News, 1888, 57, 235). Masojidek (Zeitschrift für Zuckerindustrie in Böhmen, 1881, 6, 51) and Boessneck (Chem. Zeit. 1887, 11, 1600) had previously described apparatuses on the same plan as King's. Thorpe and Robinson (Chem. Soc. Trans. 1890, 57, 44) employ an open-topped bell-jar inverted with a

siphon of this form to make a capacious apparatus.

In Jerwitz's apparatus and in Sanders's apparatus, the difficulty of the cork is avoided by causing the condensed solvent to enter the extraction vessel at the side instead of at the top; a light glass stopper can then be used to close the top of the extraction vessel, and the material undergoing extraction can easily be removed when extraction is complete, and fresh material introduced without disconnecting the condenser.

Jerwitz's apparatus (Fig. 18).—In using this the receiving flask *F* is attached to the bottom of the condenser and is held on by spiral springs. The cartridge of material to be extracted is placed in the extraction vessel *A*; ether is poured in up to the level *E*, and the vessel is closed by the glass stopper *H*, which is held in

FIG. 18.

FIG. 19.

position by spiral springs. The tap *B* is then opened, and the ether is siphoned over into *F*. On heating *F* in a water-bath, the ether vapour ascends to *E*, and is there cooled by a current of water circulating in the outer space. The condensed ether is prevented by the projecting tube *J* from flowing straight down into *F*, and is conducted through *L* into *A*, where it collects and is siphoned off intermittently through *G*. When the extraction is complete, the stopcock *B* is closed and the ether from *F* is driven off and collected in *A*. *F* is then removed, *B* is opened, and the ether is siphoned off into another vessel. The stopper *H* is then removed, and the cartridge of exhausted material is taken out by long tongs or a wire hook. At the top of the apparatus, a calcium chloride tube, *C*, prevents access of moisture to the ether, and the little tube *v* containing mercury and a plug of cotton wool acts as a safety valve should *C* get clogged (Chem. News, 1901, 83, 229).

Sanders's apparatus (Fig. 19).—In this apparatus, the material is placed in the extraction vessel *A*, which is closed by the glass stopper *H* and is held in a sloping position. The receiving flask containing the solvent is attached to the tube *F*, the taps *B* and *C* are closed, and on heating the flask, the vapour of the solvent passes up the tube *F* and through the upper part of *A* to the side tube *E*, which leads to a reflux condenser. When *A* is nearly filled with the condensed solvent, the siphon *s* discharges the

solution into the receiving flask, and continues to work intermittently as in similar apparatuses. When the extraction is complete, the tap *c* is opened and the solvent is collected at the end of the tube *f*. If the tap *b* is left open during the operation, continuous percolation instead of intermittent infusion is effected. In a simpler form, the tap *b* and the cross connection between the legs of the siphon are absent. The apparatus can be made on a large scale of tinned copper, the extracting vessel having the capacity of one litre (Chem. Soc. Proc. 1910, 26, 227).

When oil seed is crushed for analysis some of the oil is lost in the machine. Max Lehmann (Chem. Zeit. 1894, 18, 412), to meet the difficulty, designed a very small mill in which 5 grams can be crushed, and then the lower part of it containing the meal can be put in a Soxhlet for extraction. Another uncommon apparatus is that of C. Lehmann (Pflüger's Archiv Physiol. 1903, 97, 419 and 606) for extracting the fat from animal tissues, yeast, &c.; it is composed of a bottle with stoppered mouths at top and bottom, in which the substance is placed, together with the solvent and a number of porcelain balls. This is rotated in a motor, and is then made to form part of a Soxhlet apparatus.

Large Forms.

Apparatuses designed to deal with several pounds of substance are described by: Thorpe and Robinson (Chem. Soc. Trans. 1890, 57, 41), to hold 14 lbs. of bark; Buss (Chem. Zeit. 1903, 27, 813), for the hot extraction of several kilograms; Jackson and Clarke (Amer. Chem. J. 1909, 42, 287), for 18 kilograms of turmeric; Roberts (*ibid.* 1910, 43, 418), a battery of cells in series for charges of 3 kilograms of corn meal; Halle (Biochem. Zeitsch. 1911, 36, 245), to hold 2 kilograms; Schmidt (J. Ind. Eng. Chem. 1916, 8, 165), to remove fat from several pounds; McNair (*ibid.* 838), it resembles a Wiley's apparatus (Fig. 9) made on a very large scale, with a bucket in place of the crucible; Schwalbe and Schulz (Chem. Zeit. 1918, 42, 194), for 4 to 6 litres of material.

Manufacturing Forms.

Roth's apparatus (Figs. 20 and 21).—This is employed for extracting oil from seeds by means of carbon disulphide. The solvent is stored in a reservoir, which is kept immersed in water to check evaporation. A pipe from an elevated water reservoir enters at the top of the carbon disulphide reservoir, and another pipe communicating with the extractor passes through the top of the reservoir and descends nearly to the bottom, so that when the tap of the water pipe is opened, the carbon disulphide is forced into the extractor. The latter is a cylindrical vessel, shown in section in Fig. 20; it is provided with a perforated false bottom, *f*, supported by struts *g, g*. The false bottom *f* is covered with sackcloth, and on it the ground seed or oil cake is placed and filled in up to another perforated plate, *j*, also covered with sackcloth. The top of the extractor is fastened on with screw clamps so as to be readily removable. At the bottom is a T-piece, communicating by the opening *b* with the carbon disulphide reservoir and, by the branch *c*, with

a steam boiler. When filled and closed, carbon disulphide is forced in through *b*, and when it has dissolved the oil, fresh carbon disulphide is forced in at *b*, causing the first charge to overflow down the pipe *L*, the entrance to which is protected with a strainer, and to pass to the distilling apparatus. A gauge, *q*, shows the

FIG. 20.

level of the liquid, and also allows samples to be drawn. The material is treated some three times or so with the fresh solvent until a sample taken at *q* is found to be free from oil; half of the last charge is then conducted through the

FIG. 21.

tap *b*, and a pipe connected with it to another similar extractor, and the other half is returned to the carbon disulphide reservoir. In order to recover the last portions of solvent adhering to the material, the valve *N* is opened and steam is sent in through *c*; the carbon disulphide is thus boiled off and passes through *N* to a

condenser. When all carbon disulphide is driven off, the taps R and D are opened; the former allows the steam to escape and the latter allows the condensed water to run off. The cover is then removed and the extractor is emptied and refilled with fresh material.

The distilling apparatus, shown in section in Fig. 21, is a cylindrical vessel, into which the solution of oil is introduced through the tap E and pipe attached which descends nearly to the bottom. The vessel is half filled with liquid, the level being ascertained by the gauges, F, F. At the bottom of the vessel are two steam coils; the lower one is perforated with a number of small holes and is fed by the tap H; the upper one is not perforated, and is fed by the tap J, and the condensed water from it escapes through the tap L. At first, steam is slowly passed through the upper coil and heats the carbon disulphide, the vapours of which pass by the wide tube C to a special form of condenser; when nearly all the carbon disulphide has escaped, steam is passed through H, and, escaping by the perforations through the oil, removes the last traces of the solvent. The tap D allows the steam to escape at the end of the distillation. The oil is finally run off through the tap K to a reservoir, where it is allowed to stand until the condensed water has separated in a layer (Schaedler's *Technologie der Fette und Oele*, 1883, i. 292).

Leuner's apparatus (Fig. 22).—This is employed for removing fat from bones. The bones are filled into the cylindrical vessel A (shown in section in the figure), and rest on the perforated false bottom *aa*; then all the taps are closed except *p*, and steam is injected through the pipe *b*; when all the air is expelled, *p* is closed, and the bones are kept in contact with steam under pressure for a time. Steam is then shut off, and the taps *p* and one attached to the tube *d* are opened, and the condensed water is drawn off. In the cylindrical vessel B there are placed equal volumes of water and petroleum naphtha or other volatile solvent; taps *p* and *d* are closed, and taps *g* and *i* are opened, as also are the taps *q* and *r*, to allow the water and solvent to flow into A; *q* and *r* are then closed, and an equal volume of water is introduced into B. Steam is now passed through the pipe *cc*, and this heats the water which forms the lower layer in A, and the heat is communicated to the upper layer of solvent. The vapour rises through the bones and passes through the pipe *ss* to the small vessel C, and thence to the reflux condenser contained in D. The condensed liquid collects in C until it reaches the opening into *s*, when it flows back

into A and is spread over the bones by the arrangement shown at the top. Any vapour that is not condensed passes through the pipe *l*, and is led under the surface of the water in B, which is provided with a small condenser E to prevent the escape of vapour of the solvent to the air. The bones are thus subjected at the same time to the action of steam and petroleum

FIG. 22

vapour and also of liquid petroleum. After this action has gone on for some time, the tap *g* is closed and *h* is opened; the vapour evolved from A then passes to a second condenser, which is contained in D and communicates with C—it is indicated by dotted lines—and the tap *k* is opened; this allows the solvent to flow from C down the tube *nn* and collect in B. The heating is continued until all the solvent is driven off and water only enters C; this can be seen by glazed apertures in that vessel. When this occurs, the operation is finished, and a mixture of fat and of aqueous liquid is drawn off by the pipe *d*, and the latter is used in preparing glue (D. R. P. 17181, 1881; and J. Soc. Chem. Ind. 1882, 1, 155).

Merz's apparatus (Fig. 23).—This apparatus is designed for the extraction of various substances with volatile solvents; it can also be used with animal charcoal for decolourising purposes. It consists of an inner vessel, E, which is open at the top and is contained in a closed

outer vessel R. The substance is filled into E through the manhole a, and at the end of the operation it is removed through the manhole b. The solvent is stored in a reservoir S, which forms the lower part of the condensing vessel T, and is divided from the upper part by the partition d. The extractor E is filled with solvent by opening the tap t. When the level of the liquid rises as high as the top of the siphon s, the latter begins to act and runs off the liquid from E into the outer vessel R. The entrance to

FIG. 23.

the siphon is protected by the sieve arrangement shown at the bottom of E. Steam is made to circulate through the coil *eee* at the bottom of R; this causes the solvent to boil, and its vapour circulates in the space between R and E, warming the latter and its contents, and then passes to the condensing tubes *c, c, c*, round which water is circulating. The condensed liquid falls back into E, and when the level again reaches that of the top of the siphon the siphoning-off is repeated and so on over and over again. The substance is thus submitted to intermittent infusion. Samples can be drawn off at *u*, and when the extraction is found to be complete, the water that surrounds the tubes *c, c, c* is withdrawn. The solvent then boils off, and after condensation in the worm *w* returns to the reservoir *s*. The extract is drawn off by the tap *v*. By regulating the tap *u*, the substance can be made to undergo continuous instead of intermittent infusion, if desired (D. R. P. 20742, 1882; and J. Soc. Chem. Ind. 1883, 2, 234).

Van Urk (Pharm. Weekblad, 1919, 56, 1301) describes a simple apparatus.

See also the article on ORLS, and Ubbelohde's Handbuch der Chemie und Technologie der Öle und Fette, 1908, i. 574, &c., where the extraction of oils on the manufacturing scale is dealt with at some length.

The extraction of the volatile oils to which the

odour of flowers is due, forms an important industry; the apparatus employed is simple in principle, the only complexity being in the arrangement of the battery of extracting vessels, reservoirs of solvent, and stills (see Gildemeister, Die Ätherischen Öle, 2d. ed. 1910, 266).

Garnier's apparatus (Figs. 24, 25, and 26), however, presents some novelty; it consists of a cylinder, *c*, revolving on a horizontal axis inside a cylindrical vessel, *v*; the end plates *E, E* of the revolving cylinder present a number of circular rings (Fig. 25), each of which is united to the corresponding ring at the other end by a number of rods forming an open framework (Fig. 26). Into the frames formed by the rods long cylindrical baskets *B, B* of open work containing the flowers can be thrust through a manhole, *m*, at the end of the cylindrical vessel. When all the baskets are in position, the manhole is closed, and enough solvent is introduced through *r* to cover the lowest basket. The cylinder is then made to revolve, and thus one basket of flowers after another is immersed in the solvent; as the cylinder has no outer wall, the solvent can move freely through the baskets. Heat can be applied by passing steam through the spiral pipe *PR*, and the vapours of the solvent pass by the still head *s* to the condenser *K*. When extraction is complete, the solution is drawn off by the tap *T*. At the end of the operation, steam can be blown into the apparatus through the tap *U*, and the last remnants of the solvent can thus be driven off and condensed in *K*. By this apparatus, many baskets of flowers can be extracted by the same comparatively small quantity of solvent (Fr. Pat. 1904, 342534; Gildemeister, *loc. cit.* 271).

Extraction plant, solvents and methods on the manufacturing scale are discussed by Pooley in The Chemical Age, 1920, 2, 121.

Liquids.

A substance held in solution or suspension by a liquid can often be removed by treating the liquid with a solvent that is not miscible with it. In the rest of this article 'liquid' will always be used to denote the liquid submitted to extraction.

FIG. 24.

FIG. 25.

FIG. 26.

The ordinary procedure is to shake the liquid and the solvent vigorously together in a separator, which is a pear-shaped or cylindrical glass vessel terminating in a stoppered tubulure at its broad or top end, and in a stopcock and short tube at its narrow or lower end. After shaking, the vessel is allowed to stand until the liquid and the solvent have separated into two layers. The stopper is then removed, and the lowermost layer tapped off by means of the stopcock and tube. This treatment is repeated with fresh solvent until the liquid has given up as much as possible of the dissolved or suspended substance it contained.

The mathematical aspect of the process is discussed by Marden and Elliott (*J. Ind. Eng. Chem.* 1914, 6, 315 and 928), and they give the formulæ—

$$(i) x_n = x_0 \left(\frac{da}{e - da} \right)^n; (ii) d = \frac{C_1}{C_2};$$

where a is the volume of the aqueous solution containing the substance; e is the volume of the solvent used to extract it, the same volume of fresh solvent being used for each extraction; x_0 is the concentration in the aqueous liquid (that is, the amount of substance in unit volume) before commencing the extraction; x_n is the concentration in the aqueous liquid after n extractions; C_1 is the concentration in unit volume of the aqueous liquid after an extraction; and C_2 is the concentration in the same volume of the solvent after the extraction. The law of distribution of a substance between two immiscible solvents states that after shaking until equilibrium is established, the value of d , the distribution ratio, as defined above, is constant for a given temperature, irrespective of the amounts of substance present, provided the substance does not polymerise. The law does not hold good, however, for wide variations in concentration, and corrections must be made for the amounts that the solvents dissolve of each other. From the equations it follows that the smaller d is, the fewer extractions will be required to reduce the amount of substance left in the aqueous solution to an unimportant quantity; and if d is known, the number of extractions required to attain this can be calculated. The authors have determined d in the case of the alkaloids and of some other substances. Another mathematical discussion of the subject but for solids and gases is given in Lewis's *Principles of Counter Current Extraction* (*J. Ind. Eng. Chem.* 1916, 8, 825). Pinnow (*Zeitsch. Nahr. Genussm.* 1919, 37, 49) has investigated the extraction by ether and the distribution coefficients between ether and water of various organic acids.

Various forms of apparatus have been devised to effect the extraction by automatic processes similar to those employed for solids. Two different cases arise: one when the solvent is heavier than the liquid, and the other when it is lighter. In the first case, the heavier solvent must pass as a rain of drops through the liquid and escape up a side tube when a certain amount has collected, the column of liquid balancing a shorter column of solvent in the side tube. In the second case, a column of the solvent must be caused to accumulate in a tube until it acquires sufficient pressure for

some to escape at the bottom and pass up through the liquid. It is important that the apparatus be so designed as to allow a column of sufficient height to collect.

A third plan is to boil the solvent and force the vapour through the liquid; for this great efficiency is claimed, but it obviously requires great care in adjusting the apparatus and rate of working to the particular liquid and solvent, and the sucking back of the liquid into the boiling vessel when the latter cools has to be guarded against. A cooling worm, through which a current of water flows, is usually immersed in the liquid so as to help condense the vapour of the solvent and control the temperature.

The name 'perforation' has been used for all three plans by some writers, but it is not at all appropriate, as they are not processes of making holes. *Perpluviation* would be more suitable for the first two, and *injection* for the third.

Various practical points have to be attended to: thus regular boiling in the receiving vessel must be ensured by means of fragments of clay pipe, or one of the usual devices. When a heavy solvent is used some should first be poured into the extraction vessel before adding the liquid so as to prevent any of the latter entering the side tube. A tendency of the liquid and solvent to form an emulsion is apt to cause difficulties in carrying out the extraction. When this happens various plans can be tried, such as allowing time for the liquid and solvent to separate, or gentle warming, or dilution of the liquid. Wollny (*Zeitsch. anal. Chem.* 1885, 24, 53) says that at a boiling temperature an emulsion is less likely to form. If an obstinate emulsion has formed, sucking through a fine pored or hardened filter, or rotating in a centrifugal apparatus, can be tried to effect a separation. Some authors state, however, that warmth promotes emulsification. Self (*Pharm. J.* 1915, 95, 164) discusses the merits of various solvents as extracting agents and methods of dealing with emulsification. He recommends shaking with more of the solvent as the best way of breaking an emulsion. Malfatti (*Zeitsch. anal. Chem.* 1898, 37, 374), dealing with urine, which is prone to form emulsions, makes it descend a spiral of woollen thread wound round a long central tube placed in an outer tube up which ether ascends.

Kempf (*Chem. Zeit.* 1910, 34, 1365; and in *Abderhalden's Handbuch Biochem. Arbeitsmethoden*) gives the following points of importance in the practical working of extraction by ether: (A) In arranging for the heights of the liquid and of the column of ether allowance must be made for the increases in volume and changes in relative density due to (a) expansion by rise of temperature; (b) the liquid dissolving some ether and so increasing in volume it may be as much as 10 p.c.; (c) the liquid in the funnel tube at the start being pushed down and so raising the level of the liquid in the extraction vessel; (d) the drops of ether rising through the liquid also adding to the rise of level. (B) The ether will dissolve a certain amount of water and transfer it to the receiver; ether can also dissolve and transfer a small amount of sulphuric acid from a liquid containing it. (C) If the ether boils slowly the

effect of a fractionating apparatus is produced, and water accumulates in the receiver and may separate as a layer. Rapid boiling of the ether diminishes this accumulation as water vapour then accompanies that of the ether. (D) The ether should be as pure as possible, especially for extracting fat or aliphatic acids or compounds easily acted on. Commercial ether, especially if it has been long exposed to light, is apt to contain H_2O_2 and organic peroxides, alcohol, aldehydes, and acids. The alcohol would make esters with strong organic acids, and the peroxides would resinify easily oxidisable substances; they have even been known to detonate when the solution was evaporated. If the extraction is lengthy it is well to carry it on in a dark room to diminish oxidation. Tcherniac (Chem. Soc. Trans. 1919, 115, 1092) suggests saturating an aqueous liquid with sodium chloride to diminish the loss of ether caused by some being dissolved.

The forms of apparatus may be grouped into those for small quantities of liquid in which the extraction vessel is placed vertically over the receiver in which the solvent is boiled and to which the solution returns, and those for larger quantities in which the receiver is situated alongside the extraction vessel. Another diversity is that in some the hot vapour surrounds the extraction vessel and so heats the liquid during extraction, whilst in others the hot vapour passes up a side tube and so the liquid remains comparatively cool. A third diversity is that in some the floating solvent overflows back into the receiver, whilst in others it is siphoned back.

Apparatus of the Perpluviation Type.

Schwarz's apparatus (Fig. 27).—This appears to have been the first apparatus designed for the automatic extraction of liquids. The liquid is placed in the flask *E*, and the solvent, which must be lighter than the liquid, is placed in the receiving flask *R*, and is there boiled. The vapour ascends through the tube *t* to the upper vessel *V*, and thence through the tube *c* to a reflux condenser. The condensed solvent descends the tube *p*, then rises through the liquid in *E*, and collects as a layer above it until it reaches the opening into the side tube *g*, when it overflows and returns to the flask *R*. This circulation goes on automatically, and when on testing a drop of the overflowing solvent, the extraction is found to be complete, water is poured down *v* until all the solvent overflows down *q* into *R*; the parts are then disconnected, *E* is emptied, and by reconnecting and heating *R*, the solvent can be distilled off into *E*, leaving the desired substance in *R*. At *a* and *b* are mercury joints, which enable connection and disconnection to be readily made (Zeitsch. anal. Chem. 1884, 23, 368).

Yoder's apparatus (Fig. 28).—This is a simple form of apparatus which was used to extract certain organic acids from aqueous solutions by means of ether. The liquid is placed in the inner vessel *E*, which is supported at *d* by three dents in the outer tube. The vapour of the solvent passes up from the receiver through the hole *h*. If the solvent is lighter than the liquid the long funnel tube *f* is used. This is closed at the bottom, except for some small perforations

in the end, which is slightly enlarged. The solvent from the condenser *c* passes down this tube, then escaping through the perforations, it ascends through the liquid, overflows, and runs back into the receiver. The perforations must be small enough to prevent too rapid a flow of solvent, even when there is rapid condensation, or else some of the liquid may be carried over. For heavy solvents, such as chloroform, the inner vessel is shaped like *E'* and the funnel tube *f* is omitted, or else shortened so as only just to reach the surface of the liquid in *E'*, and is suspended from the top; the solvent passes downwards through the liquid, then up the narrow side tube, and overflows. When commencing, some of the solvent must be poured into *E'* before pouring in the liquid, so that the side tube may contain solvent and not the liquid (J. Ind. Eng. Chem. 1911, 3, 641).

Van Rijn's apparatus resembles Yoder's, but the inner vessel has three constrictions, so that it takes the form of three bulbs and a cylindrical upper portion, and there are holes

FIG. 27.

FIG. 28.

in the upper portion for the overflow of the solvent. At the lowest constriction there is a mark denoting the top of a definite volume in the lowest bulb (Ber. 1895, 28, 2387). Baum's apparatus for use with heavy solvents is like Yoder's, but the vessels are wider (Chem. Zeit. 1904, 28, 1172). Lenz's apparatus is much like Yoder's, but to avoid using a cork he closes the top of the wide outer tube loosely with a metal condenser, which partly rests on and partly enters into it, and which has a pointed end to condense the vapour and drop the solvent into the funnel. The bottom of the funnel tube is notched instead of being closed and perforated. For heavy solvents the tube *E'* is covered with a cup-shaped piece of nickel wire gauze. By substituting for *E* a tube ending beneath in an open point it can be used as a percolation apparatus for solids (Arbeiten aus dem Pharm. Inst. Univ. Berlin, 1909, 7, 289).

Schacherl's apparatus (Fig. 29).—This is for use with light solvents, the liquid is placed in the extraction vessel *E*, filling it up to the

bottom of the neck; if insufficient to do this, it can be diluted. The solvent is boiled in the receiver R, and the vapour passes up the tube *t* to the condenser at C; the condensed solvent drops into the funnel tube *f*, and when the column is sufficiently high, it passes up in drops through the liquid, collects in the neck of E, and overflows back into R. Corks can be avoided by using ground-in joints (Zeitsch. Nahr. Genussm. 1901, 4, 674).

FIG. 29.

reach up to the bottom of the neck. The solvent passes up through the liquid, collects in the neck of E, and overflows through the tube *q* back into R. The liquid, when sufficiently extracted, is drawn off by the siphon *s*, and fresh liquid is introduced through the funnel tube *f*, which should end below the

FIG. 30.

surface of the liquid, so that vapour cannot escape that way. In an experiment with this apparatus 540 c.c. of an aqueous solution containing 6.4 p.c. of succinic acid yielded 67 p.c. of the acid to ether in 2½ hours (Amer. Chem. J. 1909, 41, 510).

Bowman's apparatus (Chem. Soc. Proc.

1906, 22, 24) is somewhat on the same plan as Fiske's.

Friedrichs' apparatus (Fig. 31).—In order that the drops of a light solvent may traverse as long a path as possible as they rise to the surface of the liquid, Friedrichs makes use of a glass contrivance *s*, the surface of which is shaped like the thread of a screw. His condenser, only the bottom of which is shown in the figure, also employs a screw device. The vapour of the solvent passes from the receiver R up the side tube *t*, to the condenser C, and the liquefied solvent falls into the funnel tube *f*, and escapes by apertures at the bottom beneath the screw contrivance, and then follows a winding course along the thread till it collects above the liquid and is siphoned off by the tube *s*. The funnel tube *f* passes down the centre of *s*, into which no liquid enters. The siphon tube *s* runs outside the extraction vessel until it reaches *e*, where it passes into the bottom tube and returns the solvent to the receiver. The side funnel F and the tap T serve to introduce and remove liquid from the extraction vessel as required (J. Amer. Chem. Soc. 1912, 34, 285; and Zeitsch. angew. Chem. 1912, 25, 158). Friedrichs has also described a somewhat similar form, but with the receiving flask at the side, in Zeitsch. anal. Chem. 1911, 50, 756; and an apparatus for using liquefied gases as solvents for extraction at low temperatures in Zeitsch. angew. Chem. 1913, 26, Aufsatz. 201; and in J. Amer. Chem. Soc. 1913, 35, 244.

Kempf's apparatus attains the same end as Friedrichs', namely, a long course for the drops of solvent rising through the liquid, by surrounding the funnel tube with a flat glass spiral winding upwards like turret stairs. This is placed in an extraction vessel, with holes near the top for overflow, and this, in turn, is placed in an outer vessel, as in Yoder's and van Rijn's forms (Chem. Zeit. 1910, 34, 1365). Kutscher and Steudel (Zeitsch. physiol. Chem. 1903, 39, 473) wind a glass spiral, apparently of thin rod, round the funnel tube. Kempf (Chem. Zeit. 1913, 37, 774) describes a form in which the liquid is kept cool by circulating water round it; in this, too, a spiral is used.

A third plan of increasing the path of the drops of solvent is to place the liquid in a spiral tube and make the solvent divided into small drops ascend through it, and then collect and return to the receiver. This is adopted by Partheil and Rose (Zeitsch. Nahr. Genussm. 1902, 5, 1049); by Jerusalem (Biochem. Zeitsch. 1908, 12, 379), who gives directions for extracting pap-like materials; and in Koolman's 2nd apparatus (*ibid.* 1911, 34, 481).

C. von der Heide's apparatus (Fig. 32).—In this a fourth way of increasing the duration of contact between the rising light solvent and the liquid is adopted, namely, by means of a series of inverted cups fused on to the funnel tube *f*, which fits into the extraction vessel E containing

FIG. 31.

the liquid. The vapour from the solvent rises up the side tube *t*, and passes through the hole *h*, which corresponds to a similar hole *h'* in the funnel tube *f*; thence it passes to the condensing cup *c*, in which is placed a condensing spiral of twelve turns closely wound round a central cylinder (not shown in the figure). The liquefied solvent escapes from the notched end of *f*, and works its way from one cup to another through the small holes on alternate sides shown in them; as these are low down in the cups a little solvent is held in each cup. After collecting above the liquid the solvent overflows through *q* back to the receiver. Von der Heide also describes a still more complicated apparatus for either light or heavy solvents in which the cup device is employed, and further gives a third apparatus of the hot vapour injection type (Zeitsch. Nahr. Genussm. 1909, 17, 315). Aron

FIG. 32

FIG. 33.

(Biochem. Zeitsch. 1913, 50, 386), like von der Heide, employs inverted cups.

A fifth way of increasing the contact is to employ a current of air or other gas; this is used in Koolman's first apparatus (Biochem. Zeitsch. 1911, 34, 481), and by Berl (*see below*). Emde's method (Apoth. Zeit. Berlin, 1909, 24, 663) differs from all others by making the liquid pass through the solvent which is placed in a separator. The liquid enters in small drops from a jet just penetrating the upper surface of the solvent, collects at the bottom, and escapes through the tap and up a side tube, whence it can be made to pass similarly through other separators. Meeker (8th Int. Congress of Applied Chem. 1912, 17, 45) describes a seventh and very original way, especially adapted to prevent emulsification. The solvent and liquid form two layers in a suitable vessel, in which there are two propellers on a vertical shaft, one in each layer. These propellers are so shaped as to thrust in opposite directions, the lower one thrusting upwards and the upper one downwards. It is claimed that at a suitable rate of rotation of the shaft fresh surfaces of liquid and solvent can be brought into contact without the formation of emulsions. A form with a

revolving stirrer is described by Zelmanowitz (Biochem. Zeitsch. 1906, 1, 253) for extracting large volumes of aqueous liquid with light solvents, and a simplification of this is described by Tolmacz (Chem. Zeit. 1913, 37, 1381).

The following are references to other apparatuses for extracting liquids by percolation.

When the solvent is heavier than the liquid: Stephani and Böcker (Ber. 1902, 35, 2698), the solvent rains through the liquid, collects, and passes down to the receiver through a tube with a tap, which has to be adjusted so that just as much flows down as falls in from the condenser. A pad of glass wool can be inserted to break up emulsions. It can also be used for solids. Pregl's apparatus (Zeitsch. anal. Chem. 1901, 40, 785), that of Berlin (D. R. P. 251459, 1911), and that of Greenwald (J. Ind. Eng. Chem. 1915, 7, 621), are ingenious and compact.

When the solvent is lighter than the liquid: Neumann's 2nd apparatus (Ber. 1885, 18, 3061). Eiloart's 2nd apparatus (Chem. News, 1886, 53, 281), it resembles that in Fig. 34, except that the tubes are arranged so that the vapour goes to the condenser and the liquefied solvent passes down into *E*. Kurbatow (J. Russ. Phys. Chem. Soc. 1894, 26, [1] 39; and Ber. 1894, 27, 314R). Wroblewski's 1st apparatus (Zeitsch. anal. Chem. 1897, 36, 671). Foerster (Chem. Zeit. 1898, 22, 421) uses a tall cylindrical jar to hold the liquid; he gives particulars about extracting with ether soap solutions obtained from fats to get cholesterol and phytosterol. Kumagawa and Suto's apparatus (Beitr. Chem. Physiol. Pathol. 1903, 4, 185) is somewhat like Yoder's, but with much more glass-blower's work. Saiki (J. Biol. Chem. Baltimore, 1909, 7, 21) adapts an ordinary Soxhlet (Fig. 14) for liquids by slipping in a small bottle with a funnel tube standing in it. Bacon and Dunbar (J. Ind. Eng. Chem. 1911, 3, 930) use a flask having a very wide neck about 16 inches long, in which is hung a test tube containing the liquid and funnel tube, in this neck there is also contained the condenser hanging from an enlargement of its top, thus there are no corks or joints.

When the solvent is either heavier or lighter than the liquid: Wollny (Zeitsch. anal. Chem. 1885, 24, 54 and 202). Grauer (Dingl. poly. J. 1886, 262, 475) forms on a manufacturing scale. Diepolder (Ber. 1897, 30, 1797). Göckel (Zeitsch. angew. Chem. 1897, 683), and Hahn (Chem. Zeit. 1913, 37, 880) forms with movable interior vessels. Landsiedl (Chem. Zeit. 1902, 26, 274), several forms with movable interior vessels for use with solvents of high or low boiling-points.

Apparatus of the Injection Type.

Mameli's apparatus (Fig. 33).—In this apparatus the plan of forcing the hot vapour of the solvent through the liquid is adopted. It is somewhat like Soxhlet's apparatus, but the siphon *s* is attached at a point rather more than halfway up the side of the extraction vessel *E*, and reaches to the bottom of the receiver *R* to prevent the vapour escaping that way, also the tube *t*, which conducts the hot vapour from *R* bends over and reaches nearly to the bottom of *E*. Thus the hot vapour is forced through the liquid, and the condensed solvent collects above the surface of the liquid until the siphon is

filled and put in action. There is a condenser at *c*, which liquefies escaping vapour and returns the solvent to *E*. A similar apparatus, but easier to fit up, employs instead of *E* a similar vessel having no siphon, but a long central tube passing down through a corked opening at *k*, and reaching from a point far up in *E* to the bottom of *R*, so that the floating solvent flows down it into *R*. The top of this tube can be bent over for a short distance if a siphoning action is desired. The side tube *t* passes through the cork of *R*, thus no glass-blower's work is required (Gazz. chim. ital. 1906, 36, 123).

Pelizza's apparatus is an injection form somewhat like Mameli's, but the floating solvent instead of being siphoned off, returns down a central tube, and the tube supplying the vapour bends down outside the extraction vessel and enters at the bottom; further, there is a close-fitting outer casing fused on to *E*, through which water circulates on its way to the condenser (Chem. Zeit. 1904, 28, 186). Moreschi and Siemoni's apparatus resembles Mameli's, but the tube in the extraction vessel down which the vapour passes is surrounded by a condensing jacket through which cold water can be made to circulate (Rend. Soc. Chim. Ital. 1913, 5, 159).

Wiloart's 1st apparatus (Fig. 34).—In this the liquid is contained in the tall jar *E*. The vapour of a light solvent, which is boiled in the flask *R*, is forced through the liquid by means of the long tube *t*, which terminates in a small inverted funnel attached by fusion. The mouth of this funnel is covered with a piece of platinum foil perforated with holes. The top of the jar is tightly corked, and the solvent, which collects as a layer on the liquid, is forced up the tube *p* to the bottom part of a condenser *c*, and returns to *R* down the tube *q*. (It would be better if the cork at the bottom of *c* could be avoided by some glass contrivance.) The tube *t* is given considerable height to prevent any of the liquid in *E* being sucked back when *R* cools (Chem. News, 1886, 53, 281).

Neumann, in 1885, described his 1st apparatus in which ether vapour is forced into the liquid contained in a tall cylindrical jar and the floating ether is siphoned back into the receiving flask (Ber. 1885, 18, 3061).

Pip employs a vessel somewhat resembling an inverted gas jar, but having a small extra tubulure near the main tubulure. The liquid is contained in this jar, and the vapour of a light solvent from a receiving flask at the side is forced in at the bottom through a cork and tube fixed in the main tubulure, and is distributed through a perforated porcelain plate. A tube which passes through the small tubulure and reaches to a point above the surface of the liquid, leads the liquefied solvent back into the receiving flask. The tube supplying the vapour rises outside the jar and well above it and then bends down to reach the cork. There is a cork cover that supports a winding cooling tube in the liquid and a funnel (Chem. Zeit. 1903, 27, 706).

Wollny's apparatus (Fig. 35).—In this apparatus an idea is borrowed from the Bunsen burner, namely, to force a jet of vapour and a jet of condensed solvent up through a tube immersed in the liquid, thus attaining a close

intermixture. The apparatus is connected by mercury joints: below to a receiving vessel, and above to a condenser. The vapour of the solvent, which can be introduced if so desired by the side tube *p* instead of from the receiving vessel, passes up the tube *t*, which rises nearly to the top of the apparatus, bends down forming an inverted U, enters the extraction vessel *E* at the bottom, and terminates in a jet. A funnel tube *f* conducts the liquefied solvent from the condenser and delivers it by a jet alongside the vapour jet in the mixing tube *m*, in which an intimate mixture of liquid and solvent is made and overflows at the top. The tube *m* is surrounded at the top by a wider tube *w*. When the solvent is heavier than the liquid the tube *q* is employed, and is placed over the exit tube *s*, which reaches down nearly to the bottom of the receiving vessel; the pressure

FIG. 34.

FIG. 35.

of the liquid then supports a column of solvent, indicated in the figure by the shading, as high as the top of *s*, and the solvent flows off down *s*. The liquid is not shown in the figure. There is no siphoning action as *q* is open at the top. When the solvent is lighter than the liquid the tube *q* is removed; the solvent now floats on the surface of the liquid and runs off down the tube *s*. The loose parts are suspended from the upper edge by platinum wire. Wollny states that the apparatus is suitable when the solvent and liquid separate quickly after intermixture, and that an emulsion is not so likely to form at boiling temperature as when the liquid and solvent are cold. [Other authors state, however, that warmth promotes emulsification.] In case of an emulsion forming, he suggests leading aside the condensed solvent out of the apparatus for a time and allowing vapour only to pass in as a means of effecting separation. He also describes several other somewhat similar forms of apparatus (Zeitsch. anal. Chem. 1885, 24, 47 and 202).

Berl's apparatus is on the same plan as Wollny's, but is even more complicated. In it the vapour of a light solvent and a current of air or some other gas are forced up a glass spiral

immersed in the liquid, so that some of the liquid accompanies them, the mixture is discharged at the top of the spiral and falling back rejoins the main body of the liquid (Chem. Zeit. 1910, 34, 429).

The following are references to other injection forms: Hagemann (Ber. 1893, 26, 1975), for heavy or light solvents. Wroblewski's 2nd apparatus (Zeitsch. anal. Chem. 1897, 36, 672), for light solvents, the tube that conveys the overflowing solvent back to the receiver dips to form a U-tube and rises again to enter the receiver. There is a tap at the bottom of the U-tube, so that any drops of the liquid that come over can be removed before reaching the receiver, and also portions of the solvent can be taken for testing. Lentz (Chem. Zeit. 1901, 25,

820), for chloroform, it can be easily fitted up with ordinary apparatus. Fritsch (Chem. Zeit. 1909, 33, 759), for use with ether, the liquid is contained in an inverted Woulfe's bottle, or by putting calcium chloride solution instead of the liquid it can be used to purify ether. C. von der Heide (Zeitsch. Nahr. Genussm. 1909, 17, 315). Tcherniac (Chem. Soc. Trans. 1919, 115, 1090), an elaborate apparatus for forcing ether vapour from one flask into an aqueous liquid contained in another, which is immersed in water so that it can be kept cold or allowed to get warm as desired. A device is employed by which any aqueous liquid carried away by the ether is returned to the extraction flask and does not reach the receiving flask. When in good order it can be left to work overnight. H. H. R.

F

F-ACID. 2-Naphthylamine-7-sulphonic acid *v.* NAPHTHALENE.

FACTIS (*Faktis*, *Factice*, *Parafactis*). A general term applied to so-called rubber substitutes prepared from oils.

White substitute is made by stirring sulphur monochloride into linseed, rape-seed, refined colza oil, or other unsaturated oil with or without admixture of petroleum spirit. A considerable rise of temperature occurs; the oil thickens, and, when the reaction has proceeded far enough, the whole is poured into trays, and solidifies to an elastic solid, somewhat resembling rubber. It is necessary to control the temperature, and therefore only limited charges of material are used.

The product is an additive compound of the oil and sulphur monochloride, and consists mainly of the glycerides of fatty acids containing chlorine and sulphur (Ulzer and Horn, Jahresh. Chem. Technol. 1890, 1177; Henriques, Chem. Zeit. 1893, 707).

Dark or French substitute is obtained by heating a vegetable oil to 200°, and stirring in sulphur. The liquid thickens, and on cooling solidifies to a black elastic solid. It is sometimes prepared from rape-seed oil or cotton-seed oil which has previously been partially oxidised by treatment with air at a high temperature (*v.*, *e.g.*, Eng. Pat. 15163, 1899). Substitutes manufactured from these 'blown oils' have a sp.gr. less than 1, and are accordingly known as 'floating substitutes' (*v.* Altschul. Zeitsch. angew. Chem. 1895, 535).

A wet method of manufacture consists in oxidising the oil with dilute nitric acid at 100°, and then adding colophony, spirit of turpentine, sodium chloride, and sodium polysulphide, and boiling till the factis has the proper consistency. It is then finally washed, dried, and rolled (*v.* Lutenaf. Rev. Prod. Chim. 3, 147; J. Soc. Chem. Ind. 1900, 673).

These preparations, however, have only a limited application as rubber substitutes because of their small elasticity and insolubility in the usual rubber solvents. Also they are easily hydrolysed by steam and other agents. If excess of oil and sulphur are first removed from the factis by treatment with carbon disulphide, acetone, &c., they may be incorporated with a proportion

of pure rubber, and their usefulness much increased (Ditmar, Fr. Pat. 377538, 1907; J. Soc. Chem. Ind. 1907, 1058; *v. also* Chercheffsky, D. R. P. 218225, 1908; J. Soc. Chem. Ind. 1910, 440; and Heil and Esch, Manufacture of Rubber Goods, 110).

FAHLORE. A partial translation of the old German name *Fahlerz*, applied, like the term 'grey-copper-ore,' to minerals of the tetrahedrite group. These are essentially sulphantimonites or sulpharsenites of copper with the general formula $R'_3R''S_3$, where R' represents copper and silver, and R'' antimony, arsenic, or, exceptionally, bismuth. In many instances, however, small amounts of iron and zinc (less often mercury, lead, or cobalt) are also present, and the formula then becomes

where R'' represents iron, &c., and n is a small fraction usually $\frac{1}{10}$ or $\frac{1}{8}$ (Prior and Spencer, Min. Mag. 1899, xii. 202). A. Kretschmer (Zeits. Kryst. Min. 1910, xlviii. 484) gives several new analyses and writes the formula in the form $(R'_xR''_y)_3R''S_{3+\frac{y}{2}}$. Owing to this

wide range of isomorphous replacement, the actual composition of fahlore is extremely variable, as is illustrated by the following analyses. Further, owing to the fact that fahlore usually forms intimate intergrowths with other minerals, more particularly copperpyrites, it is probable that many of the older analyses were made on material which was not ideally pure.

I, Tetrahedrite from Fresney d'Oisans, Isère, France (G. T. Prior, 1899); II, tetrahedrite from Horhausen, Rhenish Prussia (G. T. Prior, 1899); III, tetrahedrite from Wolfach, Baden (G. T. Prior, 1899); IV, tennantite ('binnite') from Binnenthal, Switzerland (G. T. Prior, 1899); V, argentiferous tetrahedrite (freibergite) from Freiberg, Saxony (H. Rose, 1829); VI, mercurial tetrahedrite (schwartzite) from Schwarz, Tyrol (Weidenbusch, 1849).

Many of the names which have been applied to the minerals of this group express these differences in composition. Tetrahedrite (Fr. *Panabase*) and tennantite denote the antimonial and arsenical series respectively, and these are usually regarded as species; other names take the rank of varieties under these. For example, freibergite (Ger. *Weissgiltigerz*) is a variety of tetrahedrite containing much silver; schwartzite is a mercurial tetrahedrite; and malinowskite one containing lead. In the arsenical series, or tennantite, the names sandbergerite and kupferblende are applied to varieties rich in zinc; rhönite and annivite to those containing bismuth.

Although differing so widely in chemical composition, all varieties of fahlore are identical crystallographically, the type of symmetry being that of the tetrahedral class of the cubic system. A pronounced tetrahedral habit of the crystals is extremely characteristic of the antimonial members (hence the name tetrahedrite), whilst in the arsenical series (tennantite) this is often somewhat masked by the greater development of the rhombic dodecahedron. The colour is iron-black to steel-grey, and the lustre metallic and often brilliant. The fracture of pure material is typically conchoidal, with a brilliant lustre. The streak is usually black, but in some specimens (those containing but little iron) it is dark reddish-brown; hardness, 4; sp.gr. 4.4-5.1.

Fahlore occurs in mineral-veins in association with other metallic minerals. Beautifully crystallised specimens have been found in many mining districts, notably at the Herodsfoot Mine near Liskeard in Cornwall, Clausthal in the Harz Mountains, Kapnik in Hungary, &c. In the massive condition it is, at times, found in some abundance, e.g. in Nevada and Utah, and it is then an important ore of copper. The bulk of the rich silver ores of Bolivia and Peru consist of argentiferous tetrahedrite.

L. J. S.

FARINA, or POTATO STARCH. The starch of the potato, *Solanum tuberosum* (Linn.). The tubers are placed in a cylinder furnished with teeth by means of which the starch cells are lacerated whilst the mass of potatoes is reduced to a stiff pulp. The starch granules are washed out and allowed to settle in vessels of water, when the water is drawn off. The moist starch, after being separated from the cellulose, is dried and broken up between iron rollers. It is then ready for its purpose, which is in the main the sizing of textiles.

As a material for the purpose of sizing, farina produces when boiled a thicker paste than any other starch; consequently, a small amount of it will furnish a liquor of the same density as a much larger quantity of, for instance, wheaten flour. On the other hand, the starch

cells of the potato being exceptionally large, a certain amount of coarseness is felt in cotton goods stiffened by it. For this reason, it is seldom used with China clay alone, but is usually mixed with a greater or smaller proportion of flour. It is claimed for farina that, since the potato contains a small amount of nitrogenous matter, it is not so prone to induce mildew in cotton goods as are other forms of starch.

Farina has a glistening appearance and a crisp feeling when pressed between the fingers. It contains a larger proportion of moisture than any other starch, varying from 17 to 20 p.c. The granules are very characteristic, being for the most part large, though irregular in size, and resembling an oyster-shell in form, being, moreover, marked with similar eccentric rings.

The following is the average composition of ordinary commercial farina:—

Water	16.72
Cellulose	0.36
Ash	0.22
Starch	82.70

100.00

Farina is preferred to other starches for the manufacture of British gum, its great purity making it especially suitable for this purpose (*v. STARCH*).

FARNESOL, an alcohol found by Haarmann and Reimer in the oil of quassia flowers. It is found also in Peru and tolu balsam and palmarosa oil, and also, by Elze (Chem. Zeit. 1910, 34, 857), in cananga oil from Java. It is optically inactive; sp.gr. 0.985 at 15°, and boils at 145°-146° at 3 mm.

FATTY ACIDS. A numerous and important group of acids of the general formula $C_nH_{2n}O_2$, certain members of which are essential constituents of the animal and vegetable fats. The lowest term of the series is formic acid $H\cdot COOH$; the highest term at present known is dicetylic acid $C_{34}H_{66}O_2$. As the radical C_nH_{n+1} may exist in a variety of modifications, it follows that the fatty acids are also capable of existing in numerous isomeric forms. The fatty acids may, like the monovalent alcohols, be distinguished as primary, secondary, and tertiary. The secondary acids are usually

termed *iso-acids*, whilst the acids containing the groups $\text{CH}_3\cdot\text{CH}_2\cdot\text{CH}_2\cdot$. . . are called *normal acids*.

The naturally occurring fatty acids are found partly free and partly in the form of esters. Formic acid is found in ants, caterpillars, and in the stinging-nettle; butyric acid in butter, in perspiration, and, combined with hexyl alcohol, in the fruit of *Heracleum villosum* (Fisch.); cerotic acid in bees-wax; stearic acid in animal fats, &c. The higher members of the series, in combination with glycerol, forming the so-called *glycerides*, constitute the greater part of the more important animal and vegetable fats and oils and the different varieties of the waxes.

The lower members of the series, formic, acetic, propionic, acids, &c., are mobile volatile liquids, miscible with water, alcohol, and ether in all proportions. As the number of carbon atoms increases, they become less soluble in water, more oily and viscid, and less volatile. Thus *onanthic* (heptoid) acid $\text{C}_7\text{H}_{14}\text{O}_2$ is insoluble in water; capric (decylic) acid $\text{C}_{10}\text{H}_{20}\text{O}_2$ is solid at ordinary temperatures; whilst lauric acid $\text{C}_{12}\text{H}_{24}\text{O}_2$ and the higher homologues cannot be distilled under ordinary pressure without decomposition.

The most important general methods of obtaining these acids are:

- (1) By the oxidation of the primary alcohols or aldehydes, *e.g.* ethyl alcohol \rightarrow acetic acid.
- (2) By the addition of hydrogen to the unsaturated monocarboxylic acids, *e.g.* acrylic acid \rightarrow propionic acid.
- (3) By the reduction at high temperatures of hydroxy-acids with hydriodic acid or of halogen substituted acids with sodium amalgam, *e.g.* α -hydroxypropionic acid \rightarrow propionic acid.
- (4) By heating the acid nitriles with acid or alkali, *e.g.* acetonitrile \rightarrow acetic acid.
- (5) By decomposing ketones through oxidation with potassium permanganate, *e.g.* penta-decylmethylketone (obtained from palmitic acid) \rightarrow pentadecylic and acetic acids.
- (6) By decomposing unsaturated acids by fusion with caustic potash, *e.g.* oleic acid \rightarrow palmitic and acetic acids.
- (7) By decomposing the mono- and dialkyl-acetoacetic esters with concentrated potash solution, *e.g.* diheptyl-acetoacetic ester \rightarrow diheptyl-acetic acid.
- (8) By heating dicarboxylic acids, in which the two carboxyl groups are in union with the same carbon atom; *e.g.* dicetylmaleonic acid \rightarrow dicetylic acid.

The more important transformations which the fatty acids can be made to undergo are as follows:—

- (1) Acids and alcohols yield *esters* in the presence of hydrochloric or sulphuric acids.
- (2) The halogens react, producing substitution products.
- (3) Acids or their salts, when acted on by the chlorides of phosphorus, yield *acid chlorides* and *acid anhydrides*.
- (4) The ammonium salts of the acids split off water and become *acid amides* and *acid nitriles*.
- (5) *Primary amines* are produced by the reduction of the acid nitriles and by the action of bromine and sodium hydroxide on the acid amides. In the latter case, carbon dioxide is evolved and the primary amine of the next lower acid is produced.

(6) When the calcium salts are distilled with calcium formate, *aldehydes* are produced, but, when distilled alone, the calcium salts yield *ketones*.

(7) *Paraffins* are produced by the reduction of the higher fatty acids with hydriodic acid, by the electrolysis of concentrated solutions of the potassium salts of the acids and by the distillation of the calcium salts with soda lime.

The various members of the fatty acid series are described under their separate headings.

FAVERSHAM POWDER *v.* EXPLOSIVES.

FAVIER'S EXPLOSIVE *v.* EXPLOSIVES.

FAYALITE *v.* OLIVINE.

FAYENCE *v.* POTTERY and PORCELAIN.

FEATHER-ALUM. A name (Ger. *Feder-alun*) applied by Klaproth in 1802 to the iron-alum ($\text{FeSO}_4\cdot\text{Al}_2(\text{SO}_4)_3\cdot24\text{H}_2\text{O}$) now known as halotrichite (*q.v.*). Like alunogen (*q.v.*), kalinite (potash-alum), pickeringite (magnesia-alum), &c., it occurs as a delicately fibrous efflorescence on shale and some other rocks; and it is possible that these species also may have at one time or another been included under the indefinite term 'feather-alum.'

L. J. S.

FEATHER-ORE. A popular term (Ger. *Federerz*) applied to a number of finely fibrous minerals, which possess in common a lead-grey colour with metallic lustre. The material forms delicate tufts or felt-like masses. Brittle 'feather-ore' is referable to jamesonite (*q.v.*), since this possesses a good cleavage perpendicular to the length of the fibres. On the other hand, flexible 'feather-ore' may be stibnite (Sb_2S_3), plumbosite ($2\text{PbS}\cdot\text{Sb}_2\text{S}_3$), or one of the several other fibrous sulphantimonites of lead (Spencer, Min. Mag. 1907, 14, 207).

L. J. S.

FECULOSE is the term by which the various commercial starch esters are designated. They are best formed by the action of glacial acetic acid on starch, and then washing the product with cold water to free it from uncombined acid. By varying the starch base and the time and temperature of the reaction, or the concentration of the acid, an endless variety of products may be obtained according to the purpose for which they are required.

Feculose differs little in appearance or in ordinary chemical properties from ordinary starch. On boiling with water, it gives a clear homogeneous solution which does not set or revert on standing, gives the usual blue colour with iodine, and does not reduce Barreswil's (Fehling's) solution. When a little of the solution is allowed to dry on a clean glass plate, it forms a clear flexible film equal to that of the finest gelatin. The washed feculose is neutral or slightly acid, and reacts with most chemical reagents more readily than ordinary starch.

Uses.—Feculose has been described as an ideal substitute for gelatin and vegetable gums. It has been applied as a special textile finish to confer lustre and substance to textiles in the form of yarn or cloth and also as an excellent dressing for linen, lace, and silk. It is also employed in dyeing and French cleaning; in confectionery for making jujubes and other sweets, and in paper coating as a size in place of 'chromo' glue or casein. The surface produced in the latter case has excellent printing qualities.

A permanent solution of feculose can be obtained by varying the original process of

manufacture, and by various subsidiary treatments it can be made to fulfil a large range of technical requirements (Traquair, J. Soc. Chem. Ind. 1909, 288; Farrell, J. Soc. Dyers, Dec. 1908).

FEEDING STUFFS. Under this head will be considered the principal articles in use as food for live stock.

The main constituents of feeding stuffs, apart from water, are (1) nitrogenous bodies, subdivided into albuminoid or proteid substances and non-albuminoid bodies, such as amides; (2) oil or fat; (3) carbohydrates, including easily digestible substances like sugar or starch, and indigestible or less easily digestible bodies of the cellulose type; (4) the so-called 'mineral' constituents which constitute the 'ash' left on incineration. There are also frequently present other bodies, such as resinous matters, colouring matters, enzymes, and traces of glucosides and organic bases of the alkaloidal type; but these exist in relatively small quantities, and are usually ignored in commercial analyses. Small quantities of neutral or acid organic salts are also found in roots and green fodder crops.

Albuminoids or Proteins. These are bodies consisting of highly complex molecules built up by the union of numerous amino-acids (see article on PROTEINS, vol. iv.). The various proportions in which these amino-acids are combined, and the presence or absence of some one or other of them in the complex molecule, results in there being a large variety of proteins or albuminoids; so that the proteins in one food may possess different properties from those in another food. The albuminoids of wheat, for example, have properties which sharply distinguish them from those of other cereals, such as barley, oats, or maize, and the albuminoids of the leguminous grains differ from those found in any of these. The detailed study of the albuminoids has engaged much attention at the hands of physiological chemists, and is gradually throwing light on much that has been obscure as to the relative feeding value for different purposes of albuminoids derived from different sources. Practical experience shows that a mixed diet is often productive of better results than a simpler diet which may supply the same aggregate quantity of nitrogenous matter. Of the various amino-acids constituting the albuminoid molecules, some few, such as tryptophane, cystine, arginine, and histidine, even though present in relatively small proportions, appear to be essential to satisfactory nutrition, and an albuminoid material lacking in one of these essentials consequently needs to be supplemented by another in which the missing factor is present. For example, the albuminoids of maize appear to be destitute of, or poor in, tryptophane. This affords an explanation of the fact that maize, while a satisfactory food for stock in conjunction with other foods, is unsatisfactory when given alone, its albuminoids, owing to the lack of tryptophane, being but imperfectly assimilated. The addition, however, of a small quantity of other food containing albuminoids of which tryptophane happens to be a constituent, renders the maize protein assimilable, and enables the animal to obtain the full advantage

of the feeding matter contained in the maize. Albuminoids consist of carbon, hydrogen, oxygen, nitrogen, and a small quantity of sulphur. On the average, they contain 16 p.c. of nitrogen, and are usually calculated from the nitrogen present on this assumption. In some foods (see *infra*) the proportion of non-albuminoid nitrogenous compounds is sufficient to make it desirable to separate these in analysis, and to calculate the albuminoids from the true proteid nitrogen only. But in most concentrated foods it is conventional and sufficiently near for practical purposes, to calculate the albuminoids by multiplying the total nitrogen present by 6.25.

The chief function of albuminoids in food is to build up the nitrogenous tissue of the growing animal, and to replace the daily nitrogenous waste due to the normal processes of metabolism. Hence they have long been called 'flesh-formers,' in contradistinction to fat and carbohydrates. Albuminoids, however, are also capable of being partially transformed into fat, and also of generating heat and motive energy by their oxidation. These functions, however, are mainly performed by fat and carbohydrates.

The digestion of albuminoids is effected mainly by the action of pepsin, secreted by the stomach and of trypsin, which is a constituent of the pancreatic juice. By these ferments, they are converted into soluble bodies, peptones and albumoses, and finally broken down into their constituent amino-acids, which are then absorbed into the animal system, forming the materials for the reconstruction of the various proteins or albuminoids of the body, or used directly for the production of energy.

The non-albuminoid nitrogenous constituents of food, chiefly amides, are soluble and need no digestion. They do not form muscular tissue, like the albuminoids, but they yield heat and energy, and to some extent help to preserve the nitrogenous constituents of the body itself from waste.

Oil or Fat. A large number of fats are found in vegetable tissue. For the main part they are triglycerides of one or other of the series of bodies known as the 'fatty acids'; but they also include in some cases small quantities of wax or fat in which the glyceryl radical is replaced by that of some solid alcohol like phytosterol. Lecithin, which is present in small quantities in some vegetable substances, is a fat containing nitrogen and phosphorus. In the analysis of feeding stuffs, the matter extractable by ether is usually assumed to be fat, though in the case of some foods small quantities of resinous bodies are included in the extract, as well as chlorophyll.

The function of fat as a food is to build up the fat of the body and to furnish heat and energy on its oxidation or combustion in the blood.

Fat is digested and rendered absorbable into the blood mainly by the action of bile, aided by the pancreatic secretions and those of various intestinal glands.

Carbohydrates. Sugars of various types occur in feeding stuffs, sometimes in insignificant quantity, as in ordinary grain, sometimes in large quantity, as in some roots, the feeding value of which lies principally in these constituents. Thus mangolds and beets contain sucrose or cane sugar, whilst turnips contain

dextrose or 'grape sugar.' In addition to sugars of the hexose type, some fodder plants yield sugars of the pentose type. Sugars, being soluble, need no digestion.

Starch, which is practically perhaps the most important of the carbohydrates, consists of organised cells which are insoluble in cold water though capable of being gelatinised and partially dissolved by boiling water. Starch is convertible by mineral acids into sugar (dextrose), and is resolved by certain ferments, both vegetable and animal, into the soluble bodies maltose (malt sugar), and dextrin, a viscous body devoid of sweetness. The latter resolution is effected by the ferment *ptyalin* in the saliva, and also by a ferment contained in the pancreatic juice. The acid secretions of the stomach also act on starch, and the maltose and dextrin are further modified into dextrose during passage through the intestines.

Cellulose. Numerous substances are grouped under this head. The typical form of cellulose is cotton. Material of this nature forms the coating of vegetable cells, and consequently the whole 'skeleton' of a plant. But it is modified in composition in different tissues, and sometimes partially assumes a woody form, as in straw and hay. In food analyses, the various forms of cellulose are called 'fibre,' and are determined by boiling the food successively in weak mineral acid and weak alkali, and extracting with alcohol and ether. The residue is usually described as 'fibre' or 'crude fibre,' or sometimes as 'indigestible fibre.' The last description was given on the assumption that the artificial digestion referred to was equivalent in ultimate effect to the digestive processes of the animal. But modern research has shown that bodies of the cellulose type which resist the solvent treatments referred to are to a variable extent partially digestible, especially by ruminants. This digestion is probably mainly effected by the action of bacteria in the large intestine. A ruminant can digest much more cellulose than a horse, and a horse much more than a pig. The very thorough mastication of the ruminant better prepares the fibre for such digestion as is possible than does the imperfect mastication of the horse or the still more imperfect mastication of the pig, apart from the anatomical differences in the digestive tracts of the respective animals and the relative abundance of bacteria capable of effecting cellulose digestion. How much the physical or mechanical condition of the fibre has to do with its digestion has been demonstrated by Kellner, who found that, when straw fibre was disintegrated by boiling with soda lye under pressure (as in the preparation of fibre for paper making), the fibre had a digestibility coefficient of 56 to 60 p.c., whereas, in the unprepared straw, it was only 42 p.c. But the energy spent by the animal in the partial digestion of some forms of fibrous foods sometimes exceeds the energy-producing value of the material digested, so that the result of the digestion process may sometimes be of even negative value.

Other insoluble carbohydrates are those of the pentosan type, which yield pentose sugars on treatment with acids, but the conditions affecting their digestion are not well understood,

and the feeding value of the pentoses which they yield is probably small.

The function of carbohydrates is to supply the main quantity of fuel for the generation of heat and the production of mechanical force, and, when these necessary requirements are fulfilled, the excess serves to build up fat in the body.

Mineral matters, or 'ash constituents,' are the residues left on incineration of the heterogeneous mass of organic compounds and salts contained in the food. Probably most of the 'mineral' matter thus obtained exists in the food in organic combination. The chief constituents of the ash are phosphoric acid, sulphuric acid, calcium, potassium, and magnesium, with smaller quantities of iron, sodium, and chlorine, and traces of fluorine. Silica is also a large constituent of straw, and is found in grass. Other elements are no doubt commonly present in minute traces.

The function of 'mineral' matters in food is to build up the main substance of the animal skeleton and to provide the material necessary for forming the saline constituents and inorganic acids of the blood, gastric juice, and other fluids and secretions of the body, as well as to supply elements, such as phosphorus, sulphur and iron, which form integral parts of the blood corpuscles and of muscular and other tissues.

The general composition of some of the various feeding stuffs in common use is stated in the accompanying tables. The items given are moisture (*i.e.* loss on drying at 100°C.), oil (ether extract), albuminoids, digestible carbohydrates, fibre and mineral matter (ash). The term 'digestible' as applied to carbohydrates here merely means rendered soluble during the process of successive boiling in weak mineral acid and weak alkali (for details see *Methods of analysis, infra*). The question of actual digestibility by the animal will be considered further on. The term 'albuminoids,' except where otherwise specified, means total nitrogen multiplied by 6.25, as is conventional for the purpose of commercial analysis. It has been already pointed out that the whole of the nitrogen in foods is not present in the proteid form, some portion being in the form of amides or similar bodies, but that in what are generally called 'concentrated' foods, such as seeds and seed products, the proportion of non-albuminoid nitrogen is relatively small, and not worth differentiation for the ordinary practical purposes of comparison of one sample with another. For instance, in barley, oats, maize, wheat, and rye, the actual albuminoid nitrogen is from 90 to 96 p.c. of the total nitrogen; in cotton cake, linseed cake, and ground-nut cake, and in brewers' grains, about 96 p.c.; in peas and beans, about 90 p.c.; in rice meal (rice bran), about 92 p.c.; and in wheat bran, about 86 p.c. In straw (a ripened stem, it may be noted), the proportion is about 90 p.c. In meadow hay it is less, namely, about 87 p.c. In young or immature grass or clover, the proportion is only from about 70 to 75 p.c., and in grass or clover preserved in the moist state as silage it may be only 50 to 60 p.c., owing to partial degradation of the albuminoids by fermentation. In roots, the proportion of albuminoid to total nitrogen may fall below 40 p.c. (as in mangolds). In turnips,

carrots, and potatoes, it is from about 50 to 60 p.c., and in cabbages probably about 70 p.c.

Before referring to the tabulated statement of composition of various foods, the reader should bear in mind that the analyses given are in most cases typical only of the average composition of each, and that considerable differences occur between different samples, which is, indeed, the reason why many of them are ordinarily subjected to analysis for the purposes of commercial transactions. These variations are often considerable even in natural grains such as oats, but are especially notable in the case of what may be called 'manufactured' feeding stuffs such as oil cakes. The feeding value of these is largely affected by the extent to which the oil has been pressed from the seed. Thus linseed cake, if lightly pressed, may contain 15 or 16 p.c. of oil. Under medium pressure, it may contain 12 p.c., and would still be regarded as rich in oil. Very commonly it is pressed down to 10 p.c., while very heavily pressed cake has often only 7 or 8 p.c. of oil, and sometimes, though rarely, as little as 5 or 6 p.c. Sometimes (or often in the case of cotton cake) the cake is ground and sold as meal. In such cases, it is especially important to have regard to the oil, as oil is largely extracted from some seeds, not by pressure, but by exhausting the finely ground seed with a volatile solvent such as petroleum spirit, in which case it may have only 1 p.c. of oil. This process is largely applied to rape seed, soya beans and palm-kernels. Again, in the case of linseed or rape cake, the percentage of albuminoids varies largely with the variety of seed from which the cake is made. Linseed cake, made from East Indian linseed; may contain from about 25 to about 30 p.c. of albuminoids; cake from Russian linseed, about 27 to about 35 p.c.; whilst cake made from American Western linseed sometimes contains nearly 40 p.c. of albuminoids. The composition of undecorticated cotton-seed cake varies according to whether it is made from the large smooth Egyptian seed or from the small thick-shelled and cotton-coated Indian variety. In the case of decorticated cotton-seed cake—made from American woolly seed stripped of its husk or 'hull'—the quality of the cake or meal depends largely upon the perfection with which the shelling process has been carried out. Often the separated shells are ground and partially put back after the decorticated seed has been crushed in the mills and the cakes reground to meal. Some foods are residual portions of grains, the main part of which is used for human food—as, for example, wheat-bran, rice meal (really rice-bran), and numerous foods made from various fractions of the maize kernel. These are necessarily of variable composition, according to the method and degree of separation from the other parts of the grain.

Owing to the importance of albuminoids in feeding, and to their special value for milch cows, and for balancing the natural poverty in albuminoids of natural fodders such as roots, 'concentrated' food stuffs are sometimes graded according to their richness in albuminoids. Thus, decorticated cotton cake or meal, groundnut (*Arachis*) cake, and soya-bean cake or meal, may be described as very rich in albuminoids (40 to 50 p.c.); linseed cake and rape cake as

rich (say 25 to 35 p.c.); undecorticated cotton cake, beans, peas, and dried brewers' grains as moderately rich (20 to 25 p.c.); whilst wheat, oats, rye, barley, maize, feeding flour, rice meal, bran, pollards, and millet, would be described as relatively poor in albuminoids (10 to 18 p.c.).

In the case of fodder crops, such as grass and hay, the composition varies much with the stage of growth at which they are cut, as well as with the species of plants which constitute them.

The relative manurial value of the excreta yielded by the consumption of feeding stuffs depends largely on the proportion of nitrogen they contain, and to a minor extent on the phosphoric acid and potash contained in their ash. This aspect of their value is too complex to be entered upon here. A very full discussion of this part of the subject by Voelcker and Hall in the light of modern investigation, especially with regard to the question of compensation for unexhausted manurial value under the Agricultural Holdings Act, will be found in the Journal of the Royal Agricultural Society for 1902 and 1913.

Digestibility of feeding stuffs. It never happens in practice that an animal digests the whole even of the potentially digestible matters in its food. The quantity digested depends not only on the inherent potential digestibility of the food, but also on the species, age, condition, and individual constitution of the animal, and the quantity and quality of the food supplied to it. A large number of experiments have, however, been carried out, chiefly in Germany and in America, to ascertain as nearly as is practicable the proportion of the various kinds of nutritive matter actually digested in most of the feeding stuffs in use on the farm, the experiments having been made with the various farm animals, ruminant and non-ruminant. The composition of the food supplied to the animal is ascertained by analysis and its quantity weighed. The faeces are collected, weighed, and analysed, and the difference gives the quantity of each constituent digested. The experiments are carried on for a sufficient length of time to eliminate as far as possible errors due to previous feeding, the results for the first few days being neglected. The results, especially in the case of poor and bulky foods, are vitiated to some extent by such of the secretions of the alimentary canal as are voided with the excreta; while the results obtained with concentrated foods are complicated, and probably vitiated by the fact that such foods, in the case of ruminants, must necessarily be mixed with large quantities of bulky fibrous fodder, any variations in the digestion of which, brought about by the different conditions of feeding, become credited to the account of the concentrated food, which cannot be tried by itself. Despite these and other sources of inexactness, the study of the results of a number of experiments gives the nearest approach we can get to a faithful estimate of what proportions of albuminoids or of fat or of carbohydrates will *probably* be digested and utilised in the average circumstances of farm feeding, and much credit is due to such investigators as Kuhn, Wolff, Kellner, Zuntz, Armsby, and others for their long and patient labours in this field of work, in which the pursuit

¹ By 'digestible' is here meant dissolved by successive boiling in acid and alkali (see *Methods of analysis*, infra).² Compiled chiefly from averages calculated and tabulated by R. Warington.

of truth is impeded by so many pitfalls and obstacles. Ruminants have a better power of digestion than horses, especially for fibrous foods, and in this respect horses are better digesters than pigs. The following figures, extracted from a table compiled by Kellner, show the average results obtained with ruminant animals as regards the quantity of albuminoids, fat, 'soluble' carbohydrates, and fibre, out of 100 parts of each of these constituents, when supplied in the form of the more common feeding stuffs. By 'soluble' carbohydrates are here meant those dissolved by successive boiling with dilute acid and dilute alkali, usually termed in commercial analyses 'digestible.' As the latter word would here be ambiguous, the alternative term 'soluble' is used. (In German works this item of 'soluble' carbohydrates is

usually rendered as 'nitrogen-free extract.') It will be noticed that with some foods, the experiments have been too few, having regard to the difficulty of such work, to lend any very strong validity to the figures. In other cases, the number of trials engenders more confidence in the probable general truth of the average figures, but it will be seen even in these cases that the range from minimum to maximum quantities digested in the experiments averaged is sometimes wide.

Energy equivalents of feeding stuffs. The ultimate physiological value of any food constituent is largely dependent upon the quantity of potential energy producible by its oxidation in the system, or by the oxidation of the equivalent body substance that it replaces. This energy may be manifest in maintaining the heat of the

body, or in the mechanical work effected in the various movements of the body, including locomotion, the pulsation of the heart and circulation of the blood, and the mechanism of respiration. Not a little of the energy latent in coarse fodder is expended in the mere work of mastication and the other mechanism of digestion. The excess of digested food over that portion spent in maintaining the temperature and effecting the movements incidental to quiescent existence, is stored up as body increase (as in a fattening ox) or used in the production of the foetus or of milk (as in the case of a cow). In the case of a working animal, such as a horse, the excess of food digested is spent in the production of external mechanical work, such as traction; and so, of course, with a ploughing ox. The ultimate potential energy of a food-stuff is measurable by the heat generated by its complete combustion in oxygen, now usually determined for experimental purposes by burning a weighed quantity of the material with compressed oxygen in a steel bomb immersed in a known weight of water, and measuring the rise of temperature imparted to the water. Expressing the results of such determinations in large calories (a large calorie being the heat necessary to raise 1 litre of water 1 degree centigrade), the combustion of 1 gram of each of the following food constituents is found to give approximately heat as under:—

Oil or fat	9.4
Proteins	5.8
Starch or cellulose	4.1
Cane sugar	4.0
Dextrose or glucose	3.8
Milk sugar	3.9
Asparagine	3.4

In the consumption of feeding stuffs by animals, only a portion of the theoretical potential energy, as indicated by their combustion heat, is realised. In the first place, as we have already seen, only a fractional part of the food is digested, and only the digestible part can yield energy. Furthermore, the oxidation of the digested matter is incomplete. The oxidation of completely utilised proteins goes no farther than the production of urea, and, although the great bulk of the carbon of utilised food is exhaled in the completely oxidised form of carbonic acid, a portion is also given off in the unoxidised form of hydrocarbon gas or methane. In order to ascertain the energy either actually realised or potentially stored by the animal from a given diet, it is necessary to feed it in a respiration chamber fitted with such appliances that the faeces and urine can be separately collected, and the whole of the gases expired during the experiment collected and analysed. The heat or combustion equivalent of the food consumed is determined on accurately sampled portions of the daily diet. A similar determination in the dried faeces gives, by deduction, the potential heat energy in the food actually digested. A combustion of the dried residue of the urine voided and a measurement of the carbonic acid and water produced by combustion of the dried unoxidised gases exhaled from the lungs and otherwise, give the data for deducting the fuel energy corresponding to these factors, and so the real or potential energy generated or stored in the animal is determined.

In order to trace the disposition of this energy, it is necessary, in addition to the foregoing determinations, to weigh accurately the

water as well as the dry food consumed, and to determine accurately all moisture given off by the animal in faeces, urine, breath, and perspiration, and also the carbonic acid evolved. By means of delicately constructed respiration calorimetric chambers, it is possible to make very exact determinations of the actual heat produced in or by the animal during the experiment, and from the whole of the data obtainable to calculate, not only what fraction of the total proteids, fat, and carbohydrates has been digested, but how much of them has been stored up in the form of flesh or fat, and how much is expended in what may be called maintenance energy and heat production. Some foods, such as hay, and especially straw, require so much energy for their mastication and digestion that only a relatively small portion of the actually digested matter may be available for increase of tissue or fat formation, or for the production (in a horse) of external work, a comparatively large quantity of heat being produced. In concentrated, easily digestible foods, the loss of energy between administration of the food and storage as flesh or fat is much less. Thus, Kellner has shown that, in the case of a fattening ox, only 41 p.c. of the potential energy in a pound of digested starch is lost or used in converting that which corresponds to the remainder into fat or other tissue. In the digested portion of meadow hay, the loss of energy involved in digestion and assimilation was over 58 p.c.; in that of oat straw, 62.4 p.c.; and in that of wheat straw, as much as 82 p.c. Similarly, Zuntz found in the case of the horse that only from 10 to 15 p.c. of available energy was consumed in the processes of digestion and assimilation in the case of maize, beans, and oats, the remainder being available for the performance of external mechanical work, while in the case of hay, the mere process of digestion and assimilation of the digestible portion consumed from 50 to 60 p.c. of the potential energy of such portion, leaving only from 40 to 50 p.c. available for 'work.' In the case of straw, the energy expended by the horse in mastication and digestion was found to be even greater than the whole of the potential energy in the portion digested, showing, apparently, that straw has a negative food value for horses, except as a 'filler' and diluent for more concentrated food.

Albuminoid ratio. By this term is meant the ratio of digestible protein or albuminoids to the digestible fat and digestible carbohydrates in the food. In order to state this on a uniform basis, fat is converted into its approximate equivalent in digestible carbohydrates by multiplying the fat by the factor 2.3, on the assumption that on the average the energy and fat-producing value of the latter is approximately 2.3 times that of the former. Thus, if a food contains 20 p.c. of digestible albuminoids, 10 p.c. of digestible fat, and 40 p.c. of digestible carbohydrates, the albuminoid ratio would be $20 : (10 \times 2.3 + 40)$, or $20 : 63$, or approximately 1 : 3. Linseed cake has an albuminoid ratio of about 1 : 2, which is called a 'narrow' ratio; and maize of about 1 : 10, which is called a 'wide' ratio; while in mangolds the ratio is exceedingly wide, namely, about 1 : 85. The efficacy of a mixed diet for a specific purpose is much affected by its albuminoid ratio. Fattening or

working animals get on well with a diet of a fairly wide ratio, such as from 1 : 8 to 1 : 10, though even in the case of fattening animals, the ratio should be narrower (1 : 5 or 1 : 6) in the early stages of feeding. Young growing animals, animals with young, and cows in milk, need a diet of correspondingly 'narrow' ratio, i.e. richer in proteids, such as 1 : 5.

The subject of the maintenance value, energy value, and productive value of the various feeding stuffs cannot be further pursued here. It may be advantageously studied in very thorough detail in *The Principles of Animal Nutrition*, by H. P. Armsby, of the Pennsylvania State Agricultural Experiment Station (English publishers, Chapman & Hall, Ltd., 1903). Readers may also be referred to *Chemistry of the Farm*, by R. Warington (Vinton & Co., Ltd., London, 1902); to *The Feeding of Crops and Stock*, by A. D. Hall (John Murray, London, 1911); and to Goodwin's English translation of *The Scientific Feeding of Animals*, by O. Kellner (Duckworth & Co., London, 1909). The last-named book contains very full tables showing the composition, digestibility, and energy values of most of the foods in use on the farm, and ration tables for the dieting of farm animals, compiled from the results of scientific investigation. A useful table, compiled by A. Smetham and F. Robertson Dodd, showing the composition of a large range of feeding stuffs met with in commerce, including many materials not commonly offered as such to farmers, but in extensive use for the manufacture of compound foods, may be found in a paper reprinted from the *Journal of the Royal Lancashire Agricultural Society* for 1921, and published by that Society at Liverpool, under the title of *The Valuation of Feeding Stuffs*. A pamphlet on the *Composition and Nutritive Value of Feeding Stuffs* by T. B. Wood and E. T. Halnan is also issued from the Animal Nutrition Institute of Cambridge University, and published by the Cambridge University Press.

Analysis of feeding stuffs. The following methods are those commonly in use:—

Moisture.—A weighed quantity (usually about 3 grams) of the material, finely crushed or powdered by passing through a small mill, is dried at 100°C. until it ceases to lose weight. The loss is taken to be moisture.

Oil.—This is usually determined by extraction with ethyl ether. The method officially laid down (1908) for use under the Fertilisers and Feeding Stuffs Act in England, is as follows:—

'A weighed quantity of the sample shall be placed in a Soxhlet thimble, which shall then be placed in the Soxhlet extraction tube and extracted with washed, redistilled ether. At the end of 3 to 4 hours, the thimble shall be removed from the Soxhlet tube, dried, and its contents finely ground in a small mortar previously rinsed with ether. The substance shall then be returned to the thimble, the mortar being washed out with ether, and the extraction continued for another hour.

'After evaporation of the solvent, the oil shall be dried at 100° and weighed. The oil shall be redissolved in ether, and any undissolved matter shall be weighed and deducted.

'In the case of samples containing saccharine

matter, e.g. sugar meals, the weighed portion in the Soxhlet thimble shall be washed twice with water, and then dried, previous to the extraction.

A convenient quantity to work upon for determination of oil is about 3 grams.

Albuminoids.—The percentage of albuminoids, as already stated, is, for the purpose of ordinary feeding stuff analyses, conventionally arrived at by determining the nitrogen and multiplying the percentage thereof by 6.25. Nitrogen is now almost universally determined by some modification of the Kjeldahl process. The details of the method, as officially laid down (1908) for use under the Fertilisers and Feeding Stuffs Act in England, are as follows:—

'A weighed portion of the sample shall be transferred to a Kjeldahl digestion flask; 10 grams of potassium sulphate and 25 c.c. of concentrated sulphuric acid shall be added, and the flask heated until a clear liquid, colourless or of light-straw colour is obtained. The operation may be accelerated by the addition of a small crystal of copper sulphate or a globule of mercury to the liquid in the digestion flask.

'The quantity of ammonia shall be determined by distillation into standard acid after liberation with alkali, and, where mercury has been used, with the addition also of sodium or potassium sulphide solution.

'The materials used shall be examined as to their freedom from nitrogen by means of a control experiment carried out under similar conditions with the same quantities of the reagents which have been employed in the actual analysis, one gram of pure sugar being used in place of the weighed portion of the sample. The quantity of standard acid used in this control experiment shall be deducted from the total quantity of acid found to have been neutralised in the distillation of the sample.'

A convenient quantity to work upon for the nitrogen determination will, in most cases, be found to be from 1 to 1.5 grams.

The percentage of 'true albuminoids' or proteid substances, as distinguished from nonproteid bodies such as amides, &c., is sometimes determined by what is known as the phenol method, but more commonly now by the copper oxide method.

The phenol method depends upon the coagulability of proteids by phenol. A quantity of from 1 to 2 grams of the powdered feeding stuffs is covered with a warm 4 p.c. aqueous solution of phenol, to which have been added a few drops of a freshly made aqueous solution of metaphosphoric acid. After 15 minutes, a little boiling phenol solution is added, and the mixture stirred and allowed to cool. The whole is then poured on to a small filter, which is washed with more of the same liquid, but cold. After drying, the filter and its contents are transferred to a Kjeldahl digestion flask, and the nitrogen is determined as already described (Church and Kinch).

The copper oxide method depends upon the power of moist copper hydroxide to unite with proteid substances to form insoluble compounds. The preparation of cupric hydroxide used is known as Stutzer's reagent. It is made by dissolving 100 grams of copper sulphate in 5 litres of water with the addition of 2.5 c.c. of glycerol. A dilute solution of sodium hydroxide is added until the liquid is just alkaline. The precipitate of cupric hydroxide is filtered off,

drained, transferred to a dish, and washed by decantation with water containing 5 c.c. of glycerol per litre, until the washings are no longer alkaline. The precipitate is mixed in a mortar with water containing 10 p.c. of glycerol, and transferred to a stoppered bottle. A gelatinous mixture is thus obtained which, when shaken up, can be removed by means of a pipette. The determination of albuminoid nitrogen is made as follows: About 1 gram of the feeding stuff is weighed out, mixed with 100 c.c. of water and boiled or heated in the water-bath for 10 minutes. A quantity of the cupric hydroxide paste, containing about 0.8 gram of actual cupric hydroxide, is added, and the whole thoroughly stirred, warmed for a short time, and allowed to cool. When cold it is filtered and washed with cold water. After drying, the filter and its contents are transferred to a Kjeldahl digestion flask, and the nitrogen determined as above described. Instead of adding the cupric hydroxide paste directly to the solution, it is desirable to place the requisite quantity in a separate beaker, treating it with cold water, allowing it to settle, and pouring off the water in order to eliminate the glycerol, which is used merely as a vehicle for the preservation of the reagent.

Fibre.—A weighed quantity (conveniently about 3 grams) of the ground sample, either with or without previous extraction with ether, is boiled for half an hour with 125 c.c. of a 2 p.c. solution of sulphuric acid, the loss of water due to boiling being continuously made up. The fluid is diluted with a few hundred cubic centimetres of water, and allowed to stand for some time. The bulk of the fluid is then filtered off, any matter that becomes transferred to the filter being washed back again into the original vessel. The residue is then boiled with 125 c.c. of a 2 p.c. solution of potassium hydroxide, diluted, and filtered—this time through counterpoised filters. The fibrous matter is washed on to the filter, washed with boiling water until the washings are no longer alkaline, then with a little dilute acid, and then with water until the washings are no longer acid. It is next washed several times with methylated spirit, and, if the oil was not removed prior to the fibre determination, it must be finally washed several times with ether. Finally the fibre is dried to constancy in a water-oven, and weighed.

Ash.—A quantity of the material (for example, 3 grams) is placed in a platinum capsule and heated over an argand burner turned down low. The heating is continued over a yellow flame until the residue is free from carbon. The residue under incineration should be stirred from time to time with a platinum wire, being meantime lightly covered with an arched piece of platinum foil. Ignition over a Bunsen burner is more rapid, but is liable to result in loss of potash.

Sand and other silicious matter.—The ash, after being weighed, is digested in the platinum basin with a little dilute hydrochloric acid, and the silicious matter filtered off, ignited, and weighed. This consists of sand, together with—in the case of some foods—silica derived from naturally silicious tissues, such as rice husks.

'Digestible' carbohydrates.—This item, which includes starch, sugars, mucilaginous matter, pentosan derivatives, and other bodies—sometimes

also termed 'soluble carbohydrates' or, as in Germany, 'nitrogen-free extract'—is taken by difference. For the methods of determining the various sugars, starch, &c., separately, the reader is referred to other sections of this work. B. D.

FELSPAR or Feldspar. (Fr. *Feldspath*; Ger. *Feldspath*, *Feldspat*; from the Swedish *Feltspat* or *Fältspat*, meaning 'field-spar.') A large isomorphous group of important rock-forming minerals consisting of aluminosilicates of alkalis (potassium and sodium, rarely rubidium, cesium, and lithium) and alkaline earths (calcium, and less often barium). They include polysilicates or trisilicates of the type $R'AlSi_2O_8$, and orthosilicates of the type $R''Al_2(SiO_4)_2$. The principal molecules representing the end-members of the isomorphous series are $KAlSi_3O_8$ (Or=orthoclase), $NaAlSi_3O_8$ (Ab=albite), and $CaAl_2Si_2O_8$ (An=anorthite). Others of less importance, or whose existence is only assumed on theoretical grounds, are $BaAl_2Si_2O_8$ (Ce=celcian), $Na_2Al_2Si_2O_8$ (Cg=carnegieite), and $RbAlSi_3O_8$ (rubidium-microcline).

The feldspars are usually divided crystallographically into two series, the monoclinic (or oblique) feldspars and the triclinic (or anorthic) feldspars. But, although these belong to different systems of crystallisation, they resemble one another closely in habit, cleavage, and general crystallographic characters. An important feature of all feldspars is the existence of good cleavages in two directions; the more perfect one being parallel to the basal pinakoid $c(001)$, whilst the second is parallel to the clinopinakoid or plane of symmetry $b(010)$ in the monoclinic feldspars, and parallel to the corresponding brachypinakoid $b(010)$ in the triclinic feldspars. In the monoclinic system these two cleavages are necessarily at right angles (90°), and the feldspars belonging to this system are consequently described as orthoclasic feldspars; whilst in the triclinic system the cleavage angle bc varies slightly from a right angle (in anorthite $bc = 86^\circ 50'$, and in albite $bc = 86^\circ 24'$), and for this reason these feldspars are called plagioclasic feldspars, or simply plagioclase. To these two series may be added a third—pseudo-monoclinic series—the members of which are shown by their optical characters to be triclinic, but in the external form of their crystals they do not differ from those of the monoclinic series and the cleavage angle bc does not differ appreciably from 90° . The several members of these three series of feldspars are set out in the following table:—

	Monoclinic series	Pseudo-monoclinic series	Triclinic series
$KAlSi_3O_8$	Orthoclase	Microcline	—
$mKAlSi_3O_8$	Soda-orthoclase	Anorthoclase	—
$nNaAlSi_3O_8$			
$NaAlSi_3O_8$	Barbierite	Cryptoclase	Albite
$mNaAlSi_3O_8$	—	—	{ Oligoclase, Labradorite, &c.
$nCaAl_2Si_2O_8$			
$CaAl_2Si_2O_8$	—	—	Anorthite
$Na_2Al_2Si_2O_8$	—	—	Carnegieite
$BaAl_2Si_2O_8$	Celsian	—	—
$mBaAl_2Si_2O_8$	Hyalophane	—	—
$nKAlSi_3O_8$			

The only members of practical importance are the potash-feldspars, orthoclase, and microcline (which, as noted below, are perhaps really identical); the soda-feldspar, albite; the lime-feldspar, anorthite; and the soda-lime-feldspars, oligoclase, andesine, labradorite, and bytownite. All of these, with the exception of potash-feldspar, belong to the isomorphous group of plagioclase-feldspars, of which albite and anorthite are the end-members. The limits of composition usually assigned to these are:

		SiO ₂	Al ₂ O ₃	Na ₂ O	CaO	
Plagioclase-feldspars.	Albite	Ab ₁ An ₀	68.7	19.5	11.8	—
	Oligoclase	Ab ₂ An ₁	64.9	22.1	10.0	3.0
	Andesine	Ab ₃ An ₁	62.0	24.0	8.7	5.3
	Labradorite	Ab ₄ An ₁	55.6	28.3	5.7	10.4
	Bytownite	Ab ₅ An ₃	49.3	32.6	2.8	15.3
		Ab ₁ An ₆	46.6	34.4	1.6	17.4
	Anorthite	Ab ₀ An ₁	43.2	36.7	—	20.1

A character which always enables the plagioclase-feldspars to be readily recognised is the invariable presence of lamellar twinning according to the albite-law. This is shown in thin sections of rocks when examined in polarised light by the banding due to the different directions of extinction in alternate lamellæ. In a hand-specimen it is shown on the basal plane $c(001)$, and on the perfect cleavage parallel to this face, by a system of fine striæ parallel to the edge of intersection of the two cleavages. These striæ can usually be detected with the aid of a pocket-lens when the cleavage surface is held at a suitable inclination to the light; and two sets of reflections can be obtained in albite inclined at $7^\circ 12'$, and in anorthite at $8^\circ 20'$. Albite-twinning is not present in orthoclase, but is present in microcline, though in this case the striæ are not evident on the cleavage surface. This difference often affords a ready means of distinguishing at sight a potash-feldspar from a soda-lime-feldspar. In microcline there is also a second lamellar twinning according to the pericline-law, which, in conjunction with the lamellar albite-twinning, produces a very characteristic cross-hatched structure, sometimes to be seen on the basal plane of crystals, but very evident when thin sections are examined in polarised light; this being, indeed, often the only means of distinguishing microcline. Several other twin-laws have been described for the feldspars, the important ones being the Carlsbad, Baveno, and Manebach types. The very common occurrence of repeated twinning in this group of minerals gives rise to the suggestion that the higher degree of symmetry in the monoclinic series is merely the result of twinning, and that all feldspars are really triclinic. This is obviously the case in the pseudo-monoclinic series, in which, on optical examination, the twinning is seen to be repeated on a very minute scale. If this became ultra-microscopic, then the crystal could not be distinguished from a true monoclinic crystal. The crystallographic grouping shown in the above table would then break down, while the chemical grouping alone stands. Microcline would then be identical with orthoclase, which, indeed, it is in density, refractive indices, mode of occurrence, and its practical applications.

Some of the constants of the three most important species of feldspar are given below:—

	Orthoclase (KAlSi_3O_8)	Albite ($\text{NaAlSi}_3\text{O}_8$)	Anorthite ($\text{CaAl}_2\text{Si}_2\text{O}_8$)
	p.c.	p.c.	p.c.
SiO_2	64.7	68.7	43.2
Al_2O_3	18.4	19.5	36.7
CaO	—	—	20.1
K_2O	16.9	—	—
Na_2O	—	11.8	—
Sp.gr.	2.56	2.62	2.76

" " b	+5°	+19°	-36°
Ref. Index (Na) α	1.519	1.529	1.576
" " β	1.523	1.533	1.583
" " γ	1.524	1.539	1.588
Birefringence $\gamma - \alpha$	0.005	0.010	0.012

The recognition of a mineral as feldspar is usually evident by the cleavages, dullness of colour and lustre, hardness, resistance to acids, &c.; but the discrimination of the several species is not always so easy. The optical characters of cleavage flakes afford a useful guide, and the specific gravity of fragments can be readily determined in a heavy liquid with the aid of indicators. J. Szabó (Ueber eine neue Methode die Feldspathe auch in Gesteinen zu bestimmen, Budapest, 1876; v. G. A. J. Cole, Aids to Practical Geology, 5th ed. London, 1906, 73-85) devised a method in which the intensity of coloration imparted to the Bunsen flame gives an approximate indication of the percentage of potassium and sodium present. Anorthite is decomposed by hydrochloric acid with separation of gelatinous silica. The other feldspars are only very slightly attacked by acids (except hydrofluoric), alkaline solutions, and carbonated water; but they are decomposed by hot alkaline solutions under pressure.

The following analyses are of: I, Orthoclase from Norway, as used in the manufacture of porcelain; formula $\text{Or}_{78}\text{Ab}_{22}$. II, Microcline (amazon-stone) from Antaboka, Madagascar, $\text{Or}_{71}\text{Ab}_{27}\text{An}_{2}$. III, Albite from Amelia Co., Virginia, $\text{Ab}_{98}\text{Or}_2$. IV, Oligoclase (sun-stone) from Tvedestrand, Norway, $\text{Ab}_{71}\text{An}_{29}\text{Or}_2$. V, Labradorite from Ardglass, Co. Down, $\text{Ab}_{33}\text{An}_{62}\text{Or}_5$. VI, Anorthite from Vesuvius, $\text{Ab}_4\text{An}_{94}\text{Or}_2$.

	I	II	III	IV	V	VI

Feldspars are of wide distribution, according to F. W. Clarke forming about 56 p.c. of the earth's crust. They occur as primary constituents in igneous rocks of nearly all kinds, and are abundant in gneisses and metamorphic rocks. The alkali-feldspars occur preferably in the more siliceous rocks (granite, &c.), whilst lime-feldspars are more common in basic rocks (gabbro, basalt, &c.). Anorthite is also found in certain types of meteoric stones. Feldspars are very susceptible to alteration, being attacked by carbonated, acid, and alkaline waters, and they give rise to a great variety of secondary minerals. By the action of weathering processes the alkalis and lime generally pass into solution, remaining partly in the soil, and in part being removed in solution to form eventually secondary deposits of salts and limestone; whilst kaolin and free silica remain behind to give rise to deposits of clay.

All the naturally-occurring feldspars have been prepared artificially, and in addition others containing strontium, barium, and lead in place of calcium, or potassium in place of sodium in the plagioclases. The basic feldspars crystallise readily and are easily obtained by dry fusion; but the alkali-feldspars form extremely viscous glasses, and have not been crystallised by dry fusion without fluxes. Much experimental work has been done in connection with the isomorphism of the feldspars and in rock synthesis (v. F. Fouqué and A. Michel-Lévy, Synthèse des Minéraux et des Roches, Paris, 1882; A. L. Day and E. T. Allen, The Isomorphism and Thermal Properties of the Feldspars, Carnegie Inst., Washington, 1905).

For practical purposes the feldspars find applications in several directions. Some are used as gem-stones and ornamental stones. As a rule, these minerals are dull in colour, cloudy, and imperfectly transparent, but certain varieties exhibit special optical and colour effects. *Moon-stone*, a variety of orthoclase obtained mainly from Ceylon, displays a soft bluish milky sheen (glaucescence). Somewhat similar, but with brighter colours, is *peristerite* (named from *περιστέρα*, a pigeon, on account of the colours resembling those on a pigeon's neck), a variety of albite from Ontario. *Sunstone*, or *avandurine* feldspar, exhibits a metallic spangled effect, due to the enclosure of scales of hæmatite; this is best shown in the oligoclase from Tvedestrand in Norway, but is also met with in some other feldspars. *Labradorite* in certain specimens, particularly those found abundantly as boulders on the coast of Labrador, though of a dull dark-grey colour, yet at just a particular angle with respect to the incident light they suddenly shine up with brilliant metallic colours. This change of colour or labradorescence is due to the interference of light caused by numerous minute enclosures in the mineral. The same effect is also shown by the anorthoclase in the augite-syenite (laurvikite) from Laurvik and Fredriksvårn in the south of Norway, a rock much used as a polished ornamental stone. A clear transparent oligoclase from Mitchell Co., North Carolina, has been cut in the brilliant form as a gem. *Amazon-stone* (g.v.) is a green microcline. (On the use of feldspar as gem-stones, v. M. Bauer, Precious Stones, transl. by L. J. Spencer, London, 1904.)

The chief use of felspar in the industrial arts is for the manufacture of porcelain and enamel ware of all kinds, including electrical goods. For this purpose only an alkali-felspar, preferably potash-felspar or a potash-soda-felspar, is employed; the lime-felspars not being suitable, since they readily crystallise. In the finest porcelain, felspar (10–35 p.c.) is added to the body, and as it fuses it firmly binds the particles of clay and quartz; but it is chiefly for the glaze that felspar (30–50 p.c.) is added. The best quality is used for making artificial teeth. Small amounts are used by glass manufacturers, especially for producing an opalescent glass. Fused felspar forms a firm bond for emery, corundum, and carborundum wheels.

As an abrasive, felspar is especially suitable for certain purposes. Owing to its cleavage, its powders to angular fragments; and its hardness is about the same as that of glass. It is therefore used as a cleaner and polisher of glass articles, and forms an ingredient of scouring soaps. Any felspar serves this purpose, so long as it is free from quartz. Labradorite from Duluth, Minnesota, is used as a sandpaper in wood-working. Other minor uses of felspar are the manufacture of tarred roofing material, for surfacing concrete, and as a poultry grit.

A great variety of processes have been devised and patented for utilising felspar as a source of potash (*q.v.*), but these have not been able to compete with the slowly-acting geological processes which produced the Stassfurt deposits from the same material. Ground felspar used directly as a fertiliser is slow in its action, but lasting.

Commercial felspar is all obtained by quarrying veins of granite-pegmatite. This is a very coarse-grained rock consisting of alkali-felspar, quartz, and mica, together with small amounts of tourmaline, beryl, and various rare minerals. The same quarries are sometimes worked also for quartz and mica; those of California, Maine, Connecticut, and Madagascar yield gem-stones; and those of southern Norway small amounts of rare-earth minerals, *e.g.* monazite, gadolinite, euxenite, &c. The felspar is, as a rule, orthoclase or microcline; but veins of soda-pegmatite, consisting mainly of albite with a little hornblende, are worked in Pennsylvania, Maryland, and at Villeneuve in Quebec. The largest producer is the United States, principally along the Appalachian Mountains in the eastern States, and in California. (*v.* E. S. Bastin, *Economic Geology of the Feldspar Deposits of the United States*, U.S. Geol. Survey, Bull. 420, 1910; A. S. Watts, *Mining and Treatment of Feldspar and Kaolin in the Southern Appalachian Region*, U.S. Bureau of Mines, Bull. 53, 1913; A. S. Watts, *The Feldspars of the New England and North Appalachian States*, *ibid.* Bull. 92, 1916; F. J. Katz, annual reports in *Mineral Resources*, U.S. Geol. Survey.) In Canada the principal quarries are in Frontenac Co., Ontario. Other large producing countries are Norway, Sweden, and Italy. The spar should be free from iron-bearing minerals and mica, but the presence of 15–20 p.c. of quartz is not injurious for pottery. It is sometimes calcined before being finely ground and screened.

In the British Isles there is abundance of available material in the pegmatite-veins

traversing the ancient gneisses of Sutherlandshire. The average amount of potash in the microcline of this district is 12·8 p.c., and for the whole rock 6·7 p.c. A few smaller pegmatite-veins are present in Cornwall; and the well-known Cornish china-stone is rich in partly altered felspar. The discovery of a vein of red felspar at Belleek in Co. Fermanagh led to the establishment of porcelain works at this locality. The red felspar becomes white on calcination, the iron passing into the condition of magnetite, the particles of which may be removed by means of a magnet. Other Irish occurrences are known in Co. Mayo and Co. Donegal. The abundantly occurring granites of Cornwall, Scotland, and Ireland contain, on an average, about 5 p.c. of potash, a portion of which is, however, carried in the mica. (*v.* Special Reports on the Mineral Resources of Great Britain, Mem. Geol. Survey, vol. v. 1916, 2nd edit., 1917; P. G. H. Boswell, *British Supplies of Potash-Felspar*, considered from the Glass-Making point of view, J. Soc. Glass Technology, 1918, ii. 35–71).

FENCHENE *v.* FENCHONE.

FENCHONE $C_{10}H_{16}O$. A ketone isomeric with camphor. It is optically active, *d*-, *l*-, and *r*-fenchone all being known. *d*-Fenchone was discovered by Wallach in fennel oil. The fraction boiling at 190°–195° is treated with three parts of concentrated nitric acid to oxidise anethol and other impurities. The product is poured into water, the separated oil being washed with caustic soda solution, distilled in steam, dried, and finally crystallised at a low temperature (Wallach and Hartmann, *Annalen*, 259, 324; Wallach, *ibid.* 263, 129). *d*-Fenchone also occurs in small quantities in Russian oil of anise (Bourchardat and Tardy, *Bull. Soc. chim.* [iii.] 16, 616; *Compt. rend.* 1896, 122, 624).

Pure fenchone is a colourless oil, b.p. 192°–193°; sp.gr. 0·9465 at 19°; prolonged cooling at low temperatures causes it to solidify to large crystals, m.p. 5°–6°; $\mu_D = 1·46306$ at 19°, molec. ref. = 44·23; $[\alpha]_D + 71·97^\circ$. It is not oxidised in the cold by nitric or sulphuric acids, but potassium permanganate converts it into dimethylmalonic, oxalic, and acetic acids. By heating it for six days with concentrated nitric acid, there are formed dimethylcarballylic, dimethylmalonic, isocamphoric, isobutyric, and acetic acids, together with a nitrofenchone (Gardner and Cockburn, *Chem. Soc. Trans.* 1898, 708; Semmler, *Chem. Zeit.* 1905, 29, 1213; *cf.* Konowaloff, *J. Russ. Phys. Chem. Soc.* 1903, 35, 953); and by heating with sulphuric acid at 80°, 4-aceto-1:2-xylene is formed (Marsh, *Chem. Soc. Trans.* 1899, 1058). Warming with phosphorus pentoxide yields *m*-cymene, b.p. 175°–176° (Wallach, *Annalen*, 275, 157). Reduction by sodium in amyl alcohol or treatment with phthalic anhydride yields *l*-fenchyl alcohol $C_{10}H_{17}OH$; m.p. 45°; b.p. 197°–200°; $[\alpha]_D - 10·35^\circ$ (Bertram and Halle, *J. pr. Chem.* [ii.] 61, 293). This is converted by phosphorus pentachloride into *fenchyl chloride*, b.p. 84°–86°, which, on heating with aniline, is converted into the terpene *fenchene* $C_{10}H_{16}$, b.p. 150°–152°. A solid fenchyl chloride, m.p. 92°, has been obtained by Kondakoff from fenchyl alcohol (*J. pr. Chem.* 1909, [ii.] 79, 271). Fenchene has

been prepared synthetically by treating nopinone and bromacetic ester with zinc and hydrolysing the hydroxy ester thus formed (Wallach, *Annalen*, 363, 1). Fenchene is oxidised by concentrated nitric acid, yielding *cis*-camphopyric acid and its anhydride. Phosphorus pentachloride reacts with fenchene yielding chlorfenchene phosphinic acid $C_{10}H_{14}ClPO(OH)_2$, chlorfenchene and α - and β -chlorfenchene hydrochlorides (Gardner and Cockburn, *Chem. Soc. Trans.* 1897, 1157; 1898, 275, 704). Ammonium formate reacts with fenchene, yielding the formyl derivative of *D*.*l*-fenchylamine from which the free base $C_{10}H_{17}NH_2$ is easily obtained; b.p. 195°; sp.gr. 0.9095; $[\alpha]_D -24.63^\circ$. Sodium nitrite and acetic acid react with fenchylamine, producing *D*.*l*-fenchene, an isomeric hydrocarbon, *d*-limonene and cineol (Wallach, *Annalen*, 362, 174). *D*.*l*-fenchene, when warmed with acetic and sulphuric acids, yields *isofenchyl* alcohol, b.p. 201°–202°, which, on oxidation with chromic acid, yields *isofenchone* $C_{10}H_{16}O$, b.p. 201°, sp.gr. 0.943 at 18.5°, $[\alpha]_D +9.35^\circ$. By heating fenchene and bromine in a sealed tube for 24 hours, bromofenchene, b.p. 131°–134° (18 mm.), is obtained. Alcoholic potash converts bromofenchene into γ -fencholenic acid, which on being dissolved in concentrated sulphuric acid and poured on to ice, yields an isomeric compound, m.p. 77°; three fencholenic acids are known (Wallach, *Annalen*, 315, 273; *Chem. Zentr.* 1899, ii. 1052; Czerny, *Ber.* 1900, 2287; Balbiano, *Gazz. chim. ital.* 1900, 30, ii. 382; Semmler and Bartelt, *Ber.* 1906, 3960; 1907, 432). Like camphor, fenchene reacts with sodium, forming a pinacone $C_{20}H_{34}O_2$, b.p. 219° (13 mm.), m.p. 97°. The constitution of fenchene is still under discussion, but the evidence available seems to indicate the following formula:—

(Wallach, *Annalen*, 369, 63; Semmler, *Ber.* 1907, 4591; Bouveault and Levallois, *Compt. rend.* 1908, 146, 180; cf. Glover, *Chem. Soc. Trans.* 1908, 1285).

l-Fenchone was discovered by Wallach in thuya oil. The fraction boiling at 190°–200° may be warmed with nitric acid to oxidise the thujone and then steam distilled or better be oxidised with potassium permanganate to destroy the thujone and then treated with semicarbazide hydrochloride, which reacts with the *l*-camphor, which is also present more quickly than with the *l*-fenchone, and forms an effective agent for separating them (Wallach, *J. Pharm. Chim.* 1896, 3, [9] 465; *Chem. Zentr.* 1905, ii. 675; *Annalen*, 353, 209). *l*-Fenchone has b.p. 192°–194°, m.p. 5°, $[\alpha]_D -66.94^\circ$, and forms a series of derivatives similar to those obtained from *d*-fenchone. For *r*-fenchone and its derivatives, v. Bouveault and Levallois, *Compt. rend.* 1909, 148, 1399, 1524.

For further references to fenchone and derivatives, v. Wallach, *Annalen*, 284, 324; 300, 294; Semmler, *Ber.* 1906, 2577; Mahla, *Ber.* 1901, 3777; Rimini, *Gazz. chim. ital.* 1909, 39, ii. 196; Bouveault and Levallois, *Bull. Soc.*

chim. 1910, [iv.] 963, 968; Nametkin, *J. Russ. Phys. Chem. Soc.* 1915, 47, 1590; Qvist, *Ann.* 1918, 417, 278 (v. KETONES).

FENCHYLENE

A volatile liquid with a faint odour recalling that of fenchene, obtained by heating methyl *isofenchyl*xanthate at 230°; b.p. 139°–140° (corr.); sp.gr. 0.8381 20°/4°; $n_D = 1.4494$ at 20°, and $[\alpha]_D = -68.76^\circ$ (in alcohol). Combines with bromine, yields a crystalline nitroschloride and gives *cis*-fenchocamphoric acid when oxidised with alkaline permanganate (Nametkin and Rushenceva, *J. Russ. Phys. Chem. Soc.* 1916, 48, 450; *J. Soc. Chem. Ind.* 1917, 36, 304).

FENNEL FRUIT. *Feniculi fructus*, B.P. The dried ripe fruit of *Foeniculum vulgare* (Mill.).

FENUGREEK. *Trigonella Fœnum græcum*. A plant possessing a characteristic flavour, used largely as a condiment for cattle.

According to analyses by D'Ancona (*Landw. Versuchs-Stat.* 1899, 51, 387), the dry matter contains—

Protein	Fat	N-free extract	Crude fibre	Ash
13.4	3.4	47.0	30.6	5.6

The pure ash contained—

K ₂ O	Na ₂ O	CaO	MgO	Fe ₂ O ₃	P ₂ O ₅	SO ₃	SiO ₂	Cl
19.1	7.6	29.8	1.0	4.9	8.1	4.1	23.5	1.1

In composition, fenugreek resembles crimson clover and it is recommended as a farm crop. Since, however, the peculiar flavour of the plant is transmitted to both milk and meat, the fodder is more suited for working animals than for fattening or milk production. The peculiar odour and flavour of the plant is said to be due to an oil; it is very pronounced in the spring, but becomes less when the plant ripens.

The seeds contain trigonelline $C_8H_7NO_2$, the betaine of pyridine-2-carboxylic acid (Jahns, 1885). Among the carbohydrates in the seeds of fenugreek is a mannogalactan, which, under the influence of a soluble ferment, produced on germination, hydrolyses with the formation of reducing sugars (Bourquelot and Herissey, *Compt. rend.* 1900, 130, 42, and 731). H. I.

FERBERITE v. WOLFRAMITE.

FERGANITE. A hydrated uranium vanadate $U_3(VO_4)_2 \cdot 6H_2O$, containing also a small amount of lithium. It is related to carnotite (*q.v.*), and is found as sulphur-yellow scales, together with other uranium minerals, in province Fergana, Russian Turkestan. L. J. S.

FERGUSONITE. A rare mineral consisting of columbate (and tantalate) of yttrium and cerium earths together with a small amount of uranium, the general formula being $R'''(Cb, Ta)_2O_4$. Tetragonal crystals were found in Greenland in 1826, but usually the mineral is massive with a lustrous, pitchy appearance on the fractured surfaces; sp.gr. 5.8. It is optically isotropic, owing to alteration and hydration: when heated, it suddenly shows an incandescent glow, becomes fractured and anisotropic, and gives off gases (helium, &c.). The mineral occurs in pegmatite-veins at Ytterby in Sweden, near Arendal and elsewhere in Norway, and in some abundance as large masses at Barringer Hill in

Llano Co., Texas. At the last-named locality, it has been mined, together with gadolinite (*q.v.*) and other rare-earth minerals, for the supply of yttrium, &c. Other localities are Coolegong in Western Australia, Madagascar, and the Caucasus. L. J. S.

FERMENLACTYL. A preparation of lactic acid bacilli.

FERMENTATION (including Enzyme Action and Chemical Action of Bacteria).

History of the development of ideas about fermentation. The phenomena of alcoholic fermentation seem to have been familiar to man from the earliest times in the processes of the production of wine, accompanied by effervescence and frothing, and of the baking of bread, accompanied by the rising of the dough. These obvious characteristics of fermentation find expression in the names applied in various languages both to the process itself (fermentation, Lat. *fervere*, to boil; *Gährung*, from a Teutonic root, *jesen*, to froth, from which the word *yeast* is also derived) and to the agent by which it was caused (yeast, as above, leaven, *levure*, from the Lat. *levare*, to raise; *Hefe*, Ger. *heben*, to lift; referring to the rising of the scum of yeast in fermentation and the rising of the dough in baking).

The term *fermentation* was at first applied without distinction to all changes accompanied by effervescence, but after 1659 (Sylvius de la Boë) gradually became limited to alcoholic fermentation, along with such cases of acid fermentation and putrefaction as were accompanied by evolution of gas.

Further knowledge of the chemical nature of fermentation came from the experiments of Lavoisier (1789), who showed that in alcoholic fermentation, the sugar was quantitatively decomposed into alcohol and carbon dioxide (together with some acetic acid). These relations were rendered more precise by Gay-Lussac (1810), whose conclusions may be summed up in the equation of alcoholic fermentation:

Fermentation was looked upon as a chemical process set up by an unknown agent, termed the ferment, produced by the oxygen of the air from the fruit juices, &c., which underwent the change, this view being founded on the observation (Gay-Lussac) that boiled grape juice only fermented after exposure to air. The process of fermentation had been regarded by Willis (1659) and Stahl (1697) as consisting in a violent internal motion of the particles of the fermenting substance set up by an aqueous liquid, a conception which was replaced by that of catalytic force by Berzelius (1839), according to which the ferment, like other catalytic agents, was found unchanged at the end of the process. Liebig (1839), on the other hand, held the view that the ferment was an unstable body which itself underwent decomposition and that it was the internal motion due to this which was transferred to the fermentable substance and brought about its decomposition. The action only persisted as long as this metamorphosis of the ferment was in progress, and came to an end when this ceased. The ferment itself was regarded, in agreement with Gay-Lussac, as being

formed by the action of oxygen on the nitrogenous materials of the fermentable liquid, and the amount produced was dependent on the special nature of this, and might be, as in brewing, more than sufficient to cause the decomposition of the whole of the sugar present.

These views were founded on the belief that yeast was a chemical substance comparable to any of the well-known organic products. Even before the publication of the views of Berzelius and Liebig, however, strong evidence had been brought forward that this was not the case. As early as 1680, Leeuwenhoek had described the granular appearance of yeast under the microscope and 'animalcules' of putrefying materials had also been observed; but in spite of a few other isolated observations, it was not until about 1836 that the intervention of living organisms in fermentation and putrefaction was rendered probable. In that year, Schulze showed that infusions of various animal and vegetable materials remained free from all putrefaction, if, after they had been well boiled, they were only allowed to come in contact with air which had passed through sulphuric acid. The same thing was subsequently shown by Schwann to hold if the admitted air were heated, and the observations were extended to alcoholic fermentation. The conclusion was drawn by both these investigators that putrefaction was caused by living germs present in the air, which developed in the putrescible liquid. The microscopic examination of a fermenting sugar solution revealed the presence of yeast cells capable of reproduction by budding, and Schwann attributed to this living organism, which he named 'Zuckerpilz' (sugar fungus), the production of alcoholic fermentation. Curiously enough, almost simultaneously with Schwann, two other investigators, Cagniard-Latour in France and Kützing in Germany, came independently to the same conclusion, as the result of microscopic observations. These conclusions were rejected by Berzelius and Liebig, who replied to them by the theories already mentioned, but, in spite of this powerful opposition, they gradually won for themselves a considerable body of adherents, especially in Germany and among those engaged in brewing (see *Hefe*, *Fäulniss* und *Gährung*, 208-229, Berlin, 1904).

The evidence in favour of this vitalistic view of the cause of fermentation was greatly strengthened by the experiments of Schröder and von Dusch (1864), who discovered the important fact, which has proved to be an almost indispensable feature of bacteriological technique, that air lost its power of producing putrefaction when it was simply filtered through cotton wool. Many difficulties, however, still remained unexplained, which prevented the universal acceptance of the vitalistic view. Milk, for example, was found to become sour after having been boiled, in spite of all precautions, and no organism could be recognised in it capable of producing the change. Moreover, other ferments existed, such as diastase (Dubrunfant, 1830; Payen and Persoz, 1833), which, like yeast, lost their power of action when heated, and yet were completely soluble in water and devoid of all trace of organisation.

The final proof that fermentative changes in

general, such as the alcoholic and lactic fermentations, putrefaction, &c., were actually produced by living organisms was afforded by the classical researches of Pasteur (Compt. rend. 1857, 45, 913). Pasteur showed, in the clearest possible manner, that every fermentation was produced by a specific organism. He regarded fermentation as indissolubly bound up with the life of the organism, and summed up his conclusions in the aphorism, 'No fermentation without life.' The recognition of micro-organisms as the cause of fermentation rendered it necessary to differentiate between these so-called organised ferments and the substances, such as diastase, invertase, pepsin, &c., which had gradually become known, and which could be extracted from the higher plants and animals and even from micro-organisms, and were therefore known at first as soluble ferments, and later, following the suggestion of Kühne, as *enzymes* (Έν, in; ζύμη, yeast).

A long discussion then arose on the question whether any essential difference existed between the modes of chemical action of these two classes of ferments. Moritz Traube (1858) formulated the theory that all chemical action of micro-organisms was due to enzymes produced in the cell of the organism, and he was supported by Berthelot, Hoppe-Seyler, and many others. Pasteur, on the other hand, maintained his original thesis, and, stimulated by his discovery (Compt. rend. 1861, 52, 344, 1260) that many micro-organisms could live in the absence of free oxygen, developed the view that fermentation was life without free oxygen, the physiological function of the process being to supply the organism with the oxygen or the energy necessary for its metabolism. Pasteur's theories, aided by his brilliant exposition and ingenious experiments, gained the day for the vitalistic view, especially as the supporters of Traube's conception were unable, in spite of many attempts, to adduce positive evidence of the isolation of an enzyme capable of producing one of the fermentations characteristic of living organisms. A middle path was taken by Nägeli, who suggested the idea that the power of producing fermentation was restricted to the living protoplasm of the cell, and consisted in the transference of a molecular vibration from this to the fermentable substance.

This theory was disproved and the original idea of M. Traube strikingly confirmed in 1897 by Eduard Buchner, who succeeded in preparing from yeast a liquid capable of fermenting sugar. It has since been shown that the lactic and acetic fermentations can also be produced in the absence of living cells. Buchner's experiments disprove the vitalistic theory as held by Pasteur, and the view is now generally adopted that micro-organisms produce chemical change by means of enzymes present in their cells. The chemical changes produced by micro-organisms are thus brought into line with those effected by the numerous and well-known enzymes secreted by the cells of various organs of the higher plants and animals as well as by micro-organisms, and the modern conception of fermentation embraces all the different changes produced by these various agents.

General properties of enzymes. It has been found that enzymes bring about chemical

change by acting as catalytic agents; that is to say, they greatly increase the velocity of the particular reaction in question without themselves undergoing any permanent change. No very definite criterion of an enzyme as distinguished from a catalyst in general, exists, but the term is generally limited to catalysts formed by living organisms, and it is an almost invariable rule that enzymes in solution are thermolabile, losing their activity as a rule rapidly at 70°. In the absence of moisture, on the other hand, they are much more stable, and may be heated in some cases to 110° for a considerable time without being destroyed. In this respect, the inactivation of enzymes by heat bears a close resemblance to the heat coagulation of proteins (Chick and Martin, J. Physiol. 1910, 40, 404).

Chemically, the enzymes are presumably of a very complex character, but they have, up to the present, evaded the skill of the chemist, no one of them having been isolated in a pure condition and submitted to investigation. It appears, however, to have been established with some degree of probability that certain enzymes (pepsin, diastase) are not proteins. All enzymes appear to form colloidal solutions, and in agreement with this they only possess very slight powers of diffusion, so that they only pass slowly and imperfectly through the ordinary dialysing membranes.

Ecto- and Endo-enzymes. In many cases, the enzymes, after being elaborated in the cell, are excreted into the surrounding medium, in which they produce their characteristic effects. This is the case, for example, with some of the digestive ferments of the animal body, the ptyalin of the salivary gland, the pepsin of the stomach, the trypsin of the pancreas (in this case in an inactive form) being all poured into some portion or other of the alimentary canal. In other cases, the enzyme does not pass out of the cell, the chemical change in question taking place inside the cell. The best known case of this kind is probably that of alcoholic fermentation, which occurs entirely inside the yeast cell.

A second point of difference lies in the behaviour of enzymes towards solvents. Many enzymes (*ectoenzymes*) can readily be extracted by such solvents as water, normal saline (0.8 p.c. sodium chloride solution), and glycerol from the cells after the organism has died. Thus pepsin and chymase, the enzyme of rennet, can be extracted by weak acid or glycerol from the membrane of the stomach of the calf or other animal. Others again cannot be removed from the cell in this way until the cell wall has been ruptured, or rendered permeable by drying or treatment with reagents, and these are termed *endoenzymes* or *intracellular enzymes*. The auto-elastic enzymes of the animal body are instances of this, as are also the zymase and tryptase of yeast.

Extraction of enzymes. These facts provide the clue to the practical methods adopted for the extraction of enzymes.

1. *Soluble enzymes* can be extracted by digesting the finely divided material which contains them with water, saline, or glycerol. The enzyme solution is then poured off, pressed out or separated by centrifugalisation, according to circumstances, and either used directly or

submitted to some process of purification. In some cases it is necessary or advisable to treat the material with dilute acid to convert the inactive proenzyme or zymogen of the cell into the active enzyme. As in the instances of invertase and maltase, it is often essential that the cell shall be killed before being submitted to extraction. This is best accomplished in these cases by treatment with chloroform or ether (invertase) or by drying and heating the yeast (maltase).

2. *Insoluble or endo-enzymes* are extracted by first of all rupturing the cells by some process of grinding, and then removing the liquid cell contents by simple pressure with or without the addition of some substance like kieselguhr, which greatly facilitates the process, but has the disadvantage of retaining some of the enzyme. A typical instance of this is afforded by the preparation of yeast juice from yeast by the method of E. and H. Buchner and Hahn, which is described below under the heading of *Alcoholic fermentation*. In other cases, the tissue or organ may be simply minced or frozen and finely sliced, and may then be extracted with water or saline.

Dry preparations of enzymes. A solution of an enzyme in an aqueous fluid often loses its characteristic properties very quickly, either on account of the instability of the enzyme itself, or because of the presence of other enzymes which bring about its decomposition. Such solutions are, moreover, extremely liable to infection by moulds, yeasts, and bacteria, and must either be kept at a low temperature or treated with some antiseptic. Dry preparations are found to be much more permanent, and, when quite dry, can be kept for long periods without undergoing much loss of power.

They may be obtained, in the first place, by the evaporation of the solution *in vacuo* at as low a temperature as possible, the product being usually a scaly mass. A second and often more convenient method consists in precipitation by alcohol, nearly all enzymes being insoluble in 70-90 p.c. alcohol. The chief practical difficulty of this method lies in the fact that aqueous alcohol frequently appears to exert an extremely detrimental effect on the enzyme, so that the process must in such cases be carried out with great rapidity. The final dehydration is usually effected by treatment of the precipitate with absolute alcohol and then with ether, a fine white powder being thus obtained.

It is not, however, in all cases necessary to extract the enzyme from the organism which contains it. Thus, for example, crushed castor-oil seeds are commonly used for the purpose of decomposing fats by means of the lipase which they contain. Buchner and his colleagues have, moreover, been able to effect several types of fermentation (alcoholic, lactic, acetic) by means of the cells of the organism, which have been simply killed by dry heat or killed and dehydrated by treatment with alcohol and ether or with acetone.

Purification of enzymes. The preparations obtained by the foregoing methods are all extremely crude, and contain, in addition to other enzymes, large proportions of extraneous matter, chiefly consisting of mineral salts, especially phosphates, proteins, and carbo-

hydrates. Many attempts have been made to remove these by various processes of chemical precipitation (lead acetate, &c.), salting out, dialysis, treatment with yeast to remove sugars, &c., and thus to arrive at a pure enzyme. Some of these cases are mentioned later on, and there is no doubt that a considerable degree of purification can be effected by these methods. The usual experience has, however, been that with increasing freedom from such substances, the enzyme becomes more and more susceptible of change, and finally loses its activity before anything which can be regarded as an individual chemical compound has been isolated.

Mode of action of enzymes. Enzymes act as catalysts, but differ from catalysts of known symmetrical constitution in being specific in their action. The three disaccharides, sucrose, maltose, and lactose, for example, are all hydrolysed by the same acids, although at different rates, whereas each of them requires for its enzymic hydrolysis a special enzyme, which has no action whatever on the other two. The most probable view as to the mode of action of enzymes upon the substance to be decomposed, known as the *substrate* or *zymolyte*, is that in the first place some sort of combination between the two occurs, and that this is then followed by the comparatively slow breaking up of this complex, with liberation of the enzyme and the products of decomposition of the zymolyte. As soon as a certain limit of concentration of the substrate is reached, therefore, the limit of this rate of decomposition is attained, and any further increase in the concentration of the substitute is then unable to produce any increase in the number of decompositions per unit of time, or in other words, after a certain concentration is reached, equal amounts of the substrate will be decomposed in equal times. In presence of an excess of enzyme, on the other hand, the rate of action will vary with the concentration of the substrate. These conditions appear to be realisable in most cases of enzyme action, but since the absolute concentration of the enzyme is usually very small, decomposition of equal amounts in equal times is usually the more obvious.

Most of the enzymic decompositions which have been studied from this point of view are cases of hydrolysis, which, in the presence of acids alone follow the usual course for which the equation $K = 1/t(\log a/a-x)$ holds. This same expression often but not invariably holds for the enzymic reaction when excess of enzyme is present, at all events over a short range of concentration. When, however, the relations of concentration are such that equal amounts are decomposed in equal times, K , calculated by the foregoing expression, would increase with the time instead of being constant. On the other hand, anything which lessens the effective concentration of the enzyme will lower the rate of action and lead to a decrease of K . In many enzyme actions, there are at least three causes which tend to produce this effect. In the first place, the enzyme itself tends to become inactive. This change sometimes proceeds too slowly to have any effect on the result (*e.g.* in Senter's experiments on the decomposition of hydrogen peroxide by hæmase); in other cases, it occurs so rapidly as to influence the velocity very perceptibly (*e.g.*

in alcoholic fermentation by yeast juice, in which the fermentation ceases for this reason). In the second place, the products of the reaction often diminish the rate of change to a greater or less extent. Thirdly, a state of equilibrium is often attained short of complete decomposition, and this also causes a decrease in K . Very valuable information can be obtained about the course of the reaction by determining the *initial velocity* of the change under various conditions of concentration, as these inhibiting influences are thereby, to a large extent, eliminated. In this way, A. J. Brown showed that the apparent monomolecular course of the inversion of cane sugar by invertase was, in reality, due to secondary effects. When a series of concentrations of sugar were taken, the initial rates of change were found to be equal, whereas in presence of the products the rate of change diminished almost in agreement with the monomolecular law. This same effect is obvious in the results of Hudson with cane sugar, and of Kastle and Loevenhart with the decomposition of ethyl butyrate by lipase.

It appears, therefore, that, as a rule, the velocity curve of an enzyme reaction expresses the resultant of a very complicated system of phenomena, and can only be properly interpreted when a considerable number of experiments have been made to ascertain all the factors concerned.

When the substrate is present in large excess, increase of concentration of the enzyme frequently increases the rate of change proportionally, in agreement with the usual experience with inorganic catalysts. This is, for example, true for invertase. In some cases, however, the rate increases in proportion to a fractional power of the concentration of ferment. This is the case when pepsin acts on dissolved albumins, the amount of action in equal times being proportional to the square root of the concentration of pepsin (Schütz), and a similar rule appears to hold for many enzyme actions. It is explained by Arrhenius on the ground that the enzyme combines with the products of the reaction (*Immunochemie*, Leipzig, 1907). In other cases, the amount of action is found to be constant when the product of amount of ferment and time is constant, or $F \times t = k$. This holds for the action of pepsin on coagulated albumin, for that of trypsin on caseinogen (Hedin), and in many other cases.

The inhibiting influence of the products of the reaction is in many cases specific, numerous instances of this having been observed among the sugars and amino-acids. Thus invertase is inhibited by fructose (A. J. Brown), but not by glucose (Armstrong); lactase by galactose but neither by fructose nor glucose, &c.

As regards the nature of the combination between enzyme and substrate, very little is known. Many investigators, however, adopt the view of Bayliss that it is of the nature of adsorption between the particles of the colloidal enzyme and the substrate, and find in this an explanation of such relations as are exemplified by the proportionality between amount of action and the square root of the concentration of enzyme, discussed above. It is in favour of this view that enzymes are colloidal substances and that enzyme actions are therefore cases of catalysis in heterogeneous systems (*see* Bayliss, 1919, *The Nature of Enzyme Action*, vii.).

Whatever the nature of the combination, it appears to render the enzyme less susceptible of change whether by rise of temperature, spontaneous decomposition, or the action of other enzymes.

Conditions of enzyme action. The rate of action depends on several factors, in addition to the concentrations of enzyme and substrate.

Temperature.—The effect of temperature is primarily to raise the rate of reaction. The temperature coefficients of enzyme actions are, in general, of the same order as those of ordinary chemical changes (emulsin, amylase, rennin), but are sometimes considerably higher (trypsin), and in other cases lower (lipase, catalase). The fact that rise of temperature gradually inactivates the enzyme gives rise to the phenomenon of an *optimum temperature* above which rise of temperature causes a decrease in the measurable rate of the reaction. This optimum naturally varies with the duration and conditions of the experiment.

Hydrogen ion concentration $[H^+]$. It has been shown by Sørensen (*Biochem. Zeitsch.* 1909, 21, 131, 201, 279; 22, 352) that this is a most important factor in enzyme action, affecting both the rate of reaction and the rate of inactivation of the enzyme. For each enzyme an optimum $[H^+]$ exists, and according to Michaelis (*Biochem. Zeitsch.* 1909, 16, 81, 486; 17, 231; and many other papers), who regards the enzymes as amphoteric electrolytes, this is the $[H^+]$ at which the greatest number of active molecules of enzyme exist, these being in some cases the anions (diastase, maltase, trypsin), in other the cations (pepsin), and in others the electrically neutral particles (invertase). In practice, Sørensen's 'buffer' solutions, such as mixtures of the mono- and di-hydrogen phosphates, can be used to regulate the $[H^+]$ and thus ensure the optimum or any other required condition.

Inactivation of enzymes. All enzymes in aqueous solution become inactivated when the temperature is raised sufficiently, but the rate of inactivation varies for the different enzymes, and also depends very greatly on the $[H^+]$ of the solution. It is usually very rapid at about 60° – 70° , but in a few cases (some oxidases and proteases) the enzyme is not completely inactivated by boiling for a few minutes. The process of inactivation takes the course of a monomolecular reaction (peroxidase of milk), and the temperature coefficient of the change is in this case exceedingly high (2 for 1° , Zilva, *Bio-Chem. J.* 1914, 8, 656) and almost equal to that of the denaturation of albumin by heat (1.9, Chick and Martin). Enzymes are also inactivated at atmospheric temperatures by acids, and even more readily by alkalis.

Reversibility of enzyme action: synthetic action of enzymes. Since enzymes act as catalysts, it might be expected from analogy with catalysts of known composition that they would bring about conditions of equilibrium by affecting the velocities both of the reaction itself and of the reverse reaction (Tammann, *Zeitsch. physiol. Chem.* 1892, 16, 271). Thus it might be expected that an enzyme which effected the hydrolysis of a disaccharide into two hexose molecules would, when added to a mixture of these two hexoses in the proper concentration,

synthesise the disaccharide. In each case the reaction would proceed until equilibrium was produced, and the same equilibrium would be attained whether the disaccharide or the mixed hexoses formed the starting-point.

This extremely important property of enzymes was first experimentally demonstrated by Croft Hill (Chem. Soc. Trans. 1898, 634) in the case of the action of maltase on maltose, and so many instances have since been observed that reversibility of action may now almost be taken as a general property of enzymes.

The simplest case, so far observed, is the action of lipase on esters of the fatty acids which exhibits all the characteristic features of a reversible reaction (Kastle and Loevenhart, Amer. Chem. J. 1900, 24, 491). These observers found that the hydrolysis of ethyl butyrate by the lipase of the pancreas or liver of the pig was always incomplete, and that when this enzyme was added to a mixture of butyric acid and alcohol (N/30), about 5 p.c. of the butyric acid was converted into ethyl butyrate in 40 hours at 25°, no ester being formed in a control experiment with the boiled enzyme solution.

The reaction studied by Croft Hill deserves consideration as the first observed case of synthesis resulting from enzyme action. The change in question was subsequently found to be of great complexity, and unanimity of opinion on the question has not yet been attained. The essential facts observed by Hill were: (1) that when concentrated glucose solution was acted on by the maltase of yeast, a portion of the glucose was converted into a disaccharide of higher rotation and lower reducing power; (2) that when such a solution was diluted, the disaccharide was reconverted almost completely into glucose. These observations were interpreted to mean that in concentrated solution, a certain proportion of maltose (15 p.c. of the glucose in a 45 p.c. solution) had been formed synthetically from the glucose, and that on dilution the condition of equilibrium had been shifted in the direction of almost complete decomposition of the maltose back again into glucose. It was, however, subsequently found by Emmerling (Ber. 1901, 34, 600), that the disaccharide formed consisted chiefly of a sugar isomeric with maltose, which was identified by Emmerling as the *isomaltose* obtained by Fischer by the action of acids on glucose, but was regarded by Croft Hill as a new sugar, revertose. E. F. Armstrong (Proc. Roy. Soc. B, 1905, 76, 592) confirmed Emmerling's result as to the nature of the chief product formed, and further obtained the paradoxical result that emulsin which decomposes *isomaltose*, but not maltose, converts glucose into maltose, and not, as might have been expected, into *isomaltose*. Each enzyme, therefore, according to Armstrong, produces from glucose the disaccharide which it is unable to hydrolyse.

This remarkable result has not yet been confirmed, and Armstrong did not ascertain whether the maltose formed by the action of emulsin was decomposed by the same enzyme preparation when its solution was diluted. Moreover, only a very small proportion of maltose appears to have been formed. The simplest explanation of Croft Hill's experiment seems, therefore, to be

that adopted by Bayliss, that the maltase employed contained emulsin (which has since that time been shown by Henry and Auld (Proc. Roy. Soc. 1905, B, 76, 568) to be present in yeast), and that each enzyme synthesised from glucose the particular disaccharide which it was capable of decomposing (*see also* E. F. Armstrong, The Simple Carbohydrates and Glucosides, 75; Fajans, Zeitsch. physikal. Chem. 1910, 73, 25; 75, 232).

A suggestion has also been advanced that the synthesis and hydrolysis of the same compound are effected by different enzymes which occur together but are each only able to discharge the single function of hydrolysis or synthesis (*see* Rosenthaler, Biochem. Zeitsch. 1908, 14, 238; 1909, 17, 257). This idea is rendered improbable by the fact that in many cases the same state of equilibrium is attained when enzymes of different origin are employed, and is moreover inconsistent with the conception of an enzyme as a catalyst (Bayliss).

It has, however, been pointed out by Fajans (*l.c.*) that the enzyme itself probably takes part in the equilibrium, and that therefore alteration in its concentration might affect the state of equilibrium. This fact would also explain the observation that the equilibrium in certain cases of decomposition of acid esters is not the same when attained by the use of enzyme as when brought about by acid. The practical conditions necessary for the demonstration of synthetic enzyme action are well exemplified in the work of Bourquelot (numerous papers in Compt. rend. since 1912), who has prepared a large number of glucosides from their products of hydrolysis by the action of emulsin. For this purpose he has found that the essential condition is the limitation of the amount of water present. Thus a solution of glucose in 85 p.c. alcohol is partially converted by emulsin into β -ethyl-glucoside, whereas this compound in aqueous solution is almost completely hydrolysed by the same enzyme. The synthetic action of enzymes is of enormous importance in the biological chemistry of the living organism, since it is probably by the aid of reactions of this kind that the whole work of building up the tissues is effected.

Asymmetric and selective action of enzymes. It has been shown by the researches of Marckwald, McKenzie, and others (Ber. 1904, 37, 349, 1368, 4696; Chem. Soc. Trans. 1905, 1373; 1906, 688) that in a reaction in which an asymmetric carbon atom is produced, the two possible optically active isomerides may be produced in unequal quantities provided that the possibility is afforded by the introduction of an optically active radicle that the resulting compounds shall not be optical antipodes. Thus the reduction of pyroracemic acid

leads to the formation of inactive *dl*-lactic acid $\text{CH}_3 \cdot \text{CH}(\text{OH}) \cdot \text{COOH}$, whilst the reduction of menthyl pyroracemate $\text{CH}_3 \cdot \text{CO} \cdot \text{COOC}_{10}\text{H}_{19}$ proceeds asymmetrically and yields an excess of the ester of the *l*-acid. More recently, it has been shown by Bredig and Fajans (Ber. 1908, 41, 752) that a catalytic reaction may proceed asymmetrically when the catalyst is itself optically active. This has been found to be the

case when *l*-nicotine is employed to catalyse the decomposition of *dl*-camphorcarboxylic acid, the *d*-acid being in this case the more rapidly decomposed. This is precisely analogous to what occurs in many enzyme reactions, the asymmetric catalyst being in these cases the particular enzyme involved. There is, it is true, no direct positive evidence that enzymes are optically active substances, since, as already mentioned, no enzyme has as yet been isolated, but there is a strong probability that this is the case.

A good example of this asymmetric enzyme action is to be found in the work of Dakin (J. Physiol. 1904, 30, 253), who showed that the two optically active components of inactive *dl*-mandelic ester, which are hydrolysed at equal rates by alkalis, are decomposed at different rates by the fat-splitting enzyme or lipase of the liver, the dextro-ester being the more rapidly hydrolysed, so that after the removal of the resulting acid, the residual ester is laevorotatory. This action is probably to be explained by the formation of compounds between the enzyme and each of the components of *dl*-mandelic ester. The enzyme being, as explained above, itself an optically active substance, two different compounds are formed and these are decomposed at different rates. Many instances of this asymmetry of action are known among the chemical changes produced by micro-organisms. Thus the oxidation of inactive hydroxy acids (McKenzie and Harden, Chem. Soc. Trans. 1903, 83, 424), and of the amino acids by moulds, which was used by Pasteur for the resolution of such compounds, proceeds in a precisely similar manner; both of the components are attacked, but one more rapidly than the other. Similarly, the so-called alcoholic fermentation of the amino acids by yeast, as the result of which they are converted into carbon dioxide, ammonia, and an alcohol, takes place more rapidly with one of the components than with the other, so that by this means *l*-alanine and *d*-leucine can readily be prepared from the inactive synthetic acids (Ehrlich, Biochem. Zeitsch. 1906, 1, 8), the other component being, in each case, more easily decomposed.

An extreme case of this asymmetry of action is presented by many enzymes which only act on one stereoisomeride, and leave the other entirely untouched. Some remarkable instances of this kind have been revealed by the researches of Fischer and his colleagues on the enzymes which bring about the hydrolysis of the disaccharides and the glucosides. The relations between enzyme and zymolyte, which exist in this group of compounds, have been likened by Fischer to those which exist between a lock and key. The enzyme is capable of combining with one stereoisomeride, but is of such a structure that not only does the change to the opposite optical isomeride prevent combination, but even a change in the arrangement of the groups which condition asymmetry round a single carbon atom in the molecule of the sugar, just as the change of a single ward of a lock prevents the key from fitting it. The classical example of this relation is afforded by the behaviour of maltase on the one hand, and emulsin on the other, to the various disaccharides and glucosides,

Glucose forms two stereoisomeric methyl esters, which only differ from one another in the arrangement of the groups round the terminal carbon atom, so that their configurations may be represented as follows:—

One of these is arbitrarily known as *\alpha*-methylglucoside, and the other as *\beta*-methylglucoside. Of these, the *\alpha*-compound only is attacked by maltase and the *\beta*-compound only by emulsin, and precisely similar relations exist between the *\alpha*- and *\beta*-ethyl glucosides. Hence maltase has received the more precise name of *\alpha*-glucosidase (or sometimes *\alpha*-glucase), whilst emulsin (or that constituent of the complex usually termed emulsin, which effects this particular change) is termed *\beta*-glucosidase. Neither of these enzymes will attack the *\beta*- and *\alpha*-methyl glucosides of *l*-glucose, which are the exact optical antipodes or 'mirror images' of the *\alpha*- and *\beta*-methyl, *d*-glucosides, and moreover they also have no action on the corresponding derivatives of *d*-mannose, *d*-galactose, and *l*-xylose, although in each of these three cases the difference between the unattacked compound and the corresponding glucose derivative extends only to one carbon atom. On the other hand, *\beta*-methyl tetramethylglucoside, in which four of the hydrogens of the hydroxyl-groups of *\beta*-methyl glucoside have been replaced by methyl, is hydrolysed by emulsin, so that this extensive introduction of the methyl-group has less effect than a change in the symmetry of a single carbon atom.

The other enzymes capable of hydrolysing disaccharides are equally specific. Invertase, for example, hydrolyses cane sugar (and possibly raffinose, which, like cane sugar, contains the fructose group), but has no action on maltose, lactose, or the *\alpha*- and *\beta*-methyl glucosides. Similarly, lactase only attacks lactose, and not cane sugar, &c.

The alcoholic enzyme of yeast also possesses a highly specific character, but is not affected by such small changes in configuration as are maltase and emulsin. Thus *d*-glucose, *d*-mannose, and *d*-fructose are all fermentable by yeast, whilst, on the other hand, *l*-glucose, *l*-mannose, and *l*-fructose are not fermentable, and this is also true of the pentoses.

Similar results have been obtained by Fischer and Abderhalden (Zeitsch. physiol. Chem. 1905, 46, 52) in examining the action of pancreatic juice on the synthetic polypeptides. Only one half of the inactive compound is attacked and the products of hydrolysis are always those active amino-acids which are contained in the natural proteins. Thus *dl*-alanylglycine

$\text{CH}_3\cdot\text{CH}(\text{NH}_2)\cdot\text{CO}\cdot\text{NH}\cdot\text{CH}_2\cdot\text{COOH}$
yielded glycine and *d*-alanine as hydrolysis products, *l*-alanylglycine being left untouched.

All these facts afford the strongest evidence that combination between enzyme and zymolyte precedes the decomposition of the latter, and there is little doubt that similar conditions hold generally for the synthetic action of enzymes, although but few instances of this have hitherto been studied. A striking case in point is the combination between hydrocyanic acid and benzaldehyde. Ordinarily these substances combine to form inactive benzaldehyde cyanohydrin $C_6H_5 \cdot CH(OH) \cdot CN$. When, however, this reaction is carried out in the presence of emulsin (or rather of that constituent of emulsin which is distinguished as hydroxynitrilase), the resulting product is optically active, a greater proportion of the *d*- than of the *l*-cyanohydrin having been formed (Rosenthaler, Biochem. Zeitsch. 1908, 14, 238), and in one case the *d*- compound being the sole product.

In nature, the asymmetry of action of synthetic enzymes is of the most far-reaching importance, as is evidenced by such facts as that the sugars, proteins, and many other naturally occurring compounds, are all optically active. Moreover, the asymmetry of action is so great that in many cases, *e.g.* the sugars, the optical antipodes of the compounds appear not to occur at all.

Zymogens. The formation of enzymes in the cell is a subject of great importance, about which very little is known. In many cases, however, it has been ascertained that the cell contains an inactive substance, termed a zymogen or pro-ferment, which subsequently becomes active and can often be rendered so by treatment with dilute acid. A very striking instance is afforded by the inactive trypsinogen of the pancreas. This substance is contained in pancreatic juice, and is quite inactive. When it is mixed with intestinal juice it is converted into active trypsin, by the action of a specific substance known as *enterokinase*, which is itself in all probability an enzyme. A case of even greater complexity is that of the enzyme thrombase, which brings about the clotting of blood.

Coenzymes. Some enzymes are incapable of producing their characteristic effects in the absence of a second substance, usually of a less complex character, which is therefore termed a coenzyme. The nature and functions of this class of substance are little understood (*see Alcoholic fermentation*).

Classification and nomenclature of enzymes. The nomenclature of enzymes is based on the principle that the name should indicate the substance acted upon by the enzyme, and should end with the syllable *-ase*, which is adopted as a specific termination, signifying an enzyme. This system introduces some difficulties, as certain compounds are decomposed in different ways by different enzymes (*e.g.* amygdalin and raffinose), and some enzymes decompose many different compounds (*e.g.* the digestive enzymes). These difficulties are avoided as far as possible by the use of special terms, such as emulsin, tryptase, invertase, lipase, and further specification is also sometimes attained by adding the names of the products formed.

Some confusion exists in actual practice, owing to the name, not of the substance decomposed, but of the product being prefixed to the termination *-ase*. Thus alcoholase is occa-

sionally used for the alcohol-producing enzyme of yeast, but such terms should, as far as possible, be avoided, as well as those which simply denote the origin of the enzyme, such as hæmase (for the catalase of blood).

The simplest and most natural mode of classifying enzymes is by the nature of the reactions which they catalyse. Each group may then be further subdivided according to the nature of the compound upon which the specific action is exerted.

The chief enzymes at present known thus fall into the following groups, which agree in the main with those adopted by Oppenheimer, Euler, and other writers.

A. Enzymes producing hydrolysis (hydro-lases).

1. Lipases, decomposing fats and esters; sometimes divided into:

(a) Esterases, decomposing simple esters.

(b) Lipases, decomposing fats and lipins (lipoid compounds), such as lecithin, &c.

2. Enzymes hydrolysing the nucleic acids and their primary products of hydrolysis (nucleases, &c.).

3. Enzymes hydrolysing the complex saccharides and glucosides (carbohydrases).

(a) Disaccharases, such as invertase, maltase, lactase, melibiase, &c.

(b) Tri- and tetra-saccharases, such as raffinase.

(c) Polysaccharases; such as diastase or amylase, inulase, cytase or cellulase, glycogenase, &c.

(d) Glucosidases, such as emulsin, rhamnase, &c.

4. The digestive enzymes, or proteases, hydrolysing the proteins, polypeptides, amides, and analogous compounds. This is a very complex group, the precise relations of which are not at all understood, there being at present no available information as to the number of enzymes concerned in such a process as peptic or tryptic digestion. A good deal of confusion exists in the nomenclature of these enzymes (*see* Fisher, Biochem. J. 1919, 13, 424).

(a) Simple amidases, causing the hydrolysis of various amino-compounds, such as urea, arginine, adenine, &c.

(b) Peptases and ereptases, decomposing polypeptides into amino-acids.

(c) Proteinases, which hydrolyse the albumins.

(i) Trypsin or tryptase, comprising a large number of enzymes, occurring both in animal and vegetable organisms, which decompose proteins and carry on the decomposition to the stage of polypeptides or possibly even to that of amino-acids.

(ii) Pepsin or pepsinase, comprising the enzymes of the animal stomach and of some plants, which in acid solution hydrolyse proteins, producing albumoses, peptone, and polypeptides.

B. Enzymes producing coagulation (coagula-lases).

1. Thrombase, which produces the clotting of blood.

2. Chymase, or rennet, which effects the curdling of milk.

3. Pectase, and similar enzymes.

C. Enzymes producing oxidation (oxidases and peroxidases).

1. Alcohol oxidases, oxidising alcohol to acetic acid.

2. Aldehydases, converting aldehydes into acids.

3. Purinoxidases, effecting the oxidation of the purine bases.

4. Phenolases, tyrosinases, &c., which effect the oxidation of many aromatic *p*-hydroxy- and amino- derivatives.

D. Enzymes producing reduction (reducases), or simultaneous reduction and oxidation.

E. Enzymes producing decompositions involving rupture of a carbon chain. These are sometimes known as zymases, or fermentation enzymes.

1. Enzymes of lactic acid fermentation.

2. Enzymes of alcoholic fermentation.

3. Many other enzymes doubtless fall into this group, since there is little doubt that the various fermentative changes brought about by bacteria, &c., are largely due to enzymes of this class.

F. Enzymes producing the decomposition of hydrogen peroxide into water and oxygen (catalases).

Any attempt at a detailed account of the enzymes is impossible on account of limitations of space, and only the best investigated can be even briefly described.

ENZYMES PRODUCING HYDROLYSIS.

Lipase. Enzymes capable of hydrolysing fats, lecithins, and the alcohol esters of the fatty acids occur both in the animal and vegetable kingdoms. Some authorities distinguish between the ester-decomposing enzymes, which they term esterases, and the true fat-splitting enzymes or lipases, but it is doubtful whether our knowledge of the subject is sufficient to justify this. The difficulty of discrimination between different enzymes in this group is greatly increased by the facts that not only do the enzymes themselves appear to be insoluble in water, but the fats are also insoluble. These circumstances render the determination of the rate of action extremely uncertain.

The lipases of the animal body occur practically in all the tissues, but the action of most of these appears to be confined to the decomposition of esters, such as ethyl butyrate (see Kastle and Loevenhart, *Amer. Chem. J.* 1900, 24, 491; Porter, *Biochem. J.* 1916, 10, 523).

The chief fat-splitting enzymes of the body are found in the secretions of the pancreas and intestine. It seems probable that at all events the greater part of all absorbed fat is hydrolysed before absorption, and this process takes place in the intestine. These enzymes are extremely sensitive to acids and oxidising agents; they decompose alcohol esters as well as fats. The filtered extract and the residue prepared from these insoluble enzymes are both inactive, whereas the mixture is active, and the inactive residue can be rendered active by the salts contained in bile (Magnus, *Zeitsch. physiol. Chem.* 1904, 42, 169; 1906, 48, 373; Rosenheim, *J. Physiol. Proc.* Feb. 19, 1910, 14). How far this phenomenon depends upon the solubility relations of the enzyme or the fat, is not known.

The vegetable lipases occur in the form of zymogen in the seeds, and become active during

germination. The enzyme of castor-oil seed has been the most thoroughly investigated. This seed is stated to contain an esterase, soluble in water, and a lipase, insoluble in water, which can be extracted by 1.5 N NaCl (Falk, *J. Amer. Chem. Soc.* 1912-15). The powder obtained by extracting the castor-oil bean with ether is almost inactive, but is rendered active by treatment with acid (N/10 sulphuric), and then acts most effectively when properly emulsified with the fat and a small proportion of acetic acid (Connstein, Hoyer, and Wartenberg, *Ber.* 1902, 35, 3988; Jalander, *Biochem. Zeitsch.* 1911, 36, 435; Kita, *Chem. Soc. Abstr.* 1918, i. 274, 1919, i. 503). Under favourable conditions it is so efficacious that it is employed technically for the hydrolysis of fats.

The synthetical action of animal lipase (or esterase) and its asymmetric decomposition of *dl*-esters have already been mentioned.

Invertase. Our knowledge of this enzyme, which brings about the hydrolysis of cane sugar to fructose and glucose, and owes its name to the inversion of the direction of rotation from dextro- to lævo-, which accompanies the change, is largely due to the classical researches of O'Sullivan and Tompson (*Chem. Soc. Trans.* 1890, 834). It occurs in many, but not all, species of yeast and in many moulds and bacteria, as well as in the higher plants and the intestine of animals. It is usually prepared from brewers' yeast; the enzyme can only be very imperfectly extracted from the living cells, especially when a young and vigorous culture is employed, but readily passes into solution in water when the yeast has been dried and heated or treated with chloroform, toluene, or alcohol. It is also present in the yeast-juice obtained by Buchner's grinding process, but is best prepared by allowing the pressed yeast to stand in a flask until it has become liquid, precipitating with 47 p.c. alcohol, and grinding the precipitate with absolute alcohol. Two kilos of yeast thus yield 5 grams of a grey powder containing about 3.5 p.c. of nitrogen and 5-8 p.c. of ash. The activity is usually expressed as the time taken for a solution of 0.05 gram of the material dissolved in 5 c.c. of 0.5 normal sodium dihydrogen phosphate to reduce the rotation of 20 c.c. of 20 p.c. cane sugar solution to zero at 20°, and for the preparation obtained as above, this is about 25 minutes. More active preparations can be obtained by redissolving in 25 parts of water, treating with 2.5 parts of animal charcoal for an hour, shaking with 10 parts of kaolin, and reprecipitating with alcohol. This process yields a material containing only 0.36 p.c. of nitrogen and 2.07 p.c. of ash, and having an activity of 14 minutes, this being the most active preparation so far described (Euler, Lindberg, and Melander, *Zeitsch. physiol. Chem.* 1910, 69, 152). This result, combined with earlier observations of Osborne (*ibid.* 1899, 28, 399) and Salkowski (*ibid.* 1901, 31, 306) render it improbable that invertase is a protein, but the question is by no means settled. In *Monilia candida* (Bon.), invertase occurs as a true endo-enzyme which can only be obtained from the cell by rupture of the membrane (Fischer and Lindner, *Ber.* 1895, 28, 3034; Buchner and Meisenheimer, *Zeitsch. physiol. Chem.* 40, 167). The action on cane sugar is accelerated by acids

up to a certain concentration, the optimum concentration of hydrogen ions being $10^{-4.4}$ to $10^{-4.6}$ (Sörensen, *Compt. rend. Carlsberg*, 1909, 8, 1), and is at once inhibited by alkalis. The glucose is liberated in the α -form, so that the rotation falls when an alkali is added, and considerable errors may be introduced in estimations of the rate of action by polarimetric observations from this cause (O'Sullivan and Tompkins; Hudson, *J. Amer. Chem. Soc.* 1908, 30, 1160). According to Visser (*Zeitsch. physikal. Chem.* 1905, 52, 257), equilibrium is attained in normal cane sugar solution in presence of invertase when 99 p.c. has been hydrolysed and a corresponding synthesis (1 p.c.) probably occurs in a solution of fructose and glucose, although this has not been directly proved.

Solutions of invertase hydrolyse raffinose, a trisaccharide yielding fructose, glucose, and galactose on complete hydrolysis, but it is not certain whether this is actually due to the invertase or whether a specific raffinase is present. Certain organisms appear to hydrolyse cane sugar but not raffinose (*Mycoderma*) and others are stated to hydrolyse raffinose but not cane sugar (*Schyzosaccharomyces octosporus* (Bey.)). (For the use of invertase in the estimation of cane sugar, see *J. Soc. Chem. Ind.* 1911.)

Maltase is best obtained from well-washed bottom fermentation yeast by drying it *in vacuo*, powdering, heating gradually to 100° , and then digesting for 3 days at air temperature with 10 parts of 0.1 p.c. caustic soda solution and toluene, and finally filtering through a Chamberland filter into sterile flasks (Croft Hill, *Chem. Soc. Trans.* 1898, 634), a neutral or faintly acid solution being thus obtained. It can also be extracted directly with dilute ammonia from yeast killed by toluene (Willstätter). The enzyme cannot be prepared in an active state by precipitation with alcohol (Fischer, *Ber.* 1894, 27, 1113; Röhmman, *ibid.* 3251) although alcohol does not affect the maltase content of dry yeast or the dried extract. It rapidly hydrolyses maltose into glucose, 1 c.c. of the extract prepared as described above decomposing 20 p.c. of the maltose in 20 c.c. of a 2 p.c. solution at 30° in 40 minutes. The synthetic action of this extract has already been discussed. The action of the enzyme is at once destroyed by free alkali. Maltase is very widely distributed, occurring in many yeasts (but not in *S. Marzianus* (Hansen), *S. exiguus* (Hansen), *Saccharomyces ludwigii* (Hansen), *S. apiculatus* (Rees), and the lactose-fermenting yeasts), in many bacteria and moulds, in the foliage leaves and other parts of plants, and in germinated and ungerminated cereals, being localised mainly in the aleurone layer of the endosperm (Davis, *Biochem. J.* 1916, 10, 31; Daish, *Biochem. J.* 1916, 10, 49, 56), and in the small intestine, liver, kidneys, blood, and other tissues of mammals. Maltase, as already mentioned, only hydrolyses α -glucosides, and is therefore sometimes called α -glucosidase or α -glucase. It does not affect isomaltose, which is a β -glucoside, or trehalose, which is, however, hydrolysed by a special enzyme, *trehalase*, which occurs in moulds, some yeasts, and in green malt. The enzyme is very readily inactivated by traces of acid or alkali, and has an optimum temperature of about 40° , being greatly restricted in action at 55° .

Lactase is the specific enzyme which hydrolyses lactose into glucose and galactose. It also hydrolyses the β -alkylgalactosides, but not the α -compounds, and is therefore a β -enzyme. Its rate of action is diminished by galactose, but by no other sugar, and it therefore appears to combine with this substance as well as with lactose. Lactase occurs in a few yeasts, from which it may be extracted by grinding with glass powder and treatment with water (Fischer, *Ber.* 1894, 27, 2991, 3481) or by Buchner's process, but is best prepared by extracting kefir grains with water. It also occurs in some bacteria (*B. bulgaricus* (Grigoroff), &c.), and moulds (e.g. *Allescheria gayoni* (Sacc. & Syd.)) and in the small intestine of carnivorous and omnivorous animals and of young herbivora (Plimmer, *J. physiol. Chem.* 1906, 35, 20). An enzyme which decomposes lactose also occurs in the 'emulsin' obtained from almonds (H. E. and E. F. Armstrong and Horton, *Proc. Roy. Soc.* 1908, B, 80, 321), which probably differs from yeast lactase. Lactase, like maltase, effects the synthesis of a disaccharide, isolactose (Fischer and Armstrong, *Ber.* 1902, 35, 3144).

Amylase or diastase. Enzymes capable of acting on starch with the production of a sugar appear to occur in nearly all living organisms. The whole question of the nature of these enzymes and of their action on starch is one of great complexity. The constitution of starch and of the dextrins formed from it being still unknown, no clear idea of the chemical action involved has been obtained, nor has any satisfactory criterion been found by which to judge whether only one or several enzymes are present. It is therefore impossible to do more in this place than give a very brief statement of the chief facts which have been ascertained. More complete information will be found in the article on BREWING, and in *The Principles and Practice of Brewing*, by Sykes and Ling (London, 1907).

The vegetable amylases or diastases are found in the germinating seeds and also in the leaves and other parts of the plant. The sources of the enzymes which have been chiefly investigated are malt and the mould *Aspergillus oryzae* (Ahlburg Cohn), the amylase of which is known as takadiastase. The enzyme is extracted from malt by treatment with water or dilute alcohol, and may be several times precipitated by alcohol and further purified by dialysis (Lintner), or by being salted out from aqueous solution by ammonium sulphate (Wroblewski). The greatest degree of purification appears to have been attained by Fraenkel and Hamburg (Hofm. Beitr. 1906, 8, 389), by adding a suitable amount of basic lead acetate, filtering, fermenting with yeast, and drying. This preparation was strongly active, and showed none of the albumin reactions except a very faint Millon's reaction. It appeared to contain two enzymes, one non-diffusible and the other diffusible. On the other hand, Wroblewski's purest diastase had all the properties of an albumose.

Malt amylase is most active at a hydrogen ion concentration corresponding to $P_H=4.4-4.5$, that from *A. oryzae* at $P_H=4.8$ (Sherman and colleagues, *J. Amer. Chem. Soc.* 1919, 41, 231).

Starch paste is first liquefied by malt extract, and the starch is then rapidly converted at 50° into a mixture of maltose and dextrins, about

81 p.c. of the starch being converted into maltose, and 19 p.c. into dextrin. The further conversion of this dextrin into maltose proceeds extremely slowly (Brown, Heron, Morris); but according to Maquenne and Roux, who have been confirmed by Bayliss, this 'stage' is due to insufficient activity of the enzyme, the conversion proceeding to completion when the enzyme is activated by the addition of a trace of acid. It appears to be undoubted that many complex dextrans intervene between starch and maltose, but their constitution is still unknown. The existence among the products of an isomaltose $C_{12}H_{22}O_{11}$ (Lintner), has been disproved (Ling and Baker). The action of diastase solution which has been heated to 68° – 70° , is modified, so that less maltose and more dextrin are produced and more dextrin remains unchanged, whilst a certain proportion of glucose appears. This change in the mode of action of the enzyme may be due to an actual modification of the enzyme (Ling and Davis), but is regarded by many as evidence in favour of the theory (Wijsman, Beyerinck, Pottévin, Fraenkel, and Hamburg) that at least two enzymes are present, one of which (amylase) produces dextrin and the other (dextrinase) converts this into maltose. The separation of the enzyme into two parts by dialysis, one of which liquefies starch paste, and the other hydrolyses soluble starch, is also in favour of the existence of two enzymes. A different interpretation of the facts is due to Maquenne and Roux, according to whom starch contains two substances, *amylopectin*, to which the formation of the characteristic paste is due, and *amylose*, which is soluble. The amylose is converted by one enzyme of the diastase into maltose, whilst the amylopectin yields the dextrans under the action of a second enzyme. In mammals, diastatic enzymes are secreted by the salivary glands (ptyalin), the pancreas, and the intestine, and are also present in the liver, blood, muscular tissues, and most of the organs of the body. These enzymes convert starch and glycogen into maltose, but in many cases this is further changed into glucose by the maltase also present. The optimum activity of pancreatic amylase is exerted at $P_H=7$ (Sherman).

When a solution of pancreatic amylase is dialysed it becomes inactive both towards starch (Bierry, Gaja, and Henri, Soc. Biol. 1906, 60, 479) and glycogen (Norris, Biochem. J. 1913, 7, 622), the activity being restored by the addition of certain salts, more especially those of the halogen acids, whereas sulphates are inactive.

Emulsin. This name was originally applied by Liebig and Wöhler to the enzyme contained in almonds, which brought about the hydrolysis of amygdalin into hydrocyanic acid, benzaldehyde, and glucose. Further investigations (H. E. and E. F. Armstrong and Horton, Proc. Roy. Soc. 1908, B, 80, 321; Rosenthaler, Biochem. Zeitsch. 1910, 28, 408) have shown that the 'emulsin' of these workers contains a large number of distinct enzymes, and that the hydrolysis of amygdalin is a very complex phenomenon. It is most probable that the complete decomposition of this compound involves at least three enzymes, each capable

of bringing about one stage in the reaction. Amygdalin has probably the formula

the glucose molecule being combined with the benzaldehyde residue to form a β -glucoside and the terminal glucose group as an α -glucoside. The stages of the hydrolysis are probably:

(1) Hydrolysis by *amygdalase*, forming α -glucose and *l*-mandelonitrile- β -glucoside (prunasin)

(2) Hydrolysis of this compound by a β -glucosidase (prunase) into β -glucose and *d*-benzaldehydecyanohydrin

(3) Decomposition of the cyanohydrin by δ -hydroxynitrilase or *benzocyanase*

The crude emulsin also effects the synthesis of *d*-benzaldehydecyanohydrin from benzaldehyde and hydrocyanic acid; but Rosenthaler (Biochem. Zeitsch. 1908, 14, 238; 1909, 17, 257) does not regard this as a reversed action of the enzyme, but as due to a different enzyme, and claims to have separated the two.

Amygdalase is, at all events in some cases, present in yeast (Henry and Auld, Proc. Roy. Soc. 1905, B, 76, 568); and Emmerling (Ber. 1901, 34, 600, 2206, 3810) has observed the synthetic production of amygdalin from *l*-mandelonitrile-glucoside and glucose in presence of crude yeast maltase. Emulsin also contains a lactase, to which reference has already been made.

Crude emulsin occurs in sweet almonds, from which it is extracted by digestion with chloroform water, and can be precipitated by alcohol. It is also found in many moulds as well as in yeast. The β -glucosidase also occurs in many bacteria (Twort, Proc. Roy. Soc. 1907, B, 79).

The β -glucosidase of emulsin hydrolyses the β -alkyl-glucosides and many of the natural glucosides, such as arbutin, salicin, prulaurasin, asculin, and many others. It has been largely employed by Bourquelot for the biochemical synthesis of glucosides and disaccharides (see p. 134).

Other glucosidoclastic enzymes are myrosin, which hydrolyses the sinigrin of mustard, and tannase, which decomposes the natural tannins, and many more. Of considerable technical importance is the action of the enzyme contained in the leaf of the indigo plant, which is termed *satase* or *indimulsin*, and converts the indican of the leaf into glucose and indoxyl, the latter being then converted by oxidation into indigotin.

Many other specific glucoside enzymes are known (see The Simple Carbohydrates and Glucosides, by E. F. Armstrong, London, 1919).

The digestive enzymes or *proteases* comprise a great number of hydrolytic agents capable of replacing the $-NH_2$ group by $-OH$ (amidases or *desamidases*) or of causing the decomposition:

to which the hydrolysis of the proteins appears to be mainly due. These are classed according to

the completeness of the decomposition produced and the complexity of the compounds attacked under the various heads already given :

1. *Amidases or desamidases*, the most important of which accelerate the hydrolysis of urea and the conversion of adenine into hypoxanthine, and guanine into xanthine. Similar changes are often produced by micro-organisms (see *Alcoholic fermentation*, *Ammoniacal fermentation of urea*, and *Putrefaction*). A powerful urease occurs in many plants, especially in the seeds, one of the chief sources of the enzyme being the soya bean (*Glycine hispida*). It rapidly decomposes urea in dilute solution into ammonia and carbon dioxide, and, as its action is strictly specific (Armstrong and Horton, Proc. Roy. Soc. 1912, B, 85, 109), is employed for the estimation of urea in liquids (e.g. urine), which also contain other forms of combined nitrogen (Marshall, J. Biol. Chem. 1913, 14, 283; 15, 487, 495; Plimmer and Skelton, Biochem. J. 1914, 8, 70).

2. *Enzymes capable of hydrolysing various comparatively simple nitrogenous substances*. Among these are arginase (Kossel and Dakin, Zeitsch. physiol. Chem. 1904, 41, 321; 42, 181) and creatinase.

3. *Peptases or ereptases*. The synthetic production of the polypeptides by Fischer has rendered it possible to obtain a very large amount of information with respect to the nature and limitations of action of the proteo-elastic enzymes, a line of research which has chiefly been followed by Fischer and Abderhalden (Lehrbuch physiol. Chem. Berlin, 1909). The relations appear to be very complex, and no approach to finality in the matter has yet been made.

In the blood, in all the organs and tissues, and in the intestinal juice are found enzymes which hydrolyse polypeptides, but are without action on the albumins. The relation to the polypeptides is highly specific, and only a very careful and thorough examination of the question will reveal how far the hydrolysis of various polypeptides is due to the action of different enzymes.

Of the synthetical polypeptides, only those which contain the naturally occurring optical isomerides of the amino-acids are decomposed.

Pancreatic trypsin itself decomposes many albumins down to the stage of polypeptides, and some of the latter are resolved into amino-acids, whereas others resist the further action of the enzyme, and are found in the digested liquid. It is, however, almost certain that pancreatic trypsin must be regarded as a complex consisting of a trypsin, capable of hydrolysing albumins down to the polypeptide stage, along with one or more peptases, which attack these simpler compounds (Schäffer and Terroine, J. Physiol. Path. 1910, 12, 884, 905; Wohlgemuth, Biochem. Zeitsch. 1912, 39, 302).

The decomposition of simple compounds, such as the dipeptides, alanyl-alanine, glycyl-glycine, and glycyl-tyrosine, provides an admirable opportunity for studying the kinetics of enzyme action.

4. *The Proteinases. Enzymes capable of hydrolysing the albumins*. (a) *Trypsin or tryptase*. This name belongs specifically to the enzyme secreted in the inactive (zymogen) form by the

pancreas, as already described (p. 136), but is applied, as a general term, to a large number of enzymes, both of animal and vegetable origin, which attack albumins and produce from them polypeptides. Among the most important of these are the leucocryptase of the leucocytes of the blood, the autoclastic enzymes of animal tissues and organs, and the proteoelastic enzymes of the lower animals. In the vegetable kingdom, many similar enzymes occur, notably *papayotin* in the melon tree, *Carica papaya* (Linn.); *bromelin* in the pineapple, as well as the *endocryptases* of yeast, and many bacteria.

Pancreas trypsin is most active in presence of alkalis, the exact optimum concentration of hydrogen ions being different for different preparations and for different substrates (Long and Hull, J. Amer. Chem. Soc. 1917, 39, 1081), but being approximately 10^{-8} to 5×10^{-9} for fibrin and 3×10^{-6} to 5×10^{-7} for caseinogen; 0.2 p.c. of sodium carbonate is commonly employed. It also exerts a certain amount of action in very weak acid solution. The amount of hydrolysis is proportional to the amount of enzyme and the time of action, the concentration being indifferent (Löhlein, Hofm. Beitr. 1905, 7, 120; Hedin, J. Physiol. 1904, 32, 468; 1906, 34, 370).

Trypsin is readily taken up, probably by adsorption, by fibrin, and can thus be removed from solution. It is also adsorbed by animal charcoal and cannot be re-extracted from this substance by water (Hedin).

Substances which tend to inhibit the action of the enzyme and are termed antitrypsins, occur in blood serum, in parasitic worms, and in yeast, but the nature and function of these is as yet little understood (see Hedin, Zeitsch. physiol. Chem. 1907, 52, 412; Buchner and Haehn, Biochem. Zeitsch. 1910, 26, 171; Weinland, Zeitsch. Biol. 1902, 44, 1, 46).

(b) *Pepsin or pepsinase*. This enzyme is the characteristic digestive agent of the gastric juice of all vertebrates. It is secreted by the cells of the mucous membrane of the stomach in the form of an inactive zymogen, *propepsin*, which is converted into active pepsin by the hydrochloric acid of the gastric juice. It is also secreted by Brunner's glands in the intestine, and is stated to occur in a few flesh-eating plants, such as the various species of *Nepenthes* (pitcher plant), *Dionaea* and *Drosera* (sundew). The most characteristic properties of pepsin are that it only acts in acid solution, and that it does not hydrolyse any known polypeptide. It converts the albumins (phosphoproteins, nucleoproteins, gelatin, &c.) probably first into acid albumins, and then into simpler compounds of unknown constitution. These were formerly classed as albumoses, precipitable by ammonium sulphate; and peptones, non-precipitable by this salt, but precipitable by phosphotungstic acid. The nature and individuality of the numerous compounds of these classes which have been described are still involved in obscurity, and all that can be said with certainty is that hydrolysis does not go so far as to produce simple amino-acids. The least impure form of pepsin appears to have been obtained by Pekelharing (Zeitsch. physiol. Chem. 1902, 35, 8), who simply dialysed the filtered gastric secretion of a dog, obtained by fistula, and

then dried the washed precipitate thus produced. The pepsin is deposited in perfectly transparent spheres, containing very little ash, and is quite free from phosphorus. When hydrolysed with acid, it yields a pentose, purine bases, and an acid, termed pepsinic acid, which gives the albumin reactions.

According to Schütz, the rate of hydrolysis is proportional to the square root of the concentration of the pepsin (Zeitsch. physiol. Chem. 1887, 9, 377). This is explained by Arrhenius as due to the inhibiting effect of the products of the hydrolysis, and by Bayliss as due to the fact that the combination between the pepsin and the substrate is of the nature of adsorption. When the enzyme acts on coagulated albumin, the effect, however, appears to be proportional to the concentration. The optimum temperature appears to be 40°, whilst the rate of action is greatly influenced by the concentration of the hydrogen ions present, the optimum being, according to Sörensen, 10⁻². Peptic digestions are usually carried out in presence of 0.4 p.c. HCl.

Antipepsins are said to exist in the mucous membrane of the stomach, and to prevent the autodigestion of the organ. These are probably also present in commercial pepsin and rennet. The relations between pepsin and rennet are discussed under the heading of *Rennet*.

ENZYMES PRODUCING OXIDATION.

In spite of the fact that both the higher plants and all animals supply themselves with energy exclusively by the oxidation of their various food materials by atmospheric oxygen, with the ultimate production of carbon dioxide and water, little is definitely known of the mechanism by which this oxidation is brought about or of the chemical changes involved.

On the other hand, it has been found that many animal and vegetable cells secrete materials which can be obtained in the form of press juice or extract by the aid of which various oxidations can be effected. The most completely investigated of the changes of this kind is the oxidation of phenols and allied compounds to quinones or colouring matters, which is produced by many vegetable cells and is exemplified by the production of a brown coloration when many fruits are cut open and exposed to the air, and of a blue colour when certain fungi are broken (*Russula*, *Agaricus*).

The nature of these oxidising systems has been to a considerable degree elucidated by the researches of Bach and Chodat (Biochem. Zentr. 1903, 1, 417, 457; see Bach, Oxydationsprozesse in der lebenden Substanz, in Oppenheimer's Handbuch der Biochemie der Menschen, &c., Ergänzungsband, 1913, 133), according to whom the oxidation involves the co-operation of two agents. One of these has the properties of an enzyme (*i.e.* it is a thermolabile colloidal catalyst), and has the function of catalysing the reaction between a peroxide, either hydrogen peroxide or an organic peroxide, and the oxidisable matter; this enzyme is accordingly known as a *peroxidase*. The second agent may consist of (a) hydrogen peroxide, (b) an organic peroxide. In the former case, the oxidation is effected by the oxygen of the hydrogen peroxide and ceases as soon as this has been expended. In the second case, the organic

peroxide gives up its oxygen to the oxidisable substance, and is then reformed by the combination of the residue with the oxygen of the air, so that a continuous oxidation occurs. The organic substances which thus readily form peroxides were termed *oxygenases* by Bach and Chodat, inasmuch as they function as catalysts in the transference of oxygen from the air to the substance undergoing oxidation, but this term has been criticised as being at variance with the present system of nomenclature (Oppenheimer, Moore and Whitley). The peroxidase is often found alone, unaccompanied by peroxide, and its presence can then only be detected by adding hydrogen peroxide as well as a substance to be oxidised. When both peroxidase and peroxide occur together (as in *Russula*, *Lactarius*, &c.), the system is often termed an *oxidase*. In certain cases, the peroxide and peroxidase can be separated by fractional precipitation with alcohol, and it was in this way that Bach and Chodat ascertained the foregoing facts.

The tests used for the detection of peroxidases and oxidases are, as a rule, identical, but when only peroxidase is present the addition of hydrogen peroxide is necessary. Some of the most generally used are as follows: (1) A blue coloration is produced with a freshly prepared alcoholic tincture of guaiacum resin. The use of this test for the detection of an oxidase requires great care, as a peroxide is readily formed in the alcoholic tincture itself on standing, which reacts with the peroxidase; it is therefore better to employ guaiaconic acid, which is free from this defect. (2) A dark-blue coloration is produced with *p*-phenylenediamine. (3) Dark-coloured purpurogallin is produced from pyrogallol. (4) By far the most satisfactory test for the presence of an oxidase is the direct measurement of the oxygen absorbed. (5) A test applicable only for peroxidase is the oxidation of formic acid to carbon dioxide and water in presence of peroxide of hydrogen or ethylhydroperoxide (Batelli and Stern, Biochem. Zeitsch. 1908, 13, 44). (6) The formation of blue indophenol from an alkaline mixture of *α*-naphthol and *p*-phenylenediamine.

Nature of peroxidase. Many interesting suggestions have been made as to the nature of the peroxidases. It was early pointed out (Bertrand, Compt. rend. 1897, 124, 1355) that oxidising extracts usually contained manganese or iron, and that the possibility existed that these mineral substances, perhaps in combination with proteins, might, by alternate oxidation and reduction, produce the effects observed, just as ferrous sulphate greatly modifies and increases the action of hydrogen peroxide (Fenton). Dony-Hénault (Bull. Acad. Belg. 1908, 105) has, in fact, prepared a colloidal suspension of oxide of manganese in gum arabic which has the properties of laccase (*q.v.*), and can be precipitated by alcohol and redissolved without losing these powers; whilst Euler and Bolin (Zeitsch. physiol. Chem. 1908, 57, 80) found that manganese salts, in presence of sodium salts of organic hydroxy-acids, produced analogous effects. Somewhat similar mixtures, containing colloidal iron salts, also act in many ways like the peroxidases (de Stoecklin, Compt. rend. 1908, 147, 1489; Wolff, *ibid.* 1908, 146, 142,

781, 1217). Bach (Ber. 1910, 43, 364) has, however, prepared active oxidases entirely free from manganese and iron, and it is probable that, when present, the salts of these metals only exert a secondary accelerating action on the oxidation process. The attempt of Willstätter and Stoll (Annalen, 1918, 416, 21) to isolate the enzyme from horse-radish resulted in a preparation having 3000 times the activity of the original material as measured by the production of purpurogallin from pyrogallol under standardised conditions. Chemically it appears to consist of a nitrogenous glucoside yielding a pentose and probably a hexose on hydrolysis. It contains 5.5 p.c. of ash, 0.46 of which is iron. The chief types of oxidising enzymes known are the following:

1. **The peroxidases**, which occur in all parts of plants. Their occurrence in animal tissues is difficult to establish, as blood produces all the reactions ascribed to peroxidases, and must therefore be absent before the presence of the latter can be proved (Batelli and Stern, Biochem. Zeitsch. 1908, 13, 44). A vigorous peroxidase occurs in milk.

2. **The enzymes producing coloured compounds from aromatic phenols, &c.** These may be known as phenolases. They produce the most varied oxidations, accompanied by colour changes, and according to Bach (Bach and Maryanovitch, Biochem. Zeitsch. 1912, 42, 417) the enzymes obtained from various sources must be regarded as identical, since they all produce the same primary oxidising effects, although these are variously modified by the presence of salts, &c. The work of Bach and Chodat, discussed above, applies to these enzymes. According to Wheldale Onslow the browning of fruits on injury is due to the presence of a peroxidase and an aromatic compound containing the catechol grouping. The oxidation of the latter is effected by atmospheric oxygen, but is catalysed by a special enzyme (oxygenene), and results in the formation of a peroxide, the whole system then constituting an oxidase, and giving a blue colour with guaiacum (Biochem. J. 1919, 13, 1; 1920, 14, 535).

Laccase occurs in the juice of the lac tree of Tonkin (*Rhus vernicifera* (D.C.)), and brings about the oxidation of the yellow juice to the black lacquer (Yoshida, Chem. Soc. Trans. 1883, 43, 472; Bertrand, Compt. rend. vols. 118-122). It has also been found in many other phanerogams (lucerne, cabbage, potatoes, &c.) and in fungi. It accelerates the oxidation of *o*- and *p*-polyphenols (but not of *m*-compounds), and has no effect on tyrosine. Its solutions only lose their oxidising powers slowly when boiled.

Tyrosinase. Enzymes capable of oxidising tyrosine with production of coloured substances occur widely, both in the animal and vegetable kingdoms, frequently accompanied by laccase. According to Gortner (Chem. Soc. Trans. 1910, 110), both soluble and insoluble forms of tyrosinase occur in the meal worm (*Tenebrio molitor*). The insoluble form contains iron, but no manganese, and is capable of oxidising a relatively large amount of tyrosine, producing a series of colour changes through pink, rose, violet, and blue-black to black (*melanin*). It also effects the oxidation of *p*-aminophenol, guaiacol, gum guaiacum, and 2:4-diaminophenol, but not of

quinol or pyrogallol. Tyrosinase also occurs in many leaves, which become black on drying, and in bran. The blue colour observed when certain mushrooms are broken is not due to the action of this enzyme but to that of laccase (Bertrand). A very large number of *p*-hydroxyphenyl derivatives, as well as nearly all derivatives of tyrosine, tryptophan, and some of its derivatives, adrenaline, phenol, and *p*-cresol are oxidised.

Bach has shown (Biochem. Zeitsch. 1914, 60, 221) that the action of tyrosinase is very complex. Tyrosinase contains (1) an *amino-acidase*, which decomposes tyrosine with formation of some compound (probably *p*-hydroxyphenylacetaldehyde) which is capable of being acted on by an oxidase, or a peroxide and hydrogen peroxide:

(2) A non-specific oxidase system (phenolase) capable of oxidising this product at the expense of atmospheric oxygen. In some cases the organic peroxide of this oxidase system is only present in traces, but the peroxidase is always abundant. The action of the aminoacidase only proceeds in the presence of a hydrogen acceptor, and this is produced from some substance present in the 'tyrosinase' by the action of atmospheric oxygen, so that the first stage of the change can only commence in presence of air.

When a mixture of tyrosine and tyrosinase is shaken in the air, oxidation commences, and a deep red coloured solution is formed. If the air be now replaced by nitrogen, this colour disappears, owing to reduction, and a colourless solution results. If this be boiled, the further action of the tyrosinase is prevented, but the liquid now gives all the colour changes characteristic of tyrosine when treated with hydrogen peroxide and a peroxidase (*e.g.* from horse-radish), although these have no action whatever on tyrosine itself.

The various oxidative fermentations brought about by micro-organisms are discussed later.

ENZYMES PRODUCING REDUCTION. REDUCASES.

Enzymes are also known in presence of which many compounds (colouring matters, aldehydes) are reduced. They occur very widely in animal tissues (liver, muscle), and in the higher plants, as well as in yeasts and bacteria. The source of the hydrogen in these reductions is water, and the change only proceeds in the presence of an oxidisable substance, which can act as an acceptor for the oxygen of this water. Hence these enzymes produce both reduction and oxidation simultaneously, and, as the process also involves the decomposition of water, it has been termed a hydroclastic oxidation-reduction (Oppenheimer). According to Bach (Biochem. Zeitsch. 1911, 31, 443), whose views, however, require further experimental confirmation, the hydrogen forms an unstable perhydride of oxygen H_2O_2 , which is decomposed in the presence of the enzyme, the hydrogen being passed on to the reducible substance. Hence he terms the enzyme a *perhydridase*, and regards the whole process as closely analogous to oxidation by means of a peroxide and a peroxidase.

On the other hand, Wieland and Thunberg (Stand. Arch. Physiol. 1920, 40, 1, where the literature is quoted) considered that the hydrogen is transferred directly from the oxidisable substance to the reducible substance by the enzyme, which is accordingly termed *dehydrogenase*.

Milk has long been known to contain an enzyme of this class (Schardinger's enzyme), which brings about the reduction of methylene blue in the presence of formaldehyde, but not in its absence, the aldehyde acting as oxygen acceptor. It has now been shown that the reducing enzymes of the tissues (Bach), and of yeast and some bacteria (Harden and Norris, Harden and Zilva), are of the same type. Dried yeast and zymyn (p. 149), *Bacillus coli communis*, and rabbit muscle can be freed from the oxygen acceptor by washing, and then only reduce methylene blue in the presence of certain definite oxidisable substances, which, however, differ for the enzymes derived from different materials, so that these cannot be regarded as identical. The oxygen acceptor, in the case of the tissue reducases, is probably an aldehyde (Bach).

A special case of reducase action is the conversion of an aldehyde into an equimolecular mixture of the corresponding alcohol and acid (Cannizzaro's reaction), one molecule being reduced and a second acting as oxygen acceptor and being oxidised. This is brought about by an enzyme termed *aldehydase*, or better *aldehydomutase*, which occurs in the liver, lungs, and spleen (Parnas, Biochem. Zeitsch. 1910, 28, 274; Battelli and Stern, Biochem. Zeitsch. 1910, 29, 130). The oxidising effect of this enzyme on aldehydes, such as salicylaldehyde, had been known for some time (see Jacoby, Virchow's Arch. 1899, 157, 235; Zeitsch. physiol. Chem. 1900, 30, 135; 1901, 33, 128) before the simultaneous reducing action was observed.

Analogous to this enzyme, but distinct from it, is the *glyoxalase* of Dakin and Dudley (J. Biol. Chem. 1913, 14, 155, 423; 15, 463; 1914, 16, 505), which occurs in many animal tissues in the higher plants and in yeast, and converts glyoxal and its derivatives into the corresponding hydroxy-acids, oxidation and reduction occurring in the same molecule:

It is strongly inhibited by pancreatic extract.

CATALASE.

This name was given by Loew (Bull. Agric. Washington, 1900) to the enzyme which has the power of catalysing the decomposition of hydrogen peroxide into water and oxygen. It has long been known that animal and vegetable tissues have the property of producing this decomposition, and, at one time, this was thought to be a general characteristic of all enzymes (Schönbein, J. pr. Chem. 1863, 89, 334). Further investigation, however, showed that this was not the case, but that this property belonged to a special, very widely distributed enzyme (Loew). The power of decomposing hydrogen peroxide is possessed by all the tissues of the animal body, and is most marked in the liver. Thus it was found by Batelli and Stern (Arch. Fisiol. 1905, 2, 471) that 0.1 gram of guinea-pig liver evolved 5800 c.c. of oxygen from 1 p.c. hydrogen peroxide at 37°, whilst the

corresponding number for the blood was 490 c.c., and for the muscle 34 c.c. The enzyme can be concentrated by extracting the tissue with water, precipitating with alcohol, extracting this with water, and again precipitating with alcohol. A similar process applied to blood yielded a clear faintly yellow solution of the enzyme, free from blood and from iron (Senter, Zeitsch. physikal. Chem. 1903, 44, 257; 1905, 51, 673). Preparations can be obtained from many plant tissues in a similar manner, as well as from yeast and many fungi and bacteria. It is not certain whether the enzymes derived from these various sources are identical, but Loew has distinguished the soluble and insoluble forms of the enzyme obtained by him from tobacco as β - and α -catalase, and Senter has named the enzyme from blood hamase.

The catalytic function of the enzyme appears to be strictly limited to the decomposition of hydrogen peroxide. The oxygen is liberated in the gaseous state, and does not effect any oxidations other than can be brought about by free oxygen. The enzyme is very sensitive to the presence of free hydrogen ions, and, according to Sørensen, acts best in neutral solution, whilst alkalis and many salts exert an inhibiting effect. Hydrocyanic acid is a powerful inhibitor, but does not cause any permanent change in the enzyme. Hydrogen peroxide itself exerts a destructive action on the enzyme, and hence accurate measurements of the rate or amount of decomposition can only be made in dilute solution and in presence of a relatively large amount of enzyme. Under these conditions, the decomposition is monomolecular, and the velocity is proportional to the concentration of enzyme and of hydrogen peroxide, whilst with increasing concentration of hydrogen peroxide the velocity becomes relatively slower (Senter). As the oxygen appears to be produced in the molecular form, it is probable that the decomposition occurs in stages, either an intermediate compound of enzyme and hydrogen peroxide being formed which then breaks down, or a compound of the enzyme and oxygen which then reacts with a second molecule of the peroxide.

The reaction is analogous in many respects to the decomposition of hydrogen peroxide by colloidal platinum (Bredig). The catalase is, however, more efficacious, a solution of 0.001 gram per litre of catalase-containing material from blood having the same effect as a solution of colloidal platinum containing 0.006 gram (Euler, Hofm. Beitr. 1906, 7, 1).

The action of catalase is measured either by titration of the hydrogen peroxide present at various stages of the reaction or by direct measurement of the oxygen evolved. Estimations of the rate or extent of decomposition of hydrogen peroxide by the catalase of milk or of malt (van Laer) have been used in the analytical examination of these materials. A solution of vegetable catalase is used to remove the excess of hydrogen peroxide from cream which has been sterilised by the addition of this substance (Budde).

The physiological function of catalase in the animal body is not definitely known, but it is conjectured that it may be to decompose hydrogen peroxide or complex peroxides formed during processes of oxidation.

THE COAGULASES.

A number of enzymes exist which have the property of bringing about changes in various liquids which result in the formation of an insoluble material. The most important of these are :

(1) The production of a curd in milk by the enzyme of rennet (chymase).

(2) The coagulation of the blood by the enzyme thrombase.

(3) The coagulation of muscle.

(4) The formation of insoluble substances from the pectins of plants (pectase).

Most of these changes are exceedingly complicated, the coagulation of the blood being one of the most complex phenomena in the whole range of physiological chemistry. The only one which can be treated here is the action of rennet on milk.

Rennet, Rennin, or Chymase. Enzymes possessing the power of coagulating milk occur in the form of zymogen in the mucous membrane of the stomach of many animals, and are secreted into the gastric juice; similar substances are also found in many plants. Milk is also curdled by pancreatic trypsin. Rennet is usually prepared by digesting the membrane of the stomach of the calf with 0.1-0.2 p.c. hydrochloric acid, or with glycerol or salicylic acid, and can be precipitated by alcohol. Some doubt exists as to the relation of rennet to pepsin, which is also secreted by the cells of the mucous membrane of the stomach. According to Pavlov (Zeitsch. physiol. Chem. 1904, 42, 415), the coagulation of milk is an effect of the action of pepsin under special conditions, whereas Hammarsten strongly supported the view that the two enzymes are distinct (Maly's Jahresb. 1872, 1874, 1877). The question is a very complex one, owing to the existence of anti-peptic and anti-rennet substances in the stomach extracts, but the balance of opinion now inclines to the belief that two independent enzymes exist.

Rennet converts the caseinogen of milk into casein, the change most probably (but not certainly) consisting in the hydrolytic decomposition of the molecule of caseinogen with production of casein and some other product. The casein thus produced is precipitated by calcium salts as an insoluble curd, and it is the formation of this precipitate which is observed in the curdling of milk by rennet. Solutions of caseinogen in the minimum amount of lime water or in caustic soda solution are not curdled by rennet, but after treatment give a precipitate with calcium salts.

The time required for curdling is proportional both to the concentration of enzyme and of caseinogen. The action is favoured by slight acidity and hindered by alkalinity. The optimum temperature is 37°-45° and the temperature coefficient of the reaction is about 3 for 10°. When the milk is boiled before being treated, the formation of curd is interfered with, probably owing to changes produced in the calcium salts of the milk. The enzyme is capable of curdling at least 1,000,000 times its weight of milk.

ALCOHOLIC FERMENTATION.

The production of carbon dioxide and alcohol from sugar is by far the most important of all technical processes of fermentation, and has, therefore, been more

thoroughly investigated than any other change produced by micro-organisms. Although both alcohol and carbon dioxide are produced from sugar by many micro-organisms belonging to the class of bacteria, the power of bringing about the typical alcoholic fermentation, of decomposing sugar almost quantitatively into these two substances, is possessed among micro-organisms only by certain moulds and by a group of unicellular fungi which belong to several closely allied families and are commonly grouped together as yeasts. The biology and mode of culture of these are treated in the article on BREWING.

Composition of yeast. The cell consists of membrane, cytoplasm, and nucleus, but much doubt exists as to the exact form of the nucleus and the changes which it undergoes during fermentation, budding, and spore formation. In the cytoplasm occur vacuoles, and at various stages in the life of the cell granules of chromatin and volutin are formed as well as fat droplets and glycogen.

Yeast, which has been pressed at about a half-ton per square inch, forms a friable, almost white mass, containing about 70 p.c. of water and alcohol, and 30 p.c. of solids. The composition of the dry matter of yeast varies so greatly with conditions of growth, &c., that no general statement is of much value. The ash, which amounts to 5-10 p.c. of the dry residue, consists essentially of potash (K_2O , 28-39 p.c.), magnesia (MgO , 4-6 p.c.), lime (CaO , 1-7 p.c.), and phosphoric oxide (P_2O_5 , 45-59 p.c.), together with smaller quantities of sulphur trioxide, iron, silica, and traces of chlorine. The exact nature of the cell membrane is as yet undecided, but it appears to be closely allied to cellulose, although true cellulose is absent. The cytoplasm contains a coagulable albumin, a nuclein, glycogen, yeast gum, and a large number of other compounds, in part derived from these by hydrolysis.

General phenomena of alcoholic fermentation. 1. *The fermentable substances.* All yeasts which ferment glucose also ferment mannose and levulose. The case of galactose is different, as some yeasts appear to ferment it imperfectly, and others not at all. It has been found by many observers and may now be regarded as established, that certain yeasts which do not normally ferment galactose readily acquire this property when they are cultivated in the presence of this sugar, as for example in hydrolysed lactose. Examples of this are *S. carlsbergensis* (H.), *S. cerevisiae* (H.), *S. thermantitronum* (Johnson), &c. Indeed, according to Lindner, all the culture yeasts exhibit this property (see Slator, Chem. Soc. Trans. 1908, 217; Lindner, Wochensch. Brauerei, 1911, 28, 61).

The higher saccharides are not directly fermentable by yeast, but must first undergo hydrolysis to the simple hexoses. This is effected by hydrolytic enzymes present in the yeast, which can, as a rule, be extracted from the cell by appropriate methods. The ordinary culture yeasts employed in brewing, &c., contain maltase and invertase, but not lactase, and are therefore able to ferment maltose and cane sugar, but not lactose. Bottom yeasts appear invariably to contain melibiase, which decomposes melibiose into glucose and galactose,

whilst this enzyme is lacking in top yeast. An analytical method for detecting bottom yeast in top yeast has been founded on this fact. In addition to this, practically all culture yeasts are able partially to ferment raffinose, which on hydrolysis yields melibiose and fructose, and they probably contain a special enzyme, *raffinase*, which produces this hydrolysis, although it is possible that this is due to the invertase. In the case of top yeasts, only the fructose thus produced undergoes alcoholic fermentation, the melibiose remaining unaltered, whereas the bottom yeasts decompose this also. Dextrin is also more or less slowly fermented by yeast, the hydrolysis being effected by a dextrinase or amylase. This property is of great importance in brewing, as a yeast which possesses a comparatively large amount of this enzyme is able to attenuate the wort to a greater extent, and to produce a larger yield of alcohol. Starch and glycogen are unaffected by yeast, probably because, owing to their highly colloidal nature, they are unable to penetrate the cell. Species of yeast are now known which are lacking in one or other of all these hydrolytic enzymes, and hence are incapable of fermenting the corresponding sugar. These have frequently been employed for the isolation of such a sugar as maltose from mixtures containing glucose or fructose, and for the analytical estimation of mixtures of sugars (Davis and Daish, *J. Agric. Sci.* 1913, 5, 437), and in fact their relations to the disaccharides are employed as a means of classification. Thus *S. marxiannus* (H.) and *S. exiguus* (H.) ferment cane sugar, but not maltose; *S. rouxi* (Boutroux) ferments maltose, but not cane sugar; *S. fragilis* (Jöng), found in kefir, ferments lactose, and *S. mali* (Duclaux) only ferments the simple sugars and is without action on the disaccharides. No yeast appears to be able to ferment the synthetic disaccharides, such as isomaltose or glucosidogalactose, and this disability extends to the isomerides of the hexoses, such as sorbose, tagatose, &c., to the optical antipodes of the fermentable sugars which have been obtained by synthesis, and to the pentoses and tetroses. Beyond the simple sugars mentioned above, no other substance appears to be directly fermentable by yeast to alcohol and carbon dioxide, with the exceptions of a synthetic 9-carbon atom sugar and of glyceraldehyde and dihydroxyacetone, which, according to Bertrand, Buchner, and Meisenheimer (*Ann. Chim. Phys.* 1904, [8] 3, 181; *Ber.* 1910, 43, 1773), and Lebedev (*Ber.* 1911, 44, 2932; 1912, 45, 3256; *Biochem. Zeitsch.* 1912, 46, 483), are acted on by yeast. Glycerol, and the higher alcohols such as mannitol and dulcitol, are not fermented. In 1911, Neuberg (*Biochem. Zeitsch.* 1911, 31, 170) made the important discovery that yeast decomposes α -ketonic acids $R\cdot CO\cdot COOH$ quantitatively into carbon dioxide and the corresponding aldehyde (*see p.* 151). Many hydroxy-acids are also slowly attacked by yeast, among these being lactic acid (Buchner and Meisenheimer, *Ber.* 1904, 37, 417; 1905, 38, 620; 1906, 39, 3201; Oppenheimer, *Zeitsch. physiol. Chem.* 1914, 89, 45), glyceric acid (Neuberg and Tir, 1911, 32, 323; Lebedev, *Ber.* 1914, 47, 660), gluconic acid, and glyoxylic acid (Lebedev, *Biochem. J.* 1918, 12, 81).

2. *The rate of fermentation by yeast* has been investigated by many authors. It is best examined by Slator's method of adding a suspension of yeast to the solution to be fermented, and determining the initial rate of fermentation. In this way, all errors due to change in the amount and condition of the yeast and to the influence of the products of decomposition are, to a large extent, avoided (*Chem. Soc. Trans.* 1906, 128). By this and other methods, it has been established that (1) the rate of fermentation is directly proportional to the number of yeast cells present; (2) the rate of fermentation increases with the concentration of the sugar up to a certain limit, and then remains approximately constant, decreasing slightly as the concentration is further augmented.

Working with a suspension of 40,000,000 cells of brewery yeast per c.c. at 30°, Slator found that the rate was almost constant for glucose concentrations between 0.5 and 10 grams per 100 c.c. The mode of action of yeast is therefore identical with that typical of enzymes which has already been discussed.

The rate increases with the temperature, but the temperature coefficient diminishes as the temperature increases. The following values were obtained by Slator for glucose; they are independent of the concentration of yeast and glucose, the class of yeast and presence and absence of nutrient materials, remaining the same when inhibiting agents are present:—

Temp.	V_{t+10}/V_t
5°	5.6
10°	3.8
15°	2.8
20°	2.25
25°	1.95
30°	1.6

The temperature coefficient for an ordinary chemical reaction is of the same order as these numbers, viz. 2–3 for 10°.

Glucose and fructose are fermented at the same rate, and this is also the case when the fermenting power of the yeast is partially destroyed by heat, antiseptics, &c. On the other hand, mannose and galactose may be fermented at a different rate from glucose, and the rates are differently affected by inhibiting agents. The temperature coefficients for fructose and mannose are the same as for glucose, that for galactose is slightly less.

3. *Heat of fermentation.* During the fermentation of sugar by yeast, a considerable amount of heat is evolved, so that the temperature of the mass rises as the fermentation proceeds. The quantity of heat evolved may be calculated from the difference between the heat of combustion of glucose (675.7 Cals.) and that of the alcohol formed from it ($2 \times 325.7 = 651.4$ Cals.), the remaining product, the carbon dioxide, being completely oxidised. This difference amounts to 22.3 Cals., so that the fermentation of 180 grams of glucose liberates enough heat to raise the temperature of 22 litres of water 1°. This theoretical number has been confirmed by the experiments of Bouffard (*Compt. rend.* 1895, 121, 357), who obtained the value 23.5 Cals. In the fermentation of a disaccharide, heat is also evolved by the hydrolysis to the simple sugars;

but this is small in amount, being 4.5 Cals. for cane sugar and 3.8 Cals. for maltose (Herzog, Zeitsch. physiol. Chem. 1903, 37, 383), so that the numbers actually observed for these sugars per gram-molecule are approximately twice that for glucose (Rubner, Arch. Hygien. 1904, 48, 260; 49, 355; A. J. Brown, J. Inst. Brewing, 1901, 7, 93).

4. *Products of fermentation.* The earlier observers (Lavoisier, Gay-Lussac) considered that in the process of fermentation the sugar was completely decomposed into carbon dioxide and alcohol, according to the equation:

Schmidt, in 1847, however, observed the occurrence of succinic acid in all fermented liquors, and the amount of this substance formed was carefully estimated by Pasteur (Compt. rend. 1858, 46, 857), who also made the important observation that glycerol was an invariable product of the fermentation of sugar. According to Pasteur, the products from 100 parts of cane sugar, which yield 105.36 parts of invert sugar, are:

Alcohol	51.11
Carbon dioxide	49.42
Succinic acid	0.67
Glycerol	3.16
Cellulose, fat, and extractive matter	1.00
		105.36

The proportions of these products were subsequently found to be variable and to depend on the condition of the yeast, the nature of the nutrient material, &c. Many other subsidiary products have now been recognised in addition to succinic acid and glycerol. Among these may be mentioned *isobutyleneglycol* (in wine and cherry brandy), formic acid, acetic acid, propionic acid, butyric acid, and several still higher acids, which occur as esters (caproic, caprylic, pelargonic, capric, ceanthyllic), and formaldehyde, acetaldehyde, and traces of higher aldehydes, propyl alcohol, *n*-butyl alcohol, *isobutyl* alcohol, *n*-amyl alcohol, *iso*-amyl alcohol, ethylmethylcarbinol, and alcohols containing 6, 7, and 9 carbon atoms.

The alcohols and aldehydes mentioned above are found in the spirit obtained by the distillation of the fermented liquids. All such spirit yields a fraction of high boiling-point, which amounts to 0.1-0.7 p.c. of the whole, and is known as fusel oil (*q.v.*). The discussion which has long raged over the origin of this fusel oil has been set at rest by the researches of Ehrlich (Zeitsch. Rüb. Zuck. Ind. 1905, 539; Biochem. Zeitsch. 1906, 2, 52; 1909, 18, 391; Ber. 1906, 39, 4072; and many other papers), who has proved in the most conclusive manner that the higher alcohols and probably the corresponding acids and aldehydes which are observed in fermented liquids are formed by the yeast, not from the sugar, but from the amino-acids produced by the hydrolysis of the proteins of the medium and of the yeast cell itself.

The reaction is a general one, and requires the presence of living yeast and sugar as well as the amino-acid. Under these circumstances, the yeast not only ferments the sugar to alcohol

and carbon dioxide in the usual way, but also brings about what Ehrlich terms the alcoholic fermentation of the amino-acids, according to the equation:

The ammonia appears to be invariably assimilated by the yeast and is not found in the medium. This fact probably affords the key to the biological significance of the reaction. It is by means of this change that the yeast acquires the nitrogen necessary for its existence from the amino-acids, which are usually the chief available source of this element. The whole change is rendered possible by the utilisation of some of the energy evolved by the fermentation of sugar, which is proceeding simultaneously. Ehrlich has shown, by careful experiments, that in this way, leucine

yields the *iso*amyl alcohol

and *isoleucine* $C_6H_5 \cdot CH(CH_3) \cdot CH(NH_2) \cdot COOH$ the *d*-amyl alcohol $C_5H_5 \cdot CH(CH_3) \cdot CH_2 \cdot OH$, which are the main constituents of fusel oil.

The other amino-acids yield corresponding products, tyrosine

being converted into *p*-hydroxyphenylethyl alcohol or tyrosol $OH \cdot C_6H_4 \cdot CH_2 \cdot CH_2 \cdot OH$, a substance of intensely bitter taste, and phenylalanine $C_6H_5 \cdot CH_2 \cdot CH(NH_2) \cdot COOH$ into phenylethyl alcohol $C_6H_5 \cdot CH_2 \cdot CH_2 \cdot OH$, one of the chief constituents of oil of roses. It is almost certain that many of the substances which impart flavour, bouquet, and aroma to fermented liquors have their origin in this manner, so that the subject is one of fundamental importance for the technologist.

Succinic acid is also formed by a reaction of this kind, which differs from the foregoing in so far as it involves an oxidation. The source of this substance is glutamic acid

which, instead of yielding γ -hydroxybutyric acid, as might have been expected, is converted into succinic acid

Yeast is, moreover, not only capable of producing these changes in amino-acids naturally present in the medium or purposely added to it, but also decomposes in a similar manner the amino-acids formed by the hydrolysis of its own albumin. Some of the cells evidently utilise the products of the autolysis of others which have died, and hence it comes about that even when a pure sugar solution is fermented by pure washed yeast, the fermented liquid contains a certain small proportion of fusel oil, succinic acid, &c. The amounts produced in these circumstances are, however, small, as they are also when the yeast is grown in presence of ammonium salts. It also follows from this that when yeast is grown in a synthetic medium, containing ammonium salts only as the source of nitrogen, the carbon of any fusel oil or succinic acid produced is indirectly derived from the sugar.

It seems probable, from the experiments of Neubauer and Fromherz (Zeitsch. physiol. Chem. 1911, 70, 326), that the amino-acid (I.) first undergoes indirect oxidation to the corresponding ketonic acid (III.) and ammonia, and that the acid is then decomposed by the yeast, forming carbon dioxide and an aldehyde (IV.), which then either undergoes reduction to an alcohol (e.g. fusel oil) or oxidation to an acid (e.g. succinic acid).

It is interesting to note that the reaction proceeds asymmetrically as already described (see *Enzyme action*).

It has now been proved by Neuberg and his colleagues (*v. post*) that the glycerol, which is invariably formed during fermentation, and, unlike the substances discussed above, is equally produced by yeast juice and zymine in the absence of living yeast, is derived from the sugar.

The production of by-products is influenced not only by the nature of the available nitrogen supply, as already explained, but also by many other factors. Thus, Ashdown and Hewitt (Chem. Soc. Trans. 1910, 636) have adduced evidence to show that in the presence of formates the amount of aldehyde produced diminishes.

5. *Ratio of alcohol to carbon dioxide.* All these decompositions have an influence on the ratio of alcohol to carbon dioxide produced by alcoholic fermentation. The theoretical ratio is $46/44=1.045$, and Pasteur, as quoted above, actually found 51.11 parts of alcohol to 49.42 of carbon dioxide from 100 of cane sugar. He, however, considered that succinic acid and glycerol were formed according to the equation:

and therefore ascribed 0.53 of carbon dioxide to the fermentation which had produced 0.67 of succinic acid, thus leaving 48.89 of carbon dioxide as the product of the true alcoholic fermentation, the corrected ratio being thus $51.11/48.89=1.045$, exactly the theoretical. Similar results were obtained by Jodlbauer (Zeitsch. Rüb. Zuck. Ind. 1888, 308), who found that cane sugar yielded 49.04 p.c. of carbon dioxide.

Buchner and Meisenheimer (Ber. 1910, 43, 1773), working with pure yeast (Race 792 of the Berlin Collection), obtained 49.73 p.c. of the cane sugar as alcohol, and 49.12 p.c. as carbon dioxide, the ratio being 1.01. They ascribe this excess of carbon dioxide to the oxidation corresponding to the production of glycerol, the amount of which was not estimated. In spite of the fact that no nitrogenous material was added to the medium, the carbon dioxide and alcohol only represent 98.85 parts of the 105.36 of invert sugar to be accounted for, so that 6.51 parts had undergone some other change. Any carbon dioxide formed from amino-acids produced by autolysis would be included in the amount found.

6. *Formation of glycogen: autofermentation*

of yeast. Yeast very readily converts a portion of the carbohydrate present in the medium into glycogen $\text{C}_6\text{H}_{10}\text{O}_5$, which is stored in the cell (see Harden and Young, Chem. Soc. Trans. 1902, 1224, where the literature is cited).

This material acts as a reserve carbohydrate, and, when the yeast is preserved in absence of sugar solution, is slowly broken down by a diastatic enzyme into sugar, and fermented into alcohol and carbon dioxide: this phenomenon is known as the autofermentation of yeast. As yeast may contain as much as 30-40 p.c. of its dry weight of glycogen, it follows that a very considerable amount of carbon dioxide and alcohol may be produced from yeast alone. The autofermentation proceeds more rapidly at high temperatures (Harden and Rowland, Chem. Soc. Trans. 1901, 1227), and is greatly accelerated by the addition of many salts (Harden and Paine, Chem. Soc. Proc. 1911, 103) and of toluene. The conditions of formation of glycogen have been investigated quantitatively by Pavy and Bywaters (J. Physiol. 1907, 36, 149), and microscopically by Wager and Peniston (Annals of Botany, 1910, 24, 45; J. Inst. Brewing, 1911-2).

The alcoholic enzyme of yeast. Attention has already been called to the fact that up to 1897 all attempts to isolate from a yeast an enzyme capable of producing alcoholic fermentation had failed. It had early been shown, at first by Mitscherlich (1841) and then by Helmholtz, that the process of fermentation in all probability took place within the cell and the efforts of later investigators had been rightly directed towards the extraction of an enzyme by some process of disintegration or treatment with solvents. All such efforts were, however, made in vain, as were also attempts to extract the enzyme by freezing or plasmolysis, the products obtained being either inactive or owing what activity they possessed to the presence of unbroken yeast cells or bacteria (Lüdersdorff, Schmidt, Pasteur, Marie von Manasséin, Adolf Mayer, Nägeli, and Loew). A slight modification of the grinding processes which had been used by several of these authors, led, however, to success. Hans and Eduard Buchner applied to yeast the process of grinding with sand which they had previously employed successfully for bacteria. By adding kieselguhr, at the suggestion of Hahn, to the pasty mass obtained, and submitting the mixture to a high pressure, they obtained a clear liquid which was capable of fermenting sugar (Buchner, Ber. 1897, 30, 117).

The nature of the active agent in yeast juice. Buchner at once established the facts that the yeast juice, prepared as just described, was capable in the absence of yeast cells of producing alcoholic fermentation, and that this power was not removed by the addition of chloroform, benzene, or sodium arsenite, by precipitation with alcohol, by evaporation to dryness at 30° - 35° , or by filtration through a Berkefeld candle, whereas it was completely destroyed at 50° . He therefore concluded that the fermentative power of the juice was due to a dissolved substance of the nature of an enzyme to which he gave the name of zymase. Several of the properties of this liquid, however, suggested to various investigators that it did not contain an enzyme of the ordinary kind, but rather fragments of the living protoplasm of the

yeast, which retained for some time the functions which they had possessed in the cell. This idea was in harmony with the facts that the fermenting power of the juice was rapidly lost on preservation, and that comparatively large amounts of certain antiseptics did undoubtedly greatly diminish its activity. Other objections, founded on the behaviour of the juice on dilution, &c., proved not to be well founded. Further experience of the nature of yeast juice has shown that this idea has little to recommend it. The action of antiseptics is closely analogous to their effect on other enzymes, and the loss of fermenting power has been shown to be a very complex phenomenon. No evidence of the existence in the juice of undissolved protoplasmic fragments has been put forward, and experiments on the precipitation of the juice by alcohol and ether show that if these fragments do exist they are able to withstand repeated solution in water or dilute glycerol and reprecipitation without losing their power of producing fermentation. Such properties are only consistent with the presence of an enzyme, and there seems at present no reason to doubt the existence of such an agent in yeast juice.

Preparation and properties of yeast juice. Fresh brewery yeast is washed and pressed out at about 50 kilos. per sq. cm. The resulting mass, which contains about 70 p.c. of water, is mixed with an equal weight of sand, and from 0.2-0.3 part of kieselguhr, care being taken that this is free from acid. The dry powder thus formed is then ground in small portions at a time in a large porcelain mortar by means of a heavy pestle, until the mass becomes pasty, which occurs after about 1-2 minutes' grinding. The paste is then either directly pressed out after being wrapped in a filter cloth, the pressure being gradually raised to 90 kilos per sq. cm. (Buchner), or is mixed with more kieselguhr and the dry powder pressed out between layers of chain cloth (MacFayden, Morris, and Rowland).

The yield of juice obtained from 1000 grams of bottom yeast by Buchner is about 320-460 c.c.; that obtained from English top yeasts is rather smaller, averaging 250 c.c. (Harden and Young). The product, after any suspended yeast cells have been removed by filtration or centrifugation, is a slightly viscid, brownish-yellow, opalescent, faintly acid liquid of sp.gr. 1.03-1.06. It contains about 8.5-14 p.c. of dissolved solids, and 0.7-1.7 p.c. of nitrogen, nearly all in the form of albumin, so that the liquid coagulates when heated. The ash amounts to 1.4-2 p.c. and, like that of yeast, contains a large proportion of phosphoric oxide.

An active extract, known as maceration juice, has been obtained by Lebedev (Compt. rend. 1911, 152, 49; Ann. Inst. Pasteur, 1912, 26, 8) by drying yeast at 25°-30°, and then macerating the dried material with 3 parts of water for 2 hours at 35°. The liquid is then filtered or centrifuged and a clear active extract is thus obtained. With some yeasts, and notably with many English top yeasts, the process fails, whereas bottom yeasts in general give good results. The extract closely resembles yeast juice obtained by grinding, but usually contains a larger amount of inorganic phosphate and a much smaller amount of glycogen.

When the juice is preserved, the protein

becomes hydrolysed owing to the presence of a powerful tryptic enzyme, known as *yeast endo-tryptase*. At the same time, the power of producing alcoholic fermentation is lost, and it seems probable that this is due to the action of the tryptic enzyme on the alcoholic enzyme (Buchner). When excess of sugar is added and the mixture incubated at 25°, a steady fermentation ensues, carbon dioxide being evolved and alcohol produced in nearly the theoretical ratio, at a rate which gradually decreases until the process stops, after 72-96 hours, not from exhaustion of the sugar, but owing to the destruction of the active agent of fermentation. The juice from bottom yeasts appears to be more stable and to produce a somewhat greater total fermentation than that from top yeasts, 25 c.c. of juice producing on the average at 25° an evolution of about 1-1.5 grams of carbon dioxide in the case of bottom yeast, and 0.5-1 gram in the case of top yeasts.

The juice ferments those sugars which are fermentable by the yeast from which it is prepared and, in addition, dextrin, soluble starch, and glycogen, the first of which is only slowly and imperfectly fermented by yeast, and the last two not at all, as already explained. Maltose and cane sugar are hydrolysed before being fermented, and the fermentation proceeds just as with the simple sugars, glucose, fructose, and mannose. Slight differences between the rates of fermentation and the total fermentations produced with these three sugars, have been observed by Harden and Young. A yeast, which ferments galactose, yields a juice which also ferments this sugar, but the action is often much less pronounced relatively to that on glucose than is that of the living yeast (Harden and Norris).

Yeast juice, like living yeast, exhibits the phenomenon of autofermentation, which is carried out at the expense of the glycogen present in it. A diastatic enzyme, capable of hydrolysing glycogen, exists in the juice (*glycogenase*), and hence added glycogen is also fermented, but usually at a lower rate and with a smaller total yield of gas than glucose. The autofermentation of the juice from top yeast is often very considerable in amount, and may even occasionally equal that produced with glucose, whilst it is less pronounced with juice from bottom yeast. Maceration juice is almost free from autofermentation (see Oppenheimer, Zeitsch. physiol. Chem. 1914, 89, 63).

The rate of fermentation of sugar varies with the concentration of the sugar in the manner characteristic of enzymes, and in this respect the juice closely resembles living yeast. After a certain small limit of concentration is attained, the initial rate is practically independent of the concentration of the sugar, but decreases slightly as this increases. The gradual destruction of the enzymes produces a gradual fall in rate which simulates the course of a monomolecular reaction, and is regarded by some investigators as evidence that the reaction is of this type (Euler, Zeitsch. physiol. Chem. 1905, 44, 53). Increased concentration of the sugar also increases both the duration of fermentation and the total fermentation, probably owing to a protective action on the fermenting mechanism. The rate of fermentation is diminished by

dilution, and, with juice of high fermenting power, is probably proportional to the concentration of the juice. The total fermentation produced is, at the same time, slightly diminished.

Accompanying the decomposition of the sugar into carbon dioxide and alcohol, a synthetic action proceeds, by which a portion of the glucose is converted into a polysaccharide, which is reconverted into glucose by hydrolysis with acid. Hence the observed loss of sugar as estimated by reducing power is usually considerably greater than the sum of the weights of alcohol and carbon dioxide produced. (This phenomenon is, however, differently interpreted by Euler; *see* Harden and Young, *Biochem. J.* 1913, 7, 630, where the subject is discussed.) The exact nature of this complex saccharide has not yet been determined, but observations by Cremer (*Ber.* 1899, 32, 2062) point to the possibility of the synthetic production of glycogen in yeast juice. As already mentioned, succinic acid and fusel oil are not formed by yeast juice, whereas glycerol is produced to the extent of about 3.8 p.c. of the sugar fermented.

The action of antiseptics on yeast juice has been investigated in some detail. Saturation with chloroform or toluene or the addition of 1 p.c. of thymol has practically no effect, whilst the inhibiting action of substances like phenol, formaldehyde, benzoic acid, and salicylic acid, is very small in 0.1 p.c. solution, more considerable in more concentrated solutions. The fermenting power is destroyed by 4 p.c. chloral, 1.2 p.c. phenol, 2 p.c. sodium fluoride, 0.55 p.c. ammonium fluoride, or 1.2 p.c. hydrocyanic acid; but in this last case it is restored when the hydrocyanic acid is removed by a current of air. The action of potassium arsenite is somewhat complex, and is treated later.

Fermentation by dry preparations of yeast and yeast juice. Yeast juice can be evaporated to dryness at 37° without loss of fermenting power as measured by the total fermentation produced. When the juice is brought into 10 volumes of acetone and rapidly drained, washed with ether, and dried, a white powder is obtained, which is almost completely soluble in dilute glycerol, and retains the fermenting power of the original juice. Dry preparations can also be obtained from yeast without any previous grinding, either by drying the yeast in air and then heating it to 100° for 6 hours (*hefanol*) or by treating it twice with a large volume of acetone (or alcohol and ether), washing with ether and drying. The material prepared in the latter way amounts to about 30 p.c. of the pressed yeast taken, and is known as acetone yeast, permanent yeast (*Dauer-hefe*) or zymin, and is almost anhydrous, sterile, and quite incapable of growth, but readily produces alcoholic fermentation when brought into sugar solution. The general phenomena of fermentation by its means are the same as are produced by yeast juice. Both the total fermentation and the rate of fermentation are 4-6 times greater than would be obtained with the yeast juice prepared from the same weight of yeast.

The conditions of action of the fermenting agent contained in yeast juice. The investigation of the mode of action of yeast juice on sugar has shown that the process is very complex. The enzyme is accompanied by another substance,

termed the *coenzyme*, the presence of which is essential for the production of fermentation, and, moreover, the chemical change is not a simple decomposition of sugar, according to Gay-Lussac's equation, but a complicated reaction in which a salt of phosphoric acid takes part (Harden and Young, *Proc. Roy. Soc. B.* 1906, 77, 405, 78, 369; 1908, 80, 299; 1909, 81, 336; 1910, 82, 321).

The coenzyme of yeast juice. When yeast juice is passed under pressure through a Martin filter, which consists of a Chamberland filtering candle impregnated with 7-10 p.c. gelatin, all the colloidal matter of the juice is retained on the filter, whilst the dialysable substances pass through, so that the constituents of the juice are divided into two parts. When these two portions, the residue and the filtrate, are separately incubated with sugar solution, it is found that neither of them is capable of producing fermentation. When, however, the two solutions are mixed, fermentation proceeds at almost the same rate as with the original yeast juice (Harden and Young). Yeast juice, therefore, contains a dialysable substance essential for the process of fermentation, and this is provisionally termed the *coenzyme* or *co-ferment*. It is also present in zymin, from which it can be readily removed by simple washing with water, a perfectly inactive residue being left.

Our present information with regard to the coenzyme may be summarised as follows: (1) It is thermostable, and is not destroyed when its solution is boiled. It is therefore present in the liquids obtained by boiling yeast juice and filtering, by heating yeast at 100°, or by boiling zymin with water and filtering, and is best prepared by one of these methods. (2) It is dialysable, and can be removed from yeast juice by dialysis against water (Buchner and Antoni, *Zeitsch. physiol. Chem.* 1905, 46, 136) as well as by the filtration methods already described. (3) It is destroyed by hydrolysis by acids or alkalis, and even by the continued boiling of its solution. (4) It is gradually destroyed in yeast juice, less rapidly in presence of sugar, by an enzyme, which appears to belong to the group of lipases, since the destruction proceeds more rapidly in the presence of the lipase of castor-oil seeds, but is not accelerated by trypsin (Buchner and Klatte, *Biochem. Zeitsch.* 1908, 8, 520). (5) It is not precipitated or destroyed by lead acetate, and can therefore be, to some extent, purified by means of this reagent (Harden and Young). It is precipitated by a large volume of acetone or alcohol along with the enzyme and also by colloidal ferric hydroxide (Resenscheck, *Biochem. Zeitsch.* 1908, 15, 11). The coenzyme is also present in animal tissues (Meyerhof, *Zeitsch. physiol. Chem.* 1918, 101, 165; 102, 1).

It was found by Oppenheimer (*Zeitsch. physiol. Chem.* 1915, 93, 235) that pyruvic acid and its salts, and to a smaller extent acetaldehyde, exerted a stimulating action on the fermentation of glucose by maceration juice, and Neuberg (*Biochem. Zeitsch.* 1915, 71, 1) extended this observation to other α -ketonic acids. Moreover, by adding a mixture of a large number of α -ketonic acids (along with a phosphate) to maceration juice inactivated by

dialysis, or zymine inactivated by washing, he obtained a small amount of fermentation and concluded that this mixture could partly replace the coenzyme (Neuberg and Schwenk, *Biochem. Zeitsch.* 1915, 71, 135). Harden (*Biochem. J.* 1917, 11, 64) subsequently found that acetaldehyde was capable, in presence of potassium phosphate, of reactivating washed zymine, prepared from English top yeast. This result is, however, not accepted by Neuberg (*Biochem. Zeitsch.* 1918, 88, 145). He also found that the presence of K or NH_4 ions was necessary for the process, and that these could not be replaced by Na ions. Pyruvic acid, which is converted by the carboxylase of the zymine into acetaldehyde, has a similar effect. It seems possible, therefore, that the coenzyme may turn out to be acetaldehyde or some analogous substance. Neuberg and his colleagues (*Biochem. Zeitsch.* 1918, 88, 145; 1920, 161, 239, 276; 109, 290; 1921, 120, 215) have found that a large number of reducible substances, both inorganic and organic, act as stimulants to alcoholic fermentation by yeast preparations, and in some cases by living yeast, and consider that they act as acceptors for hydrogen, and thus increase the rate of the reaction. Harden and Henley (*Biochem. J.* 1920, 14, 642; 1921, 15, 175) have found that, at all events in certain cases, the stimulation is limited to the reaction in presence of phosphate (see below). Stimulation is also produced by certain substances which are not easily reducible, such as the higher polyatomic alcohols (Neuberg).

The function of phosphates in alcoholic fermentation. The addition of a soluble phosphate to a fermenting mixture of yeast juice and sugar produces a remarkable effect. The rate of fermentation is greatly increased, gradually attains a maximum, and remains at this high value for a certain time, after which it rapidly falls until it is again approximately the same as before the addition of phosphate. During this period of enhanced fermentation, the amounts of carbon dioxide and alcohol produced exceed those which would have been formed in the absence of added phosphate by an amount exactly equivalent to the phosphate added in the ratio $\text{R}_2\text{HPO}_4 : \text{CO}_2 + \text{C}_2\text{H}_5\text{O}$ (Harden and Young, *Chem. Soc. Proc.* 1905, 21, 189). The phosphate is, at the same time, converted into a phospho-organic compound, termed a *hexosediphosphate*, of the formula $\text{C}_6\text{H}_{10}\text{O}_4(\text{PO}_4\text{R}_2)_2$, which is not precipitated by magnesium citrate mixture or uranium salts (Harden and Young; Ivanov, *Zeitsch. physiol. Chem.* 1907, 50, 281). In other words, a definite chemical reaction occurs according to the following equation, which is founded on the ratio both of sugar and phosphate to carbon dioxide and alcohol, and on the composition of the hexosediphosphate produced:

In presence of excess of sugar the esterification proceeds according to a monomolecular reaction, and is most rapid in faintly alkaline reaction (Euler and Kullberg).

The existence of this reaction renders it probable that phosphates are essential for the alcoholic fermentation of the sugars by yeast

juice, and that in their absence no fermentation can occur. This conclusion has been confirmed in a very striking manner by experiment. By making use of the methods described under the heading of the coenzyme, a mixture of enzyme, coenzyme, and sugar can be prepared which contains no free phosphate or hexosediphosphate and very little phosphorus in any form which can yield phosphate by enzymic action. Such a mixture is almost completely devoid of fermenting power, but ferments readily when a small proportion of phosphate is added. In a particular case, the phosphate-free mixture only gave 1.5 c.c. of carbon dioxide, whereas in presence of phosphate 132 c.c. were produced (Harden and Young, *Proc. Roy. Soc. B.* 1911, 83, 451). As the result of the reaction expressed by equation (1), practically the whole of the free phosphate of the juice is converted into hexosediphosphate, and the fermentation should therefore come to a close unless some means of regeneration of free phosphate were provided. Actually the necessary phosphate is supplied by the hydrolysis of the hexosediphosphate, which is effected by an enzyme, termed on this account *hexosediphosphatase*, and yields a hexose and a phosphate:

Both the hexose and the phosphate thus formed enter again into reaction (1). The phosphate thus goes through a regular cycle of changes, being first converted into hexosediphosphate and then liberated by hydrolysis.

It is now possible to understand the conditions which prevail in yeast juice in the presence and absence of added phosphate. When the proper or optimum amount of phosphate is added, reaction (1) proceeds at its maximum rate, and this rate affords a measure of the concentration of the fermenting complex present in the juice. When all the phosphate has been converted into hexosediphosphate, the rate falls to a low level, which represents the rate at which phosphate is being supplied by the hydrolysis of the hexosediphosphate. The rate of fermentation under these conditions, the so-called normal rate of fermentation, is therefore a measure of the concentration of the hexosediphosphatase. If it were possible to accelerate the rate of action of this enzyme to such an extent that the supply of phosphate was maintained at the optimum amount, the rate of fermentation would be permanently maintained at the high level observed in presence of added phosphate. Precisely this result is attained by the addition of a small amount of sodium arsenate to the juice. A large and permanent rise of rate occurs, and direct experiment shows that this is due to acceleration of the rate of action of the hexosediphosphatase (see also Meyerhof, *Zeitsch. physiol. Chem.* 1918, 102, 185). Arsenites produce a somewhat similar but much less marked effect (Harden and Young, *l.c.*).

Hexosediphosphoric acid. The phospho-organic compound produced during fermentation, which was first observed by Harden and Young, has since been studied by Ivanov (*l.c.* and *Cent. Bakt. Par. ii.* 1909, 24, 1); Lebedev (*Biochem. Zeitsch.* 1909, 20, 114; 1910, 28, 213; 1911, 36, 248; 1912, 39, 155; *Zeitsch. physiol. Chem.* 1911, 75, 499; 1913, 84, 305); Young (*Proc.*

Roy. Soc. B. 1909, 81, 528; Biochem. Zeitsch. 1911, 32, 177); Euler and his co-workers (Biochem. Zeitsch. 1911, 36, 401; 37, 313; 1912, 41, 215; Zeitsch. physiol. Chem. 1912, 77, 394; 80, 205); and Neuberg (Biochem. Zeitsch. 1917, 83, 244), who have described various modifications of the method of preparation. It is best isolated in the form of the lead salt from the boiled mixture in which fermentation has been carried out in presence of phosphate. This is decomposed by sulphuretted hydrogen, neutralised, the free phosphate removed by magnesium nitrate and alkali, and the hexosephosphate again precipitated by lead acetate. All the salts are amorphous, and the magnesium, calcium, barium, and manganese salts, which are only sparingly soluble, are more soluble in cold than in hot water, and can be purified by taking advantage of this property. The free acid has not been obtained in the pure state, but in solution is faintly dextrorotatory, $[\alpha]_D = +3.4^\circ$. It is decomposed when boiled alone or with acids yielding phosphoric acid and either pure fructose or a mixture of hexoses in which fructose predominates. Glucose, mannose, and fructose all appear to yield the same hexosephosphoric acid, which gives fructose when hydrolysed.

Some doubt exists as to the constitution of this compound. Ivanov regarded it as a triose-monophosphoric acid ester $C_3H_5O_2(PO_4H_2)$, but the evidence on which this view rests has been shown to be unsatisfactory. Lebedev, on the other hand, at first regarded it as a hexose-monophosphoric acid ester, basing this view solely on the composition of the phenylhydrazine derivative, which has the composition

and is therefore the *phenylhydrazine salt of a monophosphoric ester of hexosazone*. Young, however, supported the original view of Harden and Young, which is now accepted by Lebedev, and has been confirmed by Euler and by Neuberg, that the compound is a hexosediphosphoric ester $C_6H_{10}O_4(PO_4H_2)_2$, since analyses of the salts agree with this formula; phosphoric acid is split off during the formation of the phenylhydrazine derivative, but a *hydrazone* containing two phosphoric acid groups for one molecule of hexose has been prepared.

The formation of hexosediphosphoric acid has been attributed by Euler to the action of a special 'synthetic' enzyme, phosphatase, since he has observed esterification of phosphoric acid without any accompanying evolution of carbon dioxide by the extract of a race of yeast obtained from a Stockholm brewery. Euler has also observed that when maceration juice has been heated to 40° for 30 minutes it effects the esterification of phosphoric acid at a much greater rate than the unheated extract.

Hexosephosphates are present in freshly prepared yeast juice and in yeast extract, and are therefore almost certainly present in the living yeast cell.

It is, however, remarkable that the hexosediphosphates are not fermented by living yeast. This fact was first observed by Ivanov, and has been confirmed by Harden and Young, and by Euler and Bäckström, who have also found that the hexosephosphate accelerates the fermentation

of glucose by yeast, although it is not itself either hydrolysed or fermented.

In addition to hexosediphosphoric acid other phosphoric esters are produced in yeast juice. The exact nature of these and their relation to the process of alcoholic fermentation have not yet been definitely ascertained (*see* Harden and Robison, Chem. Soc. Proc. 1914, 16; Euler and Fodor, Biochem. Zeitsch. 1911, 36, 401; Lebedev, Biochem. J. 1918, 12, 87).

Several minor points remain for consideration with regard to the action of phosphate. In the first place, phosphate not only sets up a temporarily enhanced fermentation, but also considerably increases the total fermentation produced, apparently by means of a protective action of the hexosephosphate on the various enzymes concerned. Excess of phosphate produces a secondary inhibiting effect, and may lead to a diminished fermentation instead of an enhanced fermentation. Excess of arsenate and arsenite produce similar effects but are much more marked in their action, often leading to total inhibition. A similar effect is produced by many other salts (Meyerhof, Zeitsch. physiol. Chem. 1918, 102, 185), so that the phosphate exerts both a specific action and a general salt-effect: *see* Harden and Henley (Biochem. J. 1921, 15, 312).

Fructose produces a much greater rate of fermentation in presence of phosphate than does glucose, and the optimum concentration of phosphate is greater in presence of fructose than in presence of glucose, as shown by the following numbers referring to 10 c.c. of yeast juice:—

Optimum concentration of phosphate in terms of a molar solution		Maximum rate of fermentation in c.c. of CO_2 per 5 minutes	
Glucose	Fructose	Glucose	Fructose
0.034	0.085	7.5	32.2
0.012	0.120	5.4	28.4
0.026	0.130	8.0	17.0
0.120	0.180	16.2	31.2

These facts are, at present, not understood, but they probably indicate that fructose bears some special relation to the fermenting complex.

Zymoin also reacts with phosphate in a similar manner to yeast juice, but the rate is not so greatly increased, so that the effects are not so marked.

Period of Induction. When maceration juice is employed, a period of induction, during which no carbon dioxide is evolved and no change in the rotation can be observed, frequently precedes the commencement of fermentation of glucose or fructose (Lebedev, Ann. Inst. Past. 1912, 26, 16). This period is abolished by the presence of even a trace of hexosephosphate (Meyerhof, Zeitsch. physiol. Chem. 1918, 102, 185) and hence cannot be observed with ordinary yeast juice, in which autofermentation, accompanied by production of hexosephosphate, is constantly in progress. The induction time is lessened by addition of cane-sugar or by warming the glucose or fructose solution with a neutral phosphate mixture for several hours at 80° . The addition of hexosephosphate also greatly diminishes the time required for the maximum rate to be attained after the addition of phosphate (Meyerhof).

These phenomena have not been explained. Euler has made a somewhat similar observation

to the effect that a preliminary partial fermentation of glucose (but not of fructose) by living yeast renders it more readily susceptible of enzymic esterification with phosphates.

Carboxylase. As mentioned above, yeast decomposes α -ketonic acids into carbon dioxide and the corresponding aldehyde

This reaction is brought about by all races of brewer's yeast, and by wine yeasts, and has been traced to the presence in these of an enzyme termed by Neuberg carboxylase. From the cell this enzyme passes into yeast juice, so that this also possesses the property of decomposing α -ketonic acids. The salts are also attacked, the carbonate or bicarbonate of the metal being formed, and a certain amount of the aldehyde undergoing condensation to inactive aldol under the influence of the alkaline carbonate. The enzyme is undoubtedly distinct from zymase, and is differently affected by agents such as heat and antiseptics. Its action is, moreover, independent of the presence of the coenzyme of yeast juice (Harden, *Biochem. J.* 1913, 7, 214; Neuberg and Rosenthal, *Biochem. Zeitsch.* 1913, 51, 125).

The play of enzymes in yeast juice. It will be seen from the foregoing that the number of factors concerned in fermentation by yeast juice is very large, and that the conditions are correspondingly complex. In addition to the enzyme and coenzyme, together forming the fermenting complex, the hydrolytic enzyme hexosephosphatase, the free phosphate and the sugar, and probably the carboxylase, which are all directly involved in fermentation, a number of other agencies are at work which influence the course of the reaction. Chief among these are the hydrolytic enzymes which cause the destruction of the enzyme and coenzyme respectively. The former of these is probably proteoclastic and the latter lipoclastic, and on the relative concentration of these and of the enzyme and coenzyme themselves depends the exact course of events. During the normal fermentation in presence of excess of sugar, both the enzyme and coenzyme are gradually being destroyed, and fermentation ceases as soon as either of these has completely disappeared. In juice from top yeast, it is found that the cessation of fermentation is due to the disappearance of the enzyme. Buchner and Klatte (*Biochem. Zeitsch.* 1908, 8, 520) have, however, found that in juice from bottom yeast the coenzyme disappears first, and that the fermentation can be restarted by the addition of boiled yeast juice containing a fresh supply of coenzyme. The matter is even more complex than this, for boiled yeast juice has been found to contain an antiprotease (analogous to the antitrypsin of blood serum) which inhibits the action of the trypsin of the yeast, and thus preserves the enzyme from destruction. The presence of this agent is partly responsible for the considerable increase in total fermentation produced by the addition of boiled yeast juice to fresh yeast juice, the coenzyme and the phosphate added at the same time having also a share in the phenomenon. The hexosephosphatase appears always to outlast both the enzyme and coenzyme. The addition of sugar

alone also exerts a protective action upon the enzymes of the juice, the power of producing fermentation being retained for a much longer time in presence than in absence of the sugar. All these phenomena of protection are probably to be referred to the formation of some sort of compound or association between the substances concerned in fermentation, which renders them less capable of reaction with other substances.

The nature of the process of fermentation in the living yeast cell. When the effects produced by yeast juice and zymine are compared with those due to living yeast, it is found that yeast juice ferments glucose at a rate which is only about $\frac{1}{10}$ of that given by the yeast from which it was prepared, whilst zymine yields a rate which is $\frac{1}{10}$ of that of yeast. In the presence of fructose and phosphate, the rate of fermentation of yeast juice may be increased as much as 20-fold, then amounting to about one-half the rate of that of living yeast, whilst that of zymine may be increased to approximately the same relative value. Assuming, as appears justified, that the process of fermentation is of the same general character in yeast as in yeast juice, it follows that yeast juice contains a large fraction of the fermenting complex present in yeast, but differs from this mainly in the power of regenerating phosphate. Zymine appears to contain a somewhat smaller proportion of the fermenting complex, but has a much greater power of regenerating phosphate than yeast juice, although still considerably less than living yeast. A similar effect to that which is produced by grinding yeast, treating it with acetone or drying and heating it, is also produced, but to a smaller degree, by treating it with toluene (Harden), so that all these processes must result in some similar change which is rendered evident by the loss of the power of regenerating phosphate from hexosephosphate. Of the nature of this change we are, at present, ignorant, but the facts strongly suggest that it is in some way due to the disorganisation of the cell. Another difference between yeast juice and yeast is that the latter does not respond, like yeast juice, to the addition of phosphate or of arsenate. This is in reality another consequence of the superior phosphate-producing power of the yeast cell, whereby the optimum amount of phosphate is constantly supplied. In presence of a constant concentration of sugar, coenzyme and phosphate, the rate of fermentation is approximately proportional to the concentration of the enzyme (Meyerhof).

In the light of what has been said, the following scheme of fermentation in the yeast cell may be imagined. The sugar first diffuses into the cell, and it has been shown by Slatore and Sands that the rate of diffusion is much more than sufficient to supply the sugar necessary for fermentation, and is therefore not the controlling factor in the observed rate of fermentation (*Chem. Soc. Trans.* 1910, 922). Inside the cell, the sugar, either as such or having undergone some change such as conversion into the enolic form (E. F. Armstrong), combines with the fermenting complex, and is thereby brought into relation with phosphate, probably also combined with the fermenting complex. This association of fermenting complex, sugar, and phosphate then

breaks down with liberation of the fermenting complex, accompanied either by the formation of carbon dioxide, alcohol, and hexosephosphate, according to equation (1) previously given, or of the products of some intermediate stage of this reaction. It is probably the rate of this decomposition which is measured as the rate of fermentation. The hexosephosphate is rapidly hydrolysed and a supply of fresh phosphate thus provided, which, along with the hexose formed at the same time, and a new quantity of sugar supplied by diffusion, again enters into association with the fermenting complex, and thus continues the fermentation.

The results obtained by Slator with mannose and the facts already related with regard to galactose, suggest the possibility that the whole mechanism, or at least some portion of it, may be specific for each sugar, but definite evidence of this has not yet been obtained.

On the other hand, the facts that hexose-phosphates are not decomposed or fermented, and that phosphates are only very imperfectly esterified by living yeast, have led Neuberg (Biochem. Zeitsch. 1917, 83, 244) to the conclusion that the processes which occur in yeast juice do not represent the normal course of events in the uninjured yeast cell.

The chemical changes involved in alcoholic fermentation. Many theories have been advanced as to the stages which may be supposed to intervene between glucose and the final products of its decomposition—alcohol and carbon dioxide. Baeyer, in 1870, pointed out that the alternate removal and readdition of the elements of water might lead to an accumulation of oxygen on certain of the carbon atoms, and thus render the rupture of the carbon chain possible. Wohl has proposed a modification of this idea, which leads to the supposition that loss of water and intramolecular change result in the formation of a ketoaldehyde which undergoes hydrolysis to methylglyoxal and glyceraldehyde; the latter of which, by a similar series of changes, also forms methylglyoxal $\text{CH}_3\cdot\text{CO}\cdot\text{CHO}$. This then passes into lactic acid, and this into carbon dioxide and alcohol. This theory received a certain amount of experimental support from the fact that small quantities of lactic acid appear to be fermented by yeast juice (Buchner and Meisenheimer). The idea of the occurrence of lactic acid as a true intermediate product of alcoholic fermentation has, however, now been abandoned, largely owing to the criticisms of Slator, who pointed out that this substance should be fermented at least as quickly as glucose, and that this is not the case. The same criticism is valid against many of the 3-carbon compounds which have been proposed as intermediate products, including glyceraldehyde and dihydroxyacetone, both of which are slowly attacked by yeast, whilst dihydroxyacetone is also readily fermented by yeast juice prepared by maceration (Lebedev).

The pyruvic acid theory of fermentation. The universal presence of carboxylase in yeasts capable of producing alcoholic fermentation creates a strong presumption that the decomposition of pyruvic acid actually forms a stage in the alcoholic fermentation of sugars. The fact that the evolution of carbon dioxide from pyruvic acid commences instantly, whereas

there is a considerable delay in the case of glucose (Neuberg and Rosenthal, Biochem. Zeitsch. 1913, 51, 128) is interpreted to mean that the glucose undergoes a preliminary change which requires some time and results in the formation of pyruvic acid capable of immediate decomposition. Other explanations of this delay, which is by no means invariable, can, however, be given. A number of observations have also been made by Euler and his school which have led him to the same conclusion, that some intermediate product is formed before the production of alcohol and carbon dioxide.

Pyruvic acid has actually been isolated by Fernbach and Schoen (Compt. rend. 1913, 157, 1478) from the products formed by the alcoholic fermentation of sugar in the presence of chalk; but Kerb (Ber. 1919, 52, B, 1795), using pure cultures of yeast, was unable to confirm this observation.

The pyruvic acid theory of alcoholic fermentation (Neubauer and Fromherz, Zeitsch. physiol. Chem. 1911, 70, 326; Neuberg and Kerb, Zeitsch. Gärungsphysiol. 1912, 1, 114; Kostytshev, Zeitsch. physiol. Chem. 1912, 79, 130) involves three stages, exemplified by the following equations:—

- (i) $\text{C}_6\text{H}_{12}\text{O}_6 = 2\text{CH}_3\cdot\text{CO}\cdot\text{COOH} + 4[\text{H}]$;
- (ii) $2\text{CH}_3\cdot\text{CO}\cdot\text{COOH} = 2\text{CH}_3\cdot\text{CHO} + 2\text{CO}_2$;
- (iii) $2\text{CH}_3\cdot\text{CHO} + 4\text{H} = 2\text{CH}_3\cdot\text{CH}_2\cdot\text{OH}$

The products of decomposition of pyruvic acid by yeast being carbon dioxide and acetaldehyde, the production of alcohol from glucose by way of pyruvic acid must involve a process of reduction. That yeast possesses powerful reducing properties has long been known (philothion of Rey-Pailhade). These are shared by yeast juice and the other active preparations obtained from yeast, all of which are capable of reducing many aldehydes to alcohols and various colouring matters to their leuco-compounds, and are therefore supposed to contain a reducing enzyme or *reducase*. The intervention of this reducing enzyme of yeast in alcoholic fermentation was suggested in 1904 by Grüss (Zeitsch. ges. Brauwesen, 1904, 27, 689), and has since been supported by many workers, notably Palladin (Zeitsch. physiol. Chem. 1908, 56, 81), Kostytshev (numerous papers in Zeitsch. physiol. Chem. from 1912), and Lvov (1913). The attempts made by these investigators to show that in presence of reducible substances the fermentation of glucose was modified (Lvov; Kostytshev), or that the presence of glucose interfered with the reduction of other substances, were not conclusive. Neuberg, however (in a series of papers summarized in Ber. 1919, 52 B, 1677), has shown that in the presence of substances capable of combining with acetaldehyde the course of the fermentation is profoundly modified. For this purpose he employed normal sodium sulphite, which reacts with acetaldehyde according to the equation

In the presence of this salt, under the most favourable conditions, only about 30 per cent. of the sugar undergoes the normal fermentation, whilst the remaining 70 per cent. yields acetaldehyde, glycerol and carbon dioxide according to

the equation $C_6H_{12}O_6 = C_2H_4O + C_3H_8O_3 + CO_2$, or, including the sulphite,

The sulphite is best added after the fermentation has commenced, from 33–150 grams being used for 100 grams cane-sugar dissolved in 1–2.5 litres of water, and about 10–20 grams of yeast. Molecular proportions of acetaldehyde and glycerol are produced throughout the whole course of the fermentation, and the yield, referred to sugar, increases with the concentration of sulphite. Insoluble sulphites (Ca, Zn, Mg) can be used if the mixture is well agitated, and the process can also be carried out in faintly acid solution in the presence of acid potassium phosphate.

An enhanced production of acetaldehyde and glycerol had previously been observed by Neuberg and Färber (Biochem. Zeitsch. 1917, 78, 238), both with living yeast and maceration juice in presence of a number of alkaline salts, but the acetaldehyde found was not chemically equivalent to the glycerol. Under these circumstances, however, it has now been found that the acetaldehyde undergoes a Cannizzaro reaction, yielding alcohol and acetic acid, so that the fermentation in presence of alkalis proceeds as follows:—

One molecule of acetic acid is thus produced for every two molecules of glycerol. The yield of glycerol obtained in this way is not so high as in the presence of sulphite, amounting in the presence of sodium bicarbonate to about 35 per cent. of the theoretical (Neuberg and Hirsch, Biochem. Zeitsch. 1919, 100, 304). Neuberg explains the results obtained, on the general lines of the pyruvic acid theory, by supposing that the sulphite combines with the acetaldehyde and thus prevents its reduction to alcohol, the glycerol being formed by the action of the hydrogen thus rendered available on the precursor of pyruvic acid, which he assumes to be methylglyoxal. According to Neuberg and Kerb (Biochem. Zeitsch. 1913, 58, 158), the normal course of fermentation takes place according to the following equations:—

In the presence of sulphite or of alkalis a certain proportion of the aldehyde produced in (3) is withdrawn from the system so that reaction (4) is greatly diminished in rate and the end-products contain a large proportion of acetaldehyde and glycerol, the latter formed according to equation (2). Wo. Ostwald

(Biochem. Zeitsch. 1919, 100, 279; see also Neuberg, *ibid.* 289) has pointed out that the enhanced production of acetaldehyde would naturally follow on the removal of this substance from the sphere of action, the equilibrium being in this way constantly disturbed, so that this fact cannot in itself be regarded as a strict proof of the theory that pyruvic acid is an intermediate product in the normal course of fermentation. In view of the fact that in the modified fermentation, the acetaldehyde is produced at approximately the same rate as alcohol in the normal fermentation there can be little doubt that Neuberg's explanation is in this particular correct.

No definite experimental evidence of the participation of methylglyoxal in the process of fermentation has yet been obtained, and it is still doubtful whether Neuberg's equations represent the actual mechanism of the fermentation. It is possible that in the decomposition of glucose by way of pyruvic acid into alcohol and carbon dioxide, either the reducase combines with hydrogen and passes it on to the aldehyde or, alternatively, and more probably, that in presence of the reducing enzyme water is decomposed, the oxygen converting glucose, or some intermediate product obtained from it, into pyruvic acid, whilst the hydrogen reduces the aldehyde to alcohol as in Neuberg's equation (4). This reaction would be continuous as soon as a supply of aldehyde had been accumulated, but would not commence except in the presence of some acceptor for the hydrogen.

Much further evidence is required before any satisfactory conclusion can be arrived at with regard to this subject, and the facts must certainly be taken into account that two molecules of sugar are involved in the reaction, and that the products include hexosephosphate as well as alcohol and carbon dioxide.

Practically the possibility of producing a large proportion of glycerol from sugar by fermentation in presence of sulphite has been made the basis of a process of manufacture of this substance (the Protol process), which has been worked on such a scale as to produce a million kilos. of glycerol per month in a yield of 20–25 per cent. of the sugar employed (Connstein and Lüdecke, Ber. 1919, 52, B, 1385).

FERMENTATIONS PRODUCED BY BACTERIA.

Bacteria are capable of bringing about many fermentations which are strictly analogous to the fermentation of the sugars by yeast. Many species of bacteria are, however, much less restricted in their power of action, and decompose not only the simple hexoses and complex saccharides, but also the glucosides, the lower sugars, especially the pentoses and the corresponding alcohols including glycerol, as well as many organic acids. In addition to this, they also act upon nitrogenous compounds, and effect many oxidations and reductions. The chemical changes involved are of the most varied kind, and although they are in all probability brought about by enzymes, it is only in comparatively simple cases that the enzyme has been separated from the cell. In some cases, however, the enzymes pass into the surrounding medium, this being frequently the case with the various digestive enzymes, and possibly with the urease which

brings about the hydrolysis of urea into ammonium carbonate and water.

Interesting and important attempts have been made by Buchner to prepare extracts containing active enzymes from the bacteria of the lactic acid and acetic acid fermentations, by a process similar to that employed for yeast, but in both cases without success. He was able, however, to demonstrate the existence of such an enzyme in the cell by treating the organism with acetone, and showing that the dead and sterile material was still capable of converting sugar into lactic acid in the one case, and of oxidising alcohol to acetic acid in the other. Similar results have been obtained with a number of other bacteria.

Although the qualitative characteristics of the action of bacteria on many substances are well known and are largely used for purposes of identification and differentiation, comparatively little strictly quantitative work on the subject has been done, in which all the products derived from a known weight of a material have been estimated, and hence our knowledge of the chemistry of bacterial action remains very imperfect. Among the pioneers in this branch of the subject must be reckoned Fitz (who, however, often employed mixed cultures) and P. F. Frankland. The employment of mixed cultures is not entirely without justification, since many of the changes produced in nature by bacteria, such as putrefaction, are brought about by the combined or successive action of different organisms, some of which make use of the products of decomposition formed by others.

The chief types of fermentation produced by bacteria may be classified in much the same manner as those due to enzyme action, under the heads of (1) hydrolysis; (2) decomposition involving the rupture of a carbon chain; (3) oxidation; (4) reduction and deoxidation.

1. FERMENTATIONS BY HYDROLYSIS.

A large number of bacteria contain enzymes, which enable them to bring about processes of hydrolysis, whether of proteins or carbohydrates, and in some cases these are soluble and pass into the medium.

(a) **Liquefaction of gelatin.** Proteoclastic enzymes capable of liquefying gelatin are almost certainly present in all bacteria, but they are only excreted by certain organisms, and therefore afford a differential test often employed as an aid in identification. For this purpose, the organism is grown on nutrient gelatin, and note is taken as to whether the gelatin becomes liquefied. Prominent among the organisms which liquefy gelatin in this way are *B. fluorescens liquefaciens* (Flügge), *B. vulgaris* (Lehm. and Neum.), &c., whilst the intestinal organisms of the *B. coli* group are non-liquefiers. The liquefaction of gelatin is the first step in the hydrolysis of this substance, and is often followed by a more deep-seated decomposition of the resulting simpler compounds, which is discussed later on under the heading of *Putrefaction*. Some organisms only bring about the liquefaction of gelatin when grown in air, but do not liquefy in it an atmosphere of hydrogen or nitrogen, although growth takes place.

(b) **Hydrolysis of polysaccharides and glucosides.** It seems probable that most bacteria

resemble yeasts in the fact that, when brought into contact with polysaccharides, they do not ferment them directly, but first hydrolyse them and then ferment the resulting simple sugars; and the same thing is true of the glucosides. In most cases no strict proof of this has been brought, but in some the hydrolysis has been actually demonstrated. Thus Bertrand and Weisweiler (Ann. Inst. Pasteur, 1906, 20, 977) found that the *B. bulgaricus* (Grig.) hydrolysed milk sugar before producing lactic acid from it, and were able to prove the existence of glucose and galactose in the partially fermented solution. The determination of the fermentability or non-fermentability of the di- and tri-saccharides, starch, dextrin, inulin, and many glucosides, is now largely employed for the identification of bacteria, especially those of the *B. coli* group and the *Streptococci*. It follows from the foregoing that what is being tested for in such cases is most probably the presence or absence of the ferment requisite for the hydrolysis in question, e.g. invertase by cane sugar, maltase by maltose, lactase by lactose, β -glucosidase by many glucosides, such as saligenin, amygdalin, &c.

The presence of the hydrolytic ferment is rendered evident by the subsequent fermentation of the resulting simple sugars, &c., with production of acid or evolution of gas or both. The efficacy of the test, therefore, depends on the ability of the organism to ferment at least one of the products of the hydrolysis.

(c) **The ammoniacal fermentation of urea.** The waste nitrogen of the animal body is excreted in the urine, chiefly in the form of urea $\text{CO}(\text{NH}_2)_2$, uric acid $\text{C}_5\text{H}_4\text{O}_3\text{N}_4$, allantoin $\text{C}_4\text{H}_6\text{O}_3\text{N}_4$, and hippuric acid

In the urine of man, about 30 grams of urea are passed per diem, along with 0.7 gram of uric acid, and very small amounts of hippuric acid; whilst the urine of graminivorous animals contains comparatively large amounts of urea and hippuric acid (Liebig, 1829), the urine of a cow containing 18 grams of urea and 16 of hippuric acid per litre. On the other hand, the nitrogenous waste of birds and snakes is excreted almost entirely in the form of uric acid. The conversion of the nitrogen of these substances in the soil back into ammonia, which is then rendered available for plants by nitrifying organisms, is of vast importance, as it is in this way that the nitrogen balance of the soil is maintained, practically the whole nitrogen of natural manures being present in these forms.

When urine, which is normally sterile and acid in reaction, is exposed to air, it becomes alkaline, the urea being converted into ammonium carbonate:

This change was observed at a very early date, and was ascribed by Liebig, in accordance with his theory of fermentation, to the presence of decomposing mucus from the bladder. About 1860, however, it was established by Pasteur (Compt. rend. 1860, 50, 849), his pupil, van Tieghem (*ibid.* 1861, 52, 210; 1864, 58, 210), and Müller (J. pr. Chem. 1860, 81, 452), that the decomposition was produced by a micrococcus which was termed *Torula ammoniacale* by

Pasteur, and later *Micrococcus ureæ* by Cohn. It has since been found, as the result of numerous researches by Flüge, Heraus, Warington, Leube, Beyerinck, and especially Miquel (literature quoted in article by Miquel in Lafar, *Technische Mykologie*, iii. 71), that a large number of organisms have the power of producing this change. More than thirty varieties have been described by Miquel alone, who has also found that these organisms occur freely in water, air, and soil, the cocci being about twice as frequent as the bacilli, whilst 1-2 p.c. of the organisms of the Paris water, air, and cultivated soil belong to this class. The most characteristic and commonly occurring coccus is that originally discovered by Pasteur, now known as *Urococcus van Tieghemi* (Miquel), which is a small diplococcus, and grows well on ordinary media, not liquefying gelatin. In presence of urea, the growth on solid media becomes surrounded by dumb-bell-shaped crystals, which are insoluble in water, and consist of the phosphates and carbonates of calcium, precipitated from the medium by the ammonia produced. This is a very characteristic phenomenon, and renders it easy to detect not only this organism but any urea ferment among a number of organisms which do not attack urea. The organism readily decomposes as much as 4-4.5 p.c. of urea in the medium, but is very susceptible to antiseptics.

The most energetic decomposition of urea is brought about by the *Urobacillus Pasteurii* (Miquel) isolated from sewage. This is a motile, sporing bacillus, which grows well in alkaline broth, which it renders viscid and ropy. It ferments completely as much as 13 p.c. of urea in the medium, and has been observed to decompose 3.3 grams of urea per hour per litre of culture.

As early as 1876, Musculus (Compt. rend. 1874, 78, 132; 1876, 83, 333) found that the slimy urine of patients suffering from cystitis, and probably infected by the foregoing urobacillus, contained a soluble ferment which could be precipitated by alcohol and was capable of converting urea into ammonium carbonate in the absence of bacteria. Pasteur and Joubert, on the other hand, maintained that this action was due to the presence of an organism (Compt. rend. 1876, 83, 1).

The question of the existence and properties of this enzyme has been studied by many investigators (Leube, Lea, Beyerinck, Miquel, Moll) with somewhat discrepant results, ascribed by some to the unstable character of the enzyme. It can hardly, however, be considered as definitely proved that the enzyme has been obtained free from bacteria. According to Miquel, it can readily be obtained in solution by inoculating alkaline beef broth containing urea with one of the urea-fermenting organisms, and, after some time, filtering through a biscuit porcelain candle. The liquid is then sterile and capable of decomposing as much as 100-120 grams of urea per litre per hour at 48°. Its activity is greatly increased by cane sugar and glycerol, and is very readily inhibited by antiseptics. It may be precipitated by the addition of 2 volumes of alcohol. Musculus employed a turmeric paper moistened with a solution of the enzyme as a test for urea, the liberated ammonia producing a brown colour, and Miquel has proposed the use of solutions of the enzyme for

the quantitative estimation of urea as ammonia. On the other hand, bacteria isolated from the root tubercles of the soya bean, which have a well-marked power of hydrolysing urea, do not yield an active filtrate (Jacoby, *Biochem. Zeitsch.* 1916, 74, 109). A very powerful urease exists in the soya bean and many other seeds (p. 140).

(d) **The fermentation of uric acid.** Uric acid readily undergoes a combined bacterial oxidation and hydrolysis, but little is known as to the nature of the bacteria which produce the change (Sestini, *Gazz. chim. ital.* 1889; Gérard, *Compt. rend.* 1896, 122, 1019; 123, 185; Ulpiani, *Atti Lincei*, 1903, 12, 236). It seems probable that urea is first produced and then further hydrolysed:

(e) **The fermentation of hippuric acid.** Van Tieghem (*Compt. rend.* 1864, 58, 210) showed that the same micrococcus which fermented urea also effected the hydrolysis of hippuric acid into benzoic acid and aminoacetic acid, into which it is also converted by acids:

It has since been found that more than one of the urea-fermenting organisms produce this change (Rattone and Valenta, *Arch. Scienc. mediche*, 1886, 10, 311). In the soil, the aminoacetic acid then probably undergoes one of the characteristic changes described under *Putrefaction*, its nitrogen being liberated as ammonia.

2. FERMENTATIONS BY DECOMPOSITION ACCOMPANIED BY THE RUPTURE OF A CARBON CHAIN.

The chief chemical characteristic of this form of fermentation is that it involves the rupture of the carbon chain of the fermentable substance, the products being, as a rule, substances containing a smaller number of carbon atoms than the original compound. In many cases, however, a secondary synthesis occurs, and compounds are then found among the products containing more carbon atoms in the molecule than the original substance, the best known example of this being the production of butyric acid from glycerol.

As regards the nature of the changes produced, the same intramolecular oxidation and reduction is observed as characterises the alcoholic fermentation of sugar. Carbon dioxide is very frequently evolved, and this is often accompanied by free hydrogen, less frequently by marsh gas. The hydrogen thus formed is capable of bringing about the reduction of many substances such as nitrates, amino-acids, &c., which may be present in the medium, and thus modifying the result. In many cases in which no gas is evolved, formic acid is produced in considerable quantity, and this substance is sometimes found in comparatively small amount, even when carbon dioxide and free hydrogen have been evolved. The production of ethyl alcohol is also a feature of common occurrence, and methyl, propyl, isopropyl and *n*-butyl alcohols have all been observed as well as acetone, acetylmethylcarbinol, and butylene-glycol. Among the other products, lactic acid, which has the same empirical formula as glucose, is one of the most frequent. In some cases,

the conversion of a sugar into lactic acid is almost quantitative, whilst in others this acid forms only a small proportion of the whole product. Acetic acid, which also has the same empirical formula as glucose, is also a common product, and is sometimes accompanied by propionic and other of the fatty acids. Characteristic of one type of fermentation is the production of butyric acid, accompanied by more or less butyl alcohol. An almost invariable product of the bacterial fermentation of sugars and alcohols is succinic acid, probably in part derived, as in alcoholic fermentation, from the decomposition of amino-acids.

Although bacteria are much less specific in their power of fermentation than the yeasts, they nevertheless display great sensitiveness to small changes in chemical composition and configuration. Thus many organisms are known which attack mannitol, but not the stereoisomeric dulcitol, and similar relations are not uncommon.

Since a single species of bacterium may attack a very large number of different compounds, and the same compound may be decomposed in several distinct ways by different organisms, no very satisfactory classification of these fermentations can be effected, and they are best grouped according to the most characteristic of the products.

They will be briefly summarised here under the following heads:—

(a) **The true lactic fermentation.** In this decomposition, lactic acid is almost the sole product, the change proceeding practically in accordance with the equation:

The spontaneous souring and clotting of milk have long been known to be due to the production of lactic acid, which causes the precipitation of the caseinogen. The process was at first ascribed to the action of the caseinogen itself, which was regarded as an enzyme (Boutron; Charlard and Fremy). The souring of milk, even after it had been heated and protected from the access of air-borne germs (due to the presence of sporing bacilli), played a part of some importance in the history of the development of the theory of fermentation, and was cited by the supporters of Liebig's view, that fermentation was not due to living organisms (Gerhardt). The existence of a lactic acid producing organism was first definitely established by Pasteur (Compt. rend. 1857, 45, 813; 1858, 47, 224; Ann. Chim. Phys. 1858, [3] 52, 404), and was confirmed by Lister, in 1877, who succeeded in preparing a pure culture of an organism capable of souring milk by diluting soured milk to such an extent that a drop only contained a single organism, adding a single drop of this to sterile milk, and repeating the process several times. Since then the question has been the subject of an enormous number of investigations on account of its technical importance (see Lafar, Technische Mykologie, vol. 2; Henneberg, Gärungsbakteriologisches Praktikum, Berlin, 1909; Orla-Jensen, The Lactic Acid Bacteria, Copenhagen, 1919), and only a few of the most interesting results can be mentioned here.

It has been found that all liquids containing saccharine matter are liable to become sour,

owing to the production of lactic acid, when they are exposed to the air. The organisms capable of producing this change are extremely numerous, and the nature of the flora developed in any particular case depends on the kind of sugar present and the character of the nitrogenous nutriment available. Thus the lactic acid organism of milk is capable of fermenting milk sugar, whilst that of beer cannot attack this substance. The chief lactic acid organisms have been isolated from milk, beer, distiller's mash, baker's yeast, dough, sauerkraut, and similar materials. They are all non-motile, and do not form spores.

Lactic acid is manufactured by the action of a bacillus on various saccharine solutions prepared from barley, maize, potatoes, &c., the starch being first hydrolysed by acid or malt, and the fermentation carried on in the presence of chalk. The organism chiefly employed for this purpose is the *B. Delbrücki* (Leichmann) identical with the *B. longissimus* (Lafar), which forms long cells (3–7 μ) and grows well at 46°–47° in unhopped wort, distiller's mash, and yeast water, but not in milk or beer. It converts glucose, cane sugar, and maltose into lactic acid, and produces neither volatile acids nor alcohol. This bacillus also occurs in the unsterilised mash employed by distillers, where it is allowed to grow in order to render the liquid sufficiently acid to prevent subsequent infection by harmful bacteria during the fermentation by yeast.

A second important organism of this class is the *Saccharobacillus pastorianus* (van Laer), which frequently invades beer wort and renders the beer sour. A closely allied variety is employed in the manufacture of the Berlin white beer to impart a certain desired degree of acidity. This organism, however, produces small amounts of alcohol, acetic acid, and formic acid. It forms long cells often united to tangled threads.

The souring of milk is a very complex phenomenon, in which many bacteria belonging to different types take part, the predominant organism varying with the temperature at which the milk is preserved. The most commonly occurring organism appears to be the *Streptococcus lactis* (Kruse), formerly known as *Bact. Güntheri* (Lehmann and Neumann), *B. lactis acidi* (Kruse), *B. acidi paralactici* (Kozai). This organism, of which there appear to be many races or varieties, forms round or oval cells, grows very feebly on nutrient gelatin, and is positive to Gram's staining reaction. It converts glucose almost completely into *D*-lactic acid, traces of volatile acids being also formed. Thus Weigmann (Jahrsb. Molk. Kiel, 1890–91, 25; 1891–92, 24), and Leichmann (Milchzeit. 1896, 25, 67) have found that in milk the lactic acid produced amounts to 89–98 p.c. of that calculated for the complete conversion of the milk sugar fermented into this substance.

Another organism, which has attained a certain degree of notoriety from its use for the preparation of sour milk as an article of diet, was found by Massol in Yoghurt, a sour milk used as food in Bulgaria. It is known as *B. bulgaricus* (Grigoroff), and forms long cells which grow feebly on agar, forming tangled masses of delicate threads. Its action on milk has been very thoroughly investigated by Bertrand and Weisweiler (Ann. Inst. Pasteur,

1996, 20, 977). It has practically no action on the fat, and only hydrolyses a very small proportion of the caseinogen. On the other hand, it hydrolyses the milk sugar almost completely, and ferments the resulting galactose and glucose, forming lactic acid, containing an excess of the *d*-acid, and amounting to about 92 p.c. of the hexoses fermented, about 2 p.c. each of acetic and succinic acids, traces of formic acid, and no alcohol.

The *B. acidi lactici* of Hueppe, which was at one time thought to be the chief organism concerned in the souring of milk, is not of such common occurrence as was formerly believed, and is more closely related to the following group of organisms than to the true lactic acid bacilli.

(6) The modified lactic fermentation, in which lactic acid is always accompanied by a considerable proportion of other substances.

Under this head may be classed, along with others, the changes produced in carbohydrates and alcohols by the very varied and complex group of intestinal bacteria, of which *B. coli communis*, *B. typhi*, &c., are well-known representatives. This group of organisms has received a very large amount of attention from bacteriologists for several reasons. In the first place, the group includes a large number of pathogenic organisms, the detection of which is of the utmost importance. In the second place, owing to the universal and abundant occurrence of *B. coli communis* and allied organisms in the intestine, from which they pass into sewage, the presence of these organisms in water intended for consumption is regarded as a sign of pollution by sewage, and the examination for the presence of such organisms is part of the routine of a bacteriological examination of water. For these reasons, the chemical bacteriology of this group has been closely studied, especially on its qualitative side. These organisms possess the common characteristic of growing well at 37°–40°, aerobically in presence of bile salts (the sodium salts of taurocholic and glycocholic acids), and are thus differentiated from a great number of the commoner organisms of air, water, and soil, the growth of which is inhibited by these salts. In addition to this, they decompose glucose with production of acid, or acid and gas. The further chemical differentiation of these organisms depends on their behaviour to the various simple sugars and alcohols, such as the pentoses, hexoses, methylpentoses, glycerol, pentitols, and hexitols and to the complex saccharides and glucosides, to which reference has already been made.

They are all non-sporing bacilli, which either

do not liquefy gelatin at all or do so very slowly, are facultative anaerobes, and are negative to Gram's staining test.

They can be distinguished independently of their chemical action by their physiological effects, notably by the agglutination test of Widal. This depends on the fact that each species, and even variety, of organism, when injected into a living animal, gives rise, in the blood serum of that animal, to a substance usually highly specific, termed an agglutinine, which is able to cause clumping and aggregation of the living bacteria when added even in very dilute solution (1 in 10,000–100,000) to a suspension of the organisms. This method affords a very valuable check on the chemical reactions, and its use has shown that in the main these reactions are reliable as a means of identification, although very considerable variations can undoubtedly be produced in the chemical reaction by artificial means, and very probably occasionally occur in nature.

Organism	Glucose	Lactose	Cane sugar	Mannitol	Dulcitol	Arabinose	Indole	V. & P.
<i>B. lactis aerogenes</i> (Esch.)	AG	AG	AG	AG	—	AG	—	+
<i>B. acidi lactici</i> (Hüppe)	AG	AG	—	AG	—	AG	+	—
<i>B. coli communis</i> (Esch.)	AG	AG	—	AG	AG	AG	+	—
<i>B. Neapolitanus</i> (Emmerich)	AG	AG	AG	AG	AG	AG	+	—

<i>B. dysenteriae</i> (Shiga)	A	—	—	—	—	—	—	—
<i>B. pyogenes faecialis</i> (Passet)	A	A	A	A	A	A	+	—

The above table shows the qualitative reactions of a few of the best-defined of these organisms; AG meaning acid and gas; A, acid only; and — no change. For the sake of completeness, the production of indole from proteins (*see Putrefaction*) is included, as well as Voges and Proskauer's test for the production of acetyl-methylcarbinol (a pink colour and green fluorescence when caustic soda is added to a cultivation of the organism in glucose broth), as these are, at present, considered to be valuable tests.

The nature of the action of certain of these organisms on the carbohydrates and higher alcohols has been examined by many authors from various points of view, particularly as regards the nature of the lactic acid formed under various conditions (Péré, Ann. Inst.

Pasteur, 1893, 7, 737; 1898, 12, 63), the nature of the gas evolved (Theobald Smith, Cent. Bakt. Par. 1895, 18, 1; see Keyes, J. Medical Research, 1909, 21, 69, where the literature is quoted), and the quantitative relations of the various products (Harden, Chem. Soc. Trans. 1901, 612; J. Hygiene, 1905, 5, 488). The following are the results obtained by Harden for the action of an organism of the *B. coli* group on glucose, fructose, and mannitol, and for *B. typhosus* on glucose. The coli-like organism employed in these experiments fermented cane sugar and not dulcitol, and would therefore now be regarded as *B. coscoroba*. The products are expressed in percentages of the sugar fermented and also in terms of the number of carbon atoms of the sugar molecule represented by the product. The cultivations were all carried out in an atmosphere of nitrogen, to avoid atmospheric oxidation, and in presence of chalk to neutralise the acid produced, and thus to obtain a more complete utilisation of the sugar present. The carbon dioxide evolved by the action of the acid on the chalk has, in every case, been subtracted. The products in all cases were qualitatively the same.

The characteristics of the fermentation of glucose by this coli-like organism are that the lactic acid forms less than half of the total products, that alcohol and acetic acid are produced in almost molecular proportions, and that the ratio of hydrogen to carbon dioxide by volume is almost 1. *B. typhi* produces a similar change, with the exception that no gas is formed but an equivalent amount of formic acid is produced. Since *B. coli* and the allied *B. coscoroba* have the power of decomposing formates with the production of equal volumes of carbon dioxide and hydrogen, this would indicate that most probably formate is produced in all cases, but decomposed by *B. coli* and its allies, and left untouched by *B. typhi*. This is confirmed by the fact that small quantities of formic acid are often produced by the gas-forming organisms, and are increased when the cultivation is carried out under pressure.

The production of acetic acid and alcohol from glucose in approximately molecular proportions is characteristic of a large number of the organisms of this group, *B. coli communis*, *B. acidi lactici*, *B. coscoroba*, *B. Neapolitanus*, and *B. typhi*, all presenting this peculiarity (Harden).

The case of mannitol is interesting, as the effect of the change in constitution from glucose to mannitol is that the production of alcohol and carbon dioxide is almost doubled, whilst that of acetic and lactic acids is greatly diminished. Other types of intestinal organisms, for example, the various types of dysentery bacilli, which are much more restricted in their power of fermentation, produce somewhat similar effects on glucose, but in some cases much more lactic acid is produced, whilst alcohol and acetic acid are formed in a different ratio. Such types of fermentation appear to be intermediate between the true lactic fermentation and that just described.

Some light has been thrown on the mechanism of this type of fermentation by the observation that when *B. coli communis* is cultivated on nutrient agar in presence of sodium chloroacetate, a strain is obtained, probably by selection, which no longer produces gas in glucose-

peptone-water (Penfold, Proc. Roy. Soc. Med. 1911, 97). Quantitative examination of the products formed by such an organism (Harden and Penfold, Proc. Roy. Soc. 1912, B, 85, 415; Grey, *ibid.* 1914, B, 87, 461) shows that formic acid is still produced from glucose and mannitol, but is not decomposed. At the same time, the amount of lactic acid produced from glucose is considerably increased at the expense of the alcohol and acetic and formic acids, whereas in the case of mannitol there is no change in this respect. It seems probable, therefore, that an intermediate product is first formed, from which lactic acid, on the one hand, and alcohol, together with acetic, formic, and probably succinic acids, on the other, are produced by the aid of two independent enzymes (Grey). The production of the intermediate compound from mannitol probably involves a special enzyme, but after this stage the remainder of the change is in all probability carried on by the same enzymes as are operative in the decomposition of glucose. As regards the formation of formic acid and alcohol and acetic and succinic acid, it is possible that formic acid and acetaldehyde in molecular proportions are the primary products (see Grey, Bio-Chem. J. 1913, 7, 359), but it is also possible that formic acid is produced independently of the aldehyde, and that the acetaldehyde is then partly reduced to alcohol and partly converted into an equimolecular mixture of alcohol and acetic acid, the reduction to alcohol being much greater with mannitol than with glucose. Succinic acid is also probably derived from acetaldehyde.

The occurrence of acetaldehyde as an intermediate product in this and various other types of bacterial fermentation has been demonstrated by Neuberg and Nord (Biochem. Zeitsch. 1919, 96, 133) by the use of the "fixation" method. When the fermentation is carried out in presence of sodium sulphite a considerable amount of acetaldehyde is fixed and can be isolated from the reaction products.

Corroborative evidence of this general scheme has been afforded by the further experiments of Grey (Proc. Roy. Soc. B, 1919, 90, 75, 92; 1920, 91, 294; 1921, 92, 135), who worked with an emulsion of bacteria in a solution of glucose, and estimated the amount of change at very short intervals. It was thus found that during the first period after the introduction of the bacteria a very large proportion of them died, and that the chief products formed at this stage were alcohol and acetic, formic and succinic acids. Growth then commenced, and a large proportion of the sugar was converted into a non-reducing carbohydrate. This period was followed by the almost exclusive formation of lactic acid and the disappearance of this carbohydrate.

Production of butylene glycol. Several species of intestinal bacteria differ in a very marked manner from the foregoing types, inasmuch as they produce large quantities of β -butylene glycol $\text{CH}_3\cdot\text{CH}(\text{OH})\cdot\text{CH}(\text{OH})\cdot\text{CH}_3$, along with small quantities of the corresponding ketoalcohol, acetylmethylcarbinol

This latter substance, in presence of oxygen and alkali, gives a characteristic colour reaction with proteins, known as Voges and Proskauer's re-

action. The following quantitative results have been obtained with *B. lactis aërogenes* (Escherich) and similar ones are given by *B. cloacæ* (Jordan), (Harden and Walpole, Proc. Roy. Soc. 1906, B, 77, 421; Walpole, *ibid.* 1911, B, 83, 272; Thompson, *ibid.* 1912, B, 84, 500; Harden and Norris, *ibid.* 1912, B, 84, 492):—

	Glucose		Mannitol	
	P.c.	Catms.	P.c.	Catms.
Alcohol	18.2	1.43	32.5	2.57
Acetic acid . . .	8.6	0.2	2.1	0.12
Lactic acid . . .	9.1	0.55	8.6	0.52
Succinic acid . .	4.5	0.27	2.8	0.17
Formic acid . . .	1.7	—	1.6	—
Carbon dioxide .	35.2	1.21	35.5	1.53
Hydrogen	0.01	—	—	—
Butylene glycol (by dif.)	(22.7)	1.72	(16.9)	1.19
Vol. ratio of H_2/CO_2	0.52	—	0.79	—

This type of fermentation, therefore, is characterised alike by the large production of alcohol and the formation of butylene glycol. As in the case of the coli-like organisms, the alcohol produced from mannitol is approximately twice as much as from glucose. The ratio of H_2/CO_2 is also much lower than is observed with the coli-like organisms.

Butylene glycol may be regarded as a reduction product of acetaldehyde

and is actually formed from acetaldehyde by *B. lactis aërogenes* (Harden and Norris, Proc. Roy. Soc. 1912, B, 84, 492). Its production, therefore, falls readily into Grey's scheme of fermentation given above.

Many bacilli not of intestinal origin also give rise to similar products. Thus, Tate (Chem. Soc. Trans. 1893, 1263) found that an organism derived from ripe pears fermented glucose and mannitol to alcohol, acetic, formic, succinic, and *l*-lactic acids, and made the interesting observation that rhamnose, a methylpentose

was decomposed by the same organism, but yielded no alcohol or formic acid, the products consisting of acetic, succinic, and *dl*-lactic acids. In no case did the sum of the products obtained by Tate approach the weight of the material fermented, the discrepancy being from 20–60 p.c. Again, the pneumobacillus of Friedländer (*B. pneumoniae*) was found by Grimbart (J. Pharm. Chem. 1895, [6] 2, 529) to yield 36–58 p.c. of *l*-lactic acid from glucose and mannitol, along with alcohol, and acetic acid; whilst Frankland, Frew, and Stanley (Chem. Soc. Trans. 1891, 253) obtained no lactic acid, but only alcohol, acetic, succinic, and formic acids and a large volume of carbon dioxide and hydrogen, the products from mannitol being in the ratio

whilst relatively less alcohol was formed from glucose. The discrepancy between these results probably points to imperfect identification of the organism on the part of one or other of these observers or else to a wide difference in chemical action between different varieties of the same organism.

(c) **The butyric fermentation.** Normal butyric acid and normal butyl alcohol are formed from carbohydrates, higher alcohols, glycerol, lactic acid, and other compounds by the action of many bacteria, and, in addition to this, organisms are also known which produce butyric acid from proteins.

The butyric fermentation, well known as a means of preparing butyric acid by the inoculation of a glucose solution with decaying cheese, was first ascribed to a specific organism by Pasteur (1861). He named this organism the *Vibron butyrique*, and made the highly important observation that its motility was destroyed by the presence of oxygen, a phenomenon which led to the recognition of the existence of anaërobic organisms and to Pasteur's celebrated theory, 'La fermentation est la vie sans air.' The subsequent researches of Prazmowski, Grüber, Botkin, Beyerinck, Flügge, and many others, added to the *Vibron butyrique* of Pasteur as producers of butyric acid a large number of species of varying forms and properties. The bacteria which produce butyric acid from carbohydrates are characterised by an extreme tendency to variety and multiplicity of form. Moreover, they all form spores, many of which are extremely resistant to heat, and these facts, coupled with the difficulty of isolating pure cultures under anaërobic conditions, have given rise to the greatest confusion in the literature of the subject, and to considerable difficulty in the identification of species.

The study of the anaërobic bacteria obtained from wounds, carried out with an improved technique, has, however, resulted in a considerable advance in our knowledge of this group of organisms (see Report to Medical Research Committee, McIntosh, 1917, and Reports of the Committee upon Anaërobic Bacteria and infections, 1918, 1919, where the literature is quoted), although the chemical changes produced by them have not yet been thoroughly worked out.

These organisms are best classified according to their morphology and chemical action, as shown in the following table (Report of Anaërobe Comm. 1919, 47):—

- (a) Central or subterminal spore.
 - A. Both proteolytic and saccharolytic properties.
 1. Proteolytic properties predominating. (Coagulated serum and gelatin are liquefied.)
 - B. sporogenes*; *B. parasporogenes*; *B. hisolyticus*; *B. aerofetidus*; *B. bifementans*.
 2. Saccharolytic properties predominating. (Serum not liquefied. Gelatin liquefied.)
 - B. Welchii*; *Vibron septique*; *B. charvoei*; *B. œdematiens*; *B. botulinus*.
 - C. Saccharolytic but no proteolytic properties. (Neither serum nor gelatin liquefied.)
 - B. fallax*; *B. butyricus*; *B. multifementans tenalbus*.
- (b) Oval terminal spore.
 - C. Saccharolytic but no proteolytic properties.
 - B. tertius*.
 - D. Neither saccharolytic nor proteolytic properties.
 - B. cochlearius*.
- (c) Spherical terminal spore.
 - B. Slight proteolytic but no saccharolytic properties. (Serum not liquefied. Gelatin liquefied.)

B. tetani.

C. Saccharolytic but no proteolytic properties.

B. tetanomorphus; *B. sphenoides.*

The proteolytic group ((a) A. 1) comprises a number of different organisms, the chief chemical action of some of which is the decomposition of proteins and amino-acids (*B. histolyticus*; see under *Putrefaction*). *B. sporogenes* (Metchnikoff) occurs in animal excreta and in soil. It is a large motile bacillus, which readily forms spores. These are very resistant to heat, and are not destroyed when the liquid in which they are suspended is boiled for many minutes. It decomposes glucose in a similar manner to *B. Welchii* (see below), but from milk it produces valeric and caproic, in addition to butyric and acetic, acids (Wolf and Telfer, *Biochem. J.* 1917, 11, 197).

The non-proteolytic group ((a) A. 2) includes several organisms capable of setting up pathogenic conditions in man and other animals, more particularly gas-gangrene. *B. Welchii*, also known as *B. aerogenes capsulatus* (Welch), *B. perfringens* (Veillon and Zuber), and *B. enteritidis sporogenes* (Klein), occurs in soil, and is also regularly found in cow-dung, from which it passes into milk. It is a frequent infection of wounds, and is pathogenic to guinea-pigs. It ferments the sugars and starch, but not mannitol or cellulose, and attacks glycerol. Both from milk and glucose large quantities of butyric and acetic acid are formed, along with carbon dioxide and hydrogen and a non-volatile acid (presumably lactic acid) (Wolf and Telfer, *Biochem. J.* 1917, 11, 197). This organism, which is one of those responsible for the production of gas gangrene in cases of wound infection, when grown under suitable conditions produces a toxin, from which a potent antitoxin can be prepared (Bull).

Among other organisms in this group are the *Vibrio septique* (Pasteur and Joubert) or bacillus of malignant oedema, which is largely responsible for the gas-gangrene resulting from infected wounds; *B. chauvoci*, the bacillus of black-quarter (Rauschbrand) an impure culture of which was described by Grassberger and Schattenfroh as the non-motile butyric acid bacillus, *B. botulinus*, which has been found in certain cases of food-poisoning and *B. oedematis*. None of these has yet been carefully examined from the chemical point of view.

Another important anaërobe (Group (a) C) is *Bacillus butyricus*. This comprises Pasteur's original *Vibrio butyrique* and the organisms previously known as *B. amylobacter* (Grüber), the motile butyric acid bacillus of Grassberger and Schattenfroh, *Clostridium butyricum* (Prazmowski), *Granulobacter saccharobutyricus* (Beyerinck), *B. saccharobutyricus* (Klecki). It is found in soil, water, and cheese, but less frequently in milk, and is typically a short bacillus with rounded to almost pointed extremities. It ferments glucose, saccharose, lactose, starch, and glycerol with production of butyric and lactic acid and evolution of carbon dioxide and hydrogen (Grassberger and Schattenfroh, *Arch. Hyg.* 1902, 42, 219).

B. tetani (Group (c) B) is highly pathogenic to animals, producing tetanic convulsions (lock-jaw) and death. Several distinct types of this

organism occur, which can only be distinguished by their serological reactions. It forms a powerful toxin in broth, which is used for the preparation of an antitoxin. It does not ferment carbohydrates, and has a slight action on meat, without producing putrefaction.

In some detached instances examinations of chemical products have been made with cultures of doubtful purity. Thus the *B. butylicus* of Fitz (Ber. 1878, 11, 49), obtained from hay infusion, gave the following results with glycerol, mannitol, and invert sugar:—

	Glycerol	Mannitol	Invert sugar
	p.c.	p.c.	p.c.
<i>n</i> -Butyl alcohol .	8.1	10.2	0.5
<i>n</i> -Butyric acid .	17.4	35.4	42.5
Lactic acid .	1.7	0.4	0.3
Succinic acid .	—	0.01	trace
Trimethylene glycol	3.4	—	—

The fermentation of glycerol by this organism has been recommended by Fitz, and subsequently by Freund, as a convenient method for the preparation of *n*-butyl alcohol and of trimethylene-glycol.

Buchner and Meisenheimer (Ber. 1908, 41, 1410), also working with the *B. butylicus* of Fitz, obtained analogous results, as did also Perdrix (*Ann. Inst. Pasteur*, 1895, 5, 286) with the *B. amylozyma* (Perdrix).

An organism termed *B. amylobacter pectinovorum*, the exact position of which in the classification is not clear, has been employed for the commercial production of acetone and *n*-butyl alcohol from maize (Fernbach and Strange, 1912, Eng. Pat. 21073; Weizmann, 1915, Eng. Pat. 4845). The chemical side of the process has been described by Reilly and his colleagues (*Biochem. J.* 1920, 14, 229), and by Speakman (*J. Biol. Chem.* 1920, 41, 319; 43, 401), and the necessary plant by Speakman (*J. Soc. Chem. Ind.* 1919, 38, 155 T). A 6.5 p.c. mash of maize is employed and the organism produces from the maize 7 p.c. of acetone and 16 p.c. of butyl alcohol, together with small amounts of acetic and butyric acids and a non-volatile acid. A large volume of gas, consisting of carbon dioxide and hydrogen, is evolved, 100 lbs. of maize yielding 341 cubic feet or 40.7 p.c. of CO₂, and 209 cubic feet or 1.1 p.c. of H₂. The acetone and butyl alcohol are distilled off and purified by fractional distillation. In the presence of calcium carbonate very little acetone and butyl alcohol are formed, the products consisting of acetic acid, butyric acid, and gas. The yield of acetone is greatly increased by the addition of acetic acid and that of butyl alcohol by butyric acid, and it seems probable that in the normal fermentation acetic and butyric acids are intermediate products.

The occurrence of acetone among the products of carbohydrate fermentation had previously frequently been recorded (see Schar-dinger, *Centr. Bakt. Par.* 1905, ii. 14, 772). A considerable yield was obtained by Schar-dinger by the action of the spore-forming *B. mace-rans* on potatoes and plums, alcohol and acetic and formic acid being also produced, but no lactic or butyric acid.

The production of butyric acid and butyl alcohol from glycerol and lactic acid by means of the butyric bacillus is of great theoretical

importance, since it involves a synthesis from the primary products of the rupture of the carbon chain. It has been suggested by many observers that one of these is acetaldehyde from which the butyric acid and butyl alcohol could readily be formed by an aldol condensation, followed by reduction or a combined oxidation and reduction:

That lactic acid is not necessarily an intermediate product in the butyric fermentation, as suggested by Buchner and Meisenheimer, is shown by the fact that certain organisms will not ferment lactic acid in this way, although they produce butyric acid from sugars.

Neuberg and Arinstein (Biochem. Zeitsch. 1921, 117, 269) have applied the sulphite 'fixation' method to the fermentation of sugar produced by *B. butylicus fitzianus*, and have found that autaldehyde is produced. Neither autaldehyde itself, however, aldol nor pyruvic acid yielded butyric acid when treated with the organism, whereas the aldol of pyruvic acid

gave a good yield, and they therefore consider that this substance is produced as an intermediate product.

The detection of anaërobic butyric acid bacteria in milk (Klein's *B. enteritidis sporogenes*) forms part of the routine examination of milk for faecal contamination, and is carried out by heating the milk to 80° for 10 minutes, to destroy all vegetative forms and leave only the resistant spores, and incubating measured quantities of the liquid anaërobically. A characteristic separation of the caseinogen in flocculi, accompanied by a smell of butyric acid and the development of Gram-positive rods pathogenic to guinea-pigs, indicates the presence of the bacillus.

(d) **The fermentation of cellulose and bacterial production of methane.** The bacterial fermentation of cellulose takes place on a vast scale in the soil, especially in marshy places, and appears to be one of the chief processes by which the cellulose of plant remains is resolved into simpler products. It is to this decomposition that is due the evolution of an inflammable hydrocarbon from marshes, which was first recognised by Volta in 1776. A similar decomposition occurs in the stomachs of graminivorous animals (Tappeiner) and in heaps of manure, wool, refuse, &c. The fact that cellulose was capable of undergoing fermentation was first observed by Mitscherlich in 1850, who ascribed the gradual disappearance of the cell walls of potatoes left in water for several days to the action of bacteria. The power of destroying cellulose was subsequently (erroneously) attributed by van Tieghem (Compt. rend. 1879, 88, 205; 89, 25, 1102) to the *B. amylobacter* (Gruber), on the ground of the destructive action of this bacillus on many vegetable tissues. A considerable amount of information as to the chemical nature of the process of cellulose fermentation was afforded by the researches of Popoff (Arch. Phys. 1875, 10, 113), Tappeiner (Ber. 1881, 2375; 1882, 999; 1883, 1734; 1884, 142, 262, 587), and Hoppe-Seyler (Zeitsch. physiol.

Chem. 1886, 10, 201, 401; Ber. 1883, 16, 122). Popoff and Hoppe-Seyler worked with sewer mud, and found that it contained organisms capable of decomposing Swedish filter paper, and producing from it carbon dioxide, methane, and sometimes hydrogen. Hoppe-Seyler, indeed, was able to bring about the conversion of 25·8 grams of pure filter paper into marsh gas and carbon dioxide in 4 years at room temperature, no other products being formed. Tappeiner paid attention chiefly to the extremely interesting problem of the decomposition of cellulose in the animal intestine, which had previously been ascribed to the action of a soluble enzyme (Hofmeister). He showed that a large part, if not the whole, of this decomposition, which in ruminants may amount to as much as 75 p.c. of the cellulose ingested, is bacterial and is accompanied by the evolution of large volumes of carbon dioxide, marsh gas, and sometimes hydrogen. He was moreover able to show that two types of cellulose fermentation existed, one of which was characterised by the production of methane, the other by that of hydrogen, methane being formed when the nutrient medium contained beef extract, hydrogen when only salts of known composition were used. In both cases carbon dioxide was evolved, and aldehyde and large quantities of acetic and butyric acids were produced. No advance had, up to this time, been made in the determination of the specific bacteria to which the destruction of cellulose was due, this function being generally ascribed to *B. amylobacter*, although van Senus (Koch's Jahrb. 1890, 1, 136) considered that the presence of a second organism was necessary. Much light has been thrown on the whole subject by the long-continued researches of Omelianski (Centr. Bakt. Par. Abt. ii. 1902, 8, 193; 1904, 11, 369; 12, 33; 1906, 15, 673; article in Lafar, Technische Mykologie, 1904, iii. 245). Omelianski has found that the fermentation of cellulose is produced by anaërobic sporing bacteria, and agrees with Tappeiner in recognising the methane and hydrogen types of fermentation. These are brought about by different organisms, which can be separated if advantage be taken of the fact that when a mixed culture of the spores of both varieties, such as occurs naturally in sewer mud or manure, is inoculated into the nutrient solution described below, and cultivated anaërobically, the bacteria of the methane fermentation are the first to grow. Accordingly, when such a mixed culture is allowed to develop and is then heated to 75° for 15 minutes, the vegetative forms of the methane bacteria are killed, and a succession of inoculations and heatings suffices to remove the whole of these, and leaves a culture which produces a pure hydrogen fermentation. On the other hand, direct inoculation without heating leads to the elimination of the undeveloped spores of the hydrogen organism and the production of a pure methane fermentation. It has not so far been found possible to obtain cultures of either form on solid media, and Omelianski relies on the strongly selective character of his medium and the microscopic appearance of his cultures as the only guarantees of their purity. The medium found suitable consists of potassium phosphate, 1 gram; magnesium sulphate, 0·5 gram; ammonium sulphate or phosphate,

1 gram; sodium chloride, trace; distilled water, 1 litre. To 300 c.c. of this, 3-4 grams of Swedish filter paper and 5-6 grams of chalk are added, and the whole inoculated. The fermentation only begins after at least a week's incubation, and proceeds slowly for many months. Spots slowly appear on the paper, and these gradually become perforations, and the paper breaks up into fragments and finally disappears. The decomposing fragments are found to be densely covered with bacteria, which are very slender, isolated rods, those of the methane fermentation being somewhat the thinner of the two species. They gradually produce at one end a round spore, three times the diameter of the rod (drumstick form). The bacilli can be stained by the ordinary aniline dyes, and do not give a blue coloration with iodine.

In the absence of any isolation of the bacteria on solid media or cultivation from a single spore, it must still be regarded as doubtful whether either of these organisms has yet been obtained in pure culture.

The products of decomposition of cellulose were examined quantitatively by Omelianski, and found to be as follows:—

	Hydrogen fermentation	Methane fermentation
	p.c.	p.c.
Carbon dioxide . . .	29.1	43.2
Hydrogen	0.4	—
Methane	—	6.8
Acetic acid	35.9	43.6
Butyric acid	31.0	7.1
	96.4	100.7

Fringsheim (Centr. Bakt. Par. 1913, ii. 38, 513) has found that the fermentation of cellulose can be brought about anaerobically by many thermophilic bacteria, which have the remarkable property of growing best at 55°-60°C., temperatures at which most bacteria are killed. The products in this case are hydrogen and carbon dioxide, along with acetic and formic, but no butyric, acid. Cellulose is also decomposed by certain denitrifying organisms. The same author has shown that in all processes of the bacterial fermentation of cellulose a preliminary hydrolysis occurs, brought about by the cellulase of the organism, with formation of the disaccharide cellobiose, which is then further hydrolysed and the products fermented (Zeitsch. physiol. Chem. 1912, 78, 266). Cellulose is also attacked and disintegrated by various aerobic organisms and by certain moulds (*see* McBeth, Soil Science, 1916, 1, 437), but little is known as to their mode of action. The materials containing the cellulose-fermenting bacteria also contain organisms which are capable of producing methane from a great variety of substances, among which are acetates (Hoppe-Seyler), butyrates (Mazé), and generally the fatty acids containing an even number of carbon atoms in the molecule (Söhngen), alcohol and gum arabic (Omelianski), and, according to Tappeiner, various albumins and protein derivatives. Omelianski also obtained from decaying wood organisms which produced methane fermentation with egg albumin, glue, gelatin, wool, and peptone. Fermentations of this kind undoubtedly play a large part in the destruction of animal and vegetable remains

and are of great technical importance in the decomposition of sewage in the septic tank and in the fermentation of manure. An interesting consequence of their constant occurrence in nature is the presence of methane in the air, as much as 11.3 c.c. per 100 litres having been found by Gautier in the air of wooded rural districts, where the decomposition of vegetable matter in the soil is probably very considerable.

Other types of fermentation by decomposition. Fermentation of the hydroxy-acids and glycerol. Among the numerous other types of fermentation involving the rupture of the carbon chain of non-nitrogenous compounds, only a few can be mentioned here.

i. The *B. ethaceticus* (F.) was isolated in 1890 from sheep dung by Frankland, who carefully examined its action on a number of different substances. This organism does not appear to have been identical with any of the more recently described intestinal bacteria. It fermented glucose, mannitol, arabinose, and glycerol, forming mainly acetic acid, alcohol, formic acid, and a mixture of equal volumes of carbon dioxide and hydrogen. No lactic acid was produced, but from glucose and arabinose a fixed acid of unknown composition was probably formed (Frankland and Fox, Proc. Roy. Soc. 1890, 46, 345; Frankland and Frew, Chem. Soc. Trans. 1891, 81; Frankland and Lumsden, *ibid.* 1892, 432; Frankland and MacGregor, *ibid.* 1892, 737). This organism had the interesting property of fermenting a solution of calcium *dl*-glycerate asymmetrically, only decomposing the *l*-acid and leaving unattacked the pure *d*-acid, which was first isolated in this way. The decomposition is represented by the equation:

This organism, after repeated cultivation in calcium glycerate, however, acquired the power of slowly fermenting the *d*-acid.

ii. Glycerol undergoes fermentation by many organisms, and in some cases yields butyric acid, as has already been described.

A more usual change is its decomposition mainly into alcohol and formic acid or carbon dioxide and hydrogen:

This was observed by Fitz with an organism known as *B. ethylicus* or *fitzianus*, and this is also the type of decomposition produced by *B. coli communis* (Harden).

iii. The hydroxy-acids, such as lactic acid, malic acid, and citric acid, are readily decomposed by many organisms. Thus lactic acid, in addition to undergoing butyric fermentation, is converted by a mixed fermentation (Strecker, 1854, Fitz) into acetic acid, propionic acid, and carbon dioxide. Malic acid yields with *B. lactis aërogenes*, carbon dioxide, acetic acid, and a large amount of succinic acid (Emmerling), similar products being formed by *B. cloacæ* (Thompson), whilst citric acid is converted by these two organisms into carbon dioxide and acetic acid.

iv. The mannitol fermentation is effected by an organism which occurs as an infection in wines (Gayon and Dubourg, Ann. Inst. Pasteur, 1894, 8, 108; 1901, 15, 527). It decomposes sugars into alcohol, carbon dioxide, acetic, lactic, and succinic acids, and glycerol, but with fructose yields a considerable proportion of mannitol.

3. FERMENTATIONS BY OXIDATION.

All aerobic organisms have the power, like the higher plants and animals, of oxidising appropriate food materials, with production of carbon dioxide and water. It is, however, frequently possible, in the case of bacteria, to isolate partially oxidised products and thus ascertain some of the stages of the process, whereas this can only rarely be accomplished with higher organisms. The production of acetic acid from alcohol by bacterial action is one of the most important cases of this kind; the conversion of ammonia into nitrous acid, and this into nitric acid, being a second.

(a) **The acetic fermentation of alcohol and the oxidising properties of the bacteria which produce it.** The spontaneous souring of wine, beer, and other alcoholic liquors when exposed to air has long been known and employed for the manufacture of vinegar. Pasteur, in 1864 (*Mém. sur la fermentation acetique*; *Ann. École Norm. sup.* 235, 225; *J. Chem. Soc. Abstr.* 1881, 128; *Études sur le vinaigre*, 1868), conclusively proved that the change of alcohol into acetic acid in this process was due to the 'flowers of vinegar,' an organism which, from the circumstance that it formed a film on the surface of the liquid, he termed *Mycoderma aceti*. Pasteur carefully examined this organism, cultivated it in synthetic media, and proved that it acted as a carrier of oxygen from the air to the alcohol, and that it was capable, when no more alcohol was available, of oxidising the acetic acid to carbon dioxide and water. Traces of aldehyde were observed to be produced when the vitality of the organism was impaired. The application of Neuberg's 'fixation' method (fermentation in presence of sodium sulphite) leads to a large accumulation of acetaldehyde (Neuberg and Nord, *Biochem. Zeitsch.* 1919, 96, 158). Since Pasteur's time a large number of organisms have been found which have a similar action on alcohol, and which include those found in vinegar breweries. These are not very clearly characterised, and only one or two of the most important can be here mentioned (*see* Henneberg, various papers in *Centr. Bakt. Par. Abt.* ii. 1897-98, 1905-6; and *Gärungsbacteriologisches Praktikum*, Berlin, 1909, 510-558). *B. aceti* (Hansen) has been studied morphologically by Cohn (*Biol. d. Pflanzen*, 2, 173), and biochemically by A. J. Brown (*Chem. Soc. Trans.* 1886, 174; 1887, 638) and Hansen. It grows on the surface of culture media, forming an easily broken film, consisting of chains of cells about 2 inches in length, and slightly contracted in the middle, so that they resemble a figure of 8. It does not form spores, and readily produces involution forms, cells of 10-15 μ in length and irregularly swollen being common. As regards the production of acetic acid from alcohol, Brown fully confirmed Pasteur's observations with *Mycoderma aceti*. The highest concentration of acetic acid that can be obtained by the use of this organism is 6.6 p.c. (Henneberg).

Brown also found that this organism converts *n*-propyl alcohol into propionic acid, and glycol into glycollic acid, but does not act on methyl alcohol or erythritol, whilst it oxidises glycerol completely. The observation that this

bacillus converts glucose into gluconic acid (Boutroux, *Compt. rend.* 1878, 86, 605; 1880, 91, 236) was confirmed. Mannitol undergoes an extremely interesting reaction, being converted into fructose. All these reactions occur when the organism is grown on solutions of the various substances in yeast water, chalk being added to neutralise the acids formed.

As already mentioned, Buchner and Gaunt (*Annalen*, 1906, 349, 140) have shown that the oxidation of alcohol by this organism is due to the action of an enzyme, and can be effected by the cells after they have been killed and dehydrated by acetone.

B. xylinus (Brown) is the organism which occurs in the vinegar plant, or mother of vinegar, in which it is associated with a yeast. The mixed growth is thus capable of converting cane sugar solution into vinegar, the sugar, which is itself not attacked by the bacillus, being hydrolysed and fermented by the yeast, with production of alcohol, which is then oxidised by the bacillus. The *B. xylinus* in pure culture grows on the surface of alcoholic liquids, forming thick, tough gelatinous membranes, which sometimes on wine attain a thickness of as much as a foot. This is due to the formation of a transparent film in which the short, rod-like bacilli are embedded. This film contains a large proportion (35-63 p.c. of its dry weight) of a cellulose-like material (Brown), which, however, contains nitrogen, and is probably a glucosamine derivative (Emmerling, *Ber.* 1899, 32, 541). The chemical actions of this organism were found by Brown to agree in general with those of *B. aceti*. They have been more completely investigated by Bertrand (*Ann. Chim.* 1904, [8] 3, 181), who terms the organism the sorbose bacterium. He finds that this organism converts many polyvalent alcohols into the corresponding α -ketose, thus changing sorbitol into sorbose, mannitol into fructose, *i*-erythritol into erythulose $\text{CH}_2(\text{OH})\cdot\text{CO}\cdot\text{CH}(\text{OH})\cdot\text{CH}_2\cdot\text{OH}$, *l*-arabitol $\text{C}_5\text{H}_{12}\text{O}_6$ into arabinulose $\text{C}_5\text{H}_{10}\text{O}_5$, perseitol and volemitol $\text{C}_7\text{H}_{14}\text{O}_7$, into perseulose and volemulose $\text{C}_7\text{H}_{14}\text{O}_7$. Of great interest is its action on glycerol, which it converts into dihydroxyacetone $\text{CH}_3(\text{OH})\cdot\text{CO}\cdot\text{CH}_2\cdot\text{OH}$, entirely free from the isomeric glyceraldehyde which is invariably formed by the action of ordinary oxidising agents.

This method is by far the most convenient for the preparation of dihydroxyacetone, the organism being simply grown for about 3 weeks on a 10 p.c. solution of glycerol in yeast water, and the liquid then evaporated, precipitated by alcohol, filtered and finally evaporated *in vacuo*.

On the other hand, glycol, *l*-xylitol, and *d*-dulcitol are not attacked. The action of the bacillus is confined to the oxidation of a secondary carbinol group, which is not stereochemically in the neighbourhood of a hydrogen atom (Bertrand). The aldoses are oxidised to the corresponding acid, glucose, xylose, arabinose, and galactose all behaving normally in this respect. When the acid thus produced contains a $\text{CH}(\text{OH})$ group capable of being attacked, according to the rule just stated, this may also be oxidised. Thus gluconic acid yields the corresponding ketonic acid, oxygluconic acid $\text{CH}_2(\text{OH})\cdot\text{CO}\cdot\text{CH}(\text{OH})\cdot\text{CH}(\text{OH})\cdot\text{COOH}$, which had previously been obtained by Boutroux

by the aid of the *M. oblongus* (Bout.) (Compt. rend. 1886, 102, 924).

(b) **Nitrification.** The conversion of the nitrogen of organic matter into nitrates in the soil was familiar to chemists at a very early date, and was employed as a means of manufacturing saltpetre. From the time of Mayow onwards, it was regarded as a purely chemical action brought about by the agency of the porous soil, or, according to Liebig's characteristic view, by a ferment, i.e. some substance which was itself undergoing oxidation in the soil. The idea that this process was in reality of biological origin was suggested by Pasteur (1862), but first more fully developed by Schloesing and Müntz (Compt. rend. 1877, 84, 301; 1878, 86, 392; 1879, 89, 891, 1074), who found that nitrification ceased when the soil was sterilised by heat or antiseptics. The researches of Warington (Chem. Soc. Trans. 1878, 44; 1879, 429; 1884, 637; 1888, 727), carried out at Rothamsted, contributed, along with much information as to the conditions of nitrification, the fundamentally important facts that oxidation often only proceeded as far as the production of nitrite, and that the nitrogen was converted into ammonia before being nitrified. These conceptions were then further developed by Munro (Chem. Soc. Trans. 1886, 632), who came to the conclusion that the normal course of nitrification consisted in the production of ammonia followed by that of nitrites and nitrates. Up to this time (1888), all attempts to isolate the organisms by the aid of which the change was effected had failed, and it was not until this had been effected by Winogradsky (Ann. Inst. Pasteur, 1890, 4, 213; article in Lafar, Technische Mykologie, 1904, iii. 132-181), and almost simultaneously by Warington (see Chem. Soc. Trans. 1898, 484), that the true conditions of the process were discovered. The bacilloccoccus possessed of nitrifying power which was described by P. and G. Frankland (Proc. Roy. Soc. 1890, 47) was subsequently found not to be a pure culture. Winogradsky, convinced that the presence of organic matter was detrimental to the development of the organism, inoculated with earth a solution containing only 1 per mille of ammonium sulphate and of potassium phosphate, together with some solid basic magnesium carbonate, and by repeated sub-cultivations succeeded in obtaining strong nitrification in a liquid almost free from organisms capable of growing on the ordinary solid media. The principle involved is that of selective culture, only those organisms surviving which can avail themselves of the very limited supply of nourishment provided. The deposit of magnesium carbonate in such solutions was observed to be covered with gelatinous masses of the nitrifying organism, and when this was spread on gelatin, it was found that many particles produced no growth whatever, and were therefore free from all ordinary soil organisms. Some of these, when removed and placed in the culture fluid, produced active nitrification, and a growth in which no foreign organisms could be detected. It was subsequently found by Winogradsky that this organism was only capable of converting ammonia into nitrite, and that the final stage of the oxidation to nitrate was effected by a second organism, which was isolated (1891) in a similar manner, by repeated

sub-culture in a selective culture medium containing sodium nitrite instead of an ammonium salt. This discovery led to the explanation of the apparently capricious action of the nitrifying organisms, which sometimes yielded nitrite and at others nitrate. It was found, in confirmation of the opinion expressed by Warington, that the development of the nitrate-producing organism was inhibited by comparatively small proportions of ammonium salts. This effect is, in fact, very remarkable, and is comparable to that of the most powerful antiseptics. In a particular case as little as 0.005 gram per litre of ammonia (as sulphate) caused a perceptible diminution in the rate of nitrification of a nitrite solution, and 0.154 gram completely inhibited it. On the other hand, nitrites may be present up to at least 10 grams per litre, and nitrates to 20 grams per litre. When, however, ammonia is added to a liquid containing a well-developed culture of the nitrate-producing organism, it causes very little change in the rate of action, even in quantities of 1.8 grams per litre, so that its harmful effect is mainly one of inhibition, exerted on the development of the organism, and not on the oxidising action of the developed organism (Winogradsky).

In agreement with these facts, it is found that when an inoculation of earth is made into solutions of ammonium salts, nitrosification (the production of nitrite) proceeds until nearly all the ammonia has been converted, and only then does the production of nitrate begin. The repeated addition of fresh ammonia before this second stage sets in will limit the action entirely to the production of nitrite. If, however, nitrate production is once well established, further additions of ammonia are completely converted into nitrate. Similar conditions prevail in the nitrification of sewage, which is apparently effected by the same organisms as are found in the soil (Chick, Proc. Roy. Soc. 1906, B, 77, 241).

Another remarkable feature of these organisms is their mode of carbon assimilation. Organic carbon not only cannot be assimilated by them, but actively inhibits their development in culture solutions, compounds such as glucose and peptone totally inhibiting nitrosification in concentrations of 0.2 p.c. and nitrification in concentrations of 0.25 p.c. (glucose), and 1.25 p.c. (peptone), and behaving, therefore, in this respect like powerful antiseptics. It was this property which rendered the isolation and artificial culture of these organisms so difficult. In the soil, however, these compounds are not harmful, and even aid the process of oxidation (Coleman, Centr. Bakt. Par. 1908, ii. 20, 401). The sole source of carbon for both classes of organism appears to be carbon dioxide, derived from carbonates by the nitrosifying organism, and from bicarbonates by the nitrifying organism. The energy necessary for the reduction of carbon dioxide to assimilable compounds is apparently provided by the oxidation of the ammonia or nitrite, and a fixed ratio exists between the amounts of carbon assimilated and ammonia or nitrite oxidised. Thus the nitrosifying organism oxidises 35.4 parts of nitrogen as ammonia for 1 part of carbon assimilated (Winogradsky).

The study of the morphological characteristics of the organisms of this highly important group

has been greatly aided by the discovery of solid media on which cultivations can be made. Winogradsky first introduced a jelly of silica saturated with the culture fluid, and Omelianski has successfully used plates made of gypsum and 1 p.c. of magnesium carbonate, and even discs or strips of filter paper. More convenient are the agar plates introduced by Beyerinck (Cent. Bakt. Par. ii. 1896, 19, 258). The agar-water jelly is allowed to stand for about a fortnight under water. Fermentation occurs, accompanied by the decomposition of all the compounds which inhibit the growth of the nitrifying organisms. The agar is then washed, mixed with the culture medium and a little chalk, and finally sterilised.

The exact relations of the various organisms which have been isolated are still unknown. The general result is that several nitrifying organisms have been obtained from different regions, whereas hitherto only one nitrifying organism has been found. The nitrifying organism is termed *B. nitrosomonas* (Winog.), L. and N. The forms of the West European variety are oval bacilli ($1 \times 1.2-1.8\mu$), which produce zooglyea in fluid media, and brown colonies on solid media; these break up after some time into motile forms. The organism from Buitenzorg in Java, on the other hand, is a minute micrococcus $0.5-0.6\mu$ in diameter, and that from Quito a large coccus $1.5-1.7\mu$ in diameter, which does not form zooglyea. The organism from Japan closely resembles the European variety. Hitherto only one variety of this organism has been obtained in any one district.

B. nitrobacter (Winog.), L. and N., which converts nitrites into nitrates, is a bacillus $1 \times 0.3-0.4\mu$, possesses a gelatinous capsule, and never forms motile cells. It grows very slowly on agar, forming almost colourless, drop-like colonies.

(c) Other oxidising effects produced by bacteria. Oxidation of sulphuretted hydrogen, ferrous oxide, hydrogen, and methane. Very special interest attaches to the action of bacteria in bringing about the oxidation of sulphuretted hydrogen. This process is comparable with the nitrification of ammonia, inasmuch as it has the effect of converting sulphuretted hydrogen, a direct product of the putrefaction of proteins, into sulphates, from which plants are able to supply themselves with the sulphur essential for their growth.

Early observers noted the occurrence of characteristic micro-organisms in sulphur wells, and the presence of granules of sulphur within their cells (1870-1875), but it is to the researches of Winogradsky that we owe, in the main, our present knowledge of the sulphur bacteria. The oxidation of sulphuretted hydrogen is effected in two stages. The first product is free sulphur, which is deposited in the cell in the form of soft spherical granules of amorphous sulphur. In the presence of abundance of sulphuretted hydrogen, the cell becomes crowded with these particles. The second stage consists in the oxidation of this sulphur to form sulphuric acid, which neutralises the carbonates present in the soil to form sulphates. It seems probable that these organisms derive the whole of their carbon from carbon dioxide, the energy necessary for its decomposition being derived from the oxidation of the sulphuretted hydrogen. Many genera

of sulphur bacteria are known, the most important being *Beggiatoa* and *Thiothrix*, which form long threads, and are regarded by some authors as intermediate between the bacteria and algae. In addition to these, a large number of others have been described, many of which are characterised by the production of a red colouring matter known as bacteriopurpurin (Ray Lankester).

Another group of bacteria is known, the species of which bring about the oxidation of ferrous hydrogen carbonate to ferric hydroxide in chalybeate waters. These organisms, which, like the sulphur bacteria, form long threads, are also closely allied to the algae, and belong to the genera *Crenothrix*, *Cladothrix*, *Streptothrix*, &c. They are also able to effect the oxidation of manganese salts, and the resulting oxides are apparently deposited in the gelatinous membrane of the cell (Molisch, quoted by Rullmann, Lafar, iii.).

Other groups of bacteria are able to play the part of platinum black in bringing about the oxidation of hydrogen (Lebedev, Biochem. Zeitsch. 1907, 7, 1; Lebedev and Nabokich, Centr. Bakt. Par. ii. 1906, 17, 350; Niklewski, Centr. Bakt. Par. ii. 1907, 21, 380), whilst others can effect the oxidation of marsh gas (*B. methanicus*, Söhngen, Proc. K. Akad. Wetensch. Amsterdam, 1905, 8, 327), and an organism has been described by Beyerinck (Centr. Bakt. Par. ii. 1909, 25, 30) which can bring about reaction between nitrous oxide and hydrogen, and obtain its carbon from carbon dioxide by the aid of the energy thus liberated.

4. FERMENTATIONS BY REDUCTION AND DEOXIDATION.

(a) Reduction. The decomposition of a molecule of a carbon compound into two or more smaller molecules, some of which are relatively more oxidised and others relatively more reduced, is, as we have seen, a common feature of many fermentations by decomposition. A typical example is afforded by the alcoholic fermentation of sugar, which results in the formation of carbon dioxide on the one hand, and alcohol on the other. The decomposition sometimes results in the production of free hydrogen, and when this occurs in the presence of reducible substances, reduction often takes place. Of this secondary character are the reduction by *B. coli communis* of nitrates to nitrites in presence of sodium formate (Pakes and Jollyman, Chem. Soc. Trans. 1901, 459), and of aspartic acid in presence of glucose to ammonium succinate (Harden, *ibid.* 1901, 612), the reduction being effected by the hydrogen produced from the formate and glucose respectively. Many similar cases are known, especially among mixed fermentations (see Söhngen, Rec. trav. chim. 1910, 29, 238). In other cases the reducing action of bacteria is exercised directly upon the reducible compound, and results either in the direct removal of oxygen or the addition of hydrogen. In the former case the oxygen probably goes to produce physiological oxidation in the bacterial cell. Thus many aerobic organisms can grow in the absence of free oxygen, provided that nitrates are added to the medium, and these are thereby converted into nitrites (Pakes and Jollyman, Chem. Soc. Trans.

1901, 322; Ritter, Centr. Bakt. Par. ii. 1907-8, 20, 21).

The bacterial reduction of sulphates, thio-sulphates, and sulphites to sulphuretted hydrogen is probably due to a similar action (Beyerinck, *ibid.* 1895, 1, 1).

The direct addition of hydrogen by bacteria to certain colouring matters is a well-recognised phenomenon. Thus many organisms readily reduce methylene blue to the leuco-compound, not only when grown in its presence, but also when the organisms are suspended in a solution of the colouring matter. The same effect is produced by dry sterile preparations obtained by treating the bacteria with acetone, and is ascribed to the action of a specific reducing enzyme or reductase, which becomes inactive at about 60° (Cathcart and Hahn, Arch. Hyg. 1902, 44, 295). The chemistry of the process has already been discussed under the heading of *Reducing enzymes*.

(b) **Denitrification.** One of the best-studied instances of deoxidation by bacteria is the process of denitrification, whereby nitrates are reduced to oxides of nitrogen, free nitrogen, and ammonia. The power possessed by many bacteria of reducing nitrates to nitrites was observed as early as 1875 (Meusel), and has been investigated by many authors since that date (Frankland, Chem. News, 1888, 57, 89; Warington, *ibid.* 1888, 57, 246; Maasen, Arbeit. K. Gesund.-Amt. 1901, 18, 21; Grimbirt, Ann. Inst. Pasteur, 1899, 13, 67; Franzen and Löhmann, Zeitsch. physiol. Chem. 1909, 63, 52). The reduction to nitrite occurs in nitrate broth, is accompanied by the evolution of carbon dioxide, and, as mentioned above, is probably due to direct deoxidation, as it is effected by many bacteria which do not produce free hydrogen. The production of ammonia from nitrates is also apparently a common property of bacteria, but the relations in this case have not been so clearly established as in that of nitrite. The evolution of oxides of nitrogen from a fermenting liquid was observed by Dubrunfaut (1868), in the case of fermenting molasses; but the production of the oxides was ascribed to purely chemical causes. Since that time, however, the production of nitrous and nitric oxides from nitrites by bacteria has been frequently observed in mixed fermentations. With pure cultures the phenomenon is much less common, but an organism known as *B. denitrificans* (Stutzer and Burri), which is however probably identical with *B. pyocyanus* (Flügge), has been described, which ordinarily reduces nitrates to nitrogen, but in presence of asparagine produces nitric oxide (Gayon and Dupetit, Chem. Soc. Abstr. 1886, 823). Another organism, *B. nitroxus* (Bey. and Mink.), is chiefly responsible, according to Beyerinck and Minkmann (Centr. Bakt. Par. ii. 1909, 25, 30) for the almost universal occurrence of nitrous oxide in the gases produced when soil is added to nitrate broth. So vigorous is this process that a stream of gas may be obtained containing 80 p.c. of nitrous oxide, and capable of relighting a glowing splint. *B. pyocyanus*, *B. Stutzeri* (L. and N.), and *M. denitrificans* (Bey. and Mink.), all produce nitrous oxide from nitrates. On the other hand, *B. Harilebii*, under anaërobic conditions, produces from a nitrate and a tartrate or lactate such a considerable

amount of nitric oxide that brown fumes are seen when air is led into the flask (Lebedev, A. J., Ber. deutsch. bot. Ges. 1911, 29, 327).

Finally, in many cases, the reducing action of bacteria on nitrates proceeds as far as the production of free nitrogen. This phenomenon, since it was first attributed to bacterial action by Gayon and Dupetit in 1882 (Compt. rend. 1882, 95, 664), has been the subject of numerous investigations, on account of its importance in agriculture, since it may occur both in soil and in manure. It has been conclusively established that, in presence of suitable carbonaceous nutriment, nitrates are readily decomposed in this way by many bacteria, especially in the absence or scarcity of oxygen. Jensen has shown (Centr. Bakt. Par. ii. 1897, 3, 622; 1898, 4, 401) that in these cases the oxygen of the nitrate is utilised for the oxidation of the organic matter, and that the presence of free oxygen greatly diminishes the extent of the denitrification. It seems probable that the 'nitrogen' estimated by the older observers was really a mixture of nitrogen and nitrous oxide.

The serious loss of nitrogen which occurs in manure heaps, and may amount to as much as 25 p.c. of the total nitrogen in three months, or 50 p.c. in nine months, has been investigated by many authors (see Russell and Richards, J. Agri. Sci. 1917, 8, 495, where the literature is quoted). The phenomenon depends on the alternation of aerobic and anaërobic conditions, and may possibly be due to bacterial oxidation of the nitrogenous matter to nitrate, followed by denitrification. It has not, however, been proved that this is the actual course of events, and Russell and Richards consider that the process may be explained by the supposition that under anaërobic conditions a change is effected by bacterial action which leaves some of the nitrogen compounds present in such a condition that subsequent oxidation decomposes them with evolution of nitrogen. A similar loss of nitrogen occurs in the filtration of sewage.

Putrefaction. Decomposition of amino-acids.

The term 'putrefaction' is usually applied to the decomposition which is set up by bacteria in animal and vegetable remains at the ordinary temperature, and which is accompanied by the production of malodorous compounds and gases. The chief source of these is the protein matter of the organism, so that the characteristic feature of putrefaction is the bacterial decomposition of proteins. The process consists chemically in a hydrolysis of the proteins into simpler molecules, followed or accompanied by the decomposition of these, yielding, according to circumstances, highly oxidised substances or a series of reduction products. In the presence of an abundant supply of oxygen, the process continues until the final products are carbon dioxide, water, ammonia, and mineral salts, whereas in a limited supply or in absence of oxygen, a whole series of compounds is formed comprising bases, acids, volatile sulphur compounds, &c.; and this is the characteristic phenomenon known as putrefaction. Similar chemical changes are produced when proteins are fused with caustic alkalis at 250° (Gautier and Etard, Compt. rend. 1882, 94, 1357).

The immediate origin of the products of putrefaction is then to be sought in the various

products of hydrolysis of the proteins. These consist, as is well known, chiefly of amino-acids, diamino-acids, such as arginine and lysine, and a number of other compounds. As of special importance may be mentioned histidine, or β -iminazole- α -aminopropionic acid (α -amino- β -glyoxaline-4 (or 5)-propionic acid), tryptophan or indole- α -aminopropionic acid, and cystine ($\text{COOH}\cdot\text{CH}(\text{NH}_2)\cdot\text{CH}_2\cdot\text{S}\cdot\text{S}\cdot\text{CH}(\text{NH}_2)\cdot\text{COOH}$).

The amino-acids undergo decomposition in at least two different ways. In the first place, the amino group may be removed by reduction (deamination), yielding the corresponding fatty acid (equation *a*), which then either undergoes oxidation (equation *b*), yielding a lower acid or simply loses carbon dioxide (equation *c*):

Thus leucine (CH_3)₂CH·CH₂·CH(NH₂)·COOH yields valeric acid, and it is probable that formic, acetic, propionic, butyric, and caproic acids, which are all present in the products of putrefaction, are formed in a similar way.

Of special interest are the products obtained in this way from tryptophan, a substance which was discovered by Hopkins and Cole (J. Physiol. 1902, 27, 418), among the products of hydrolysis of proteins by trypsin, and which is the mother substance of the various indole derivatives to which the characteristic odour of faeces is largely due. Tryptophan has been found by Ellinger (Ber. 1907, 40, 3029) to be indole- α -aminopropionic acid, of the formula

and is decomposed by putrefaction in the manner described above, yielding successively indole-propionic acid $\text{C}_8\text{H}_7\text{N}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{COOH}$, indole-acetic acid $\text{C}_8\text{H}_7\text{N}\cdot\text{CH}_2\cdot\text{COOH}$, and indole $\text{C}_8\text{H}_7\text{N}$. A certain amount of skatole or α -methylindole $\text{NH} \begin{array}{c} \diagup \text{C}_6\text{H}_4 \diagdown \\ \diagdown \text{CH} \diagup \end{array} \text{C}\cdot\text{CH}_3$ is also formed,

probably by a reaction of the type (c) given above. By similar reactions phenylalanine $\text{C}_6\text{H}_5\cdot\text{CH}_2\cdot\text{CH}(\text{NH}_2)\cdot\text{COOH}$ yields successively phenylpropionic acid, phenylacetic acid, and benzoic acid, whilst tyrosine, or *p*-hydroxyphenylaminopropionic acid

is converted into *p*-hydroxyphenylpropionic acid (hydroparacumaric acid, Baumann, 1879), *p*-hydroxyphenylacetic acid (Salkowski, E. and H., Ber. 1879, 12, 648; 1880, 13, 189, 2217), *p*-cresol, *p*-hydroxybenzoic acid, and phenol. In an abundant supply of oxygen even these simple aromatic compounds are completely oxidised; thus a bacillus has been isolated which in pure culture readily oxidises dilute solutions of phenol (Fowler, Arden, and Lockett, Proc. Roy. Soc. B, 1910, 83, 149).

Succinic acid, which is always formed in putrefaction, is probably derived from aspartic acid $\text{COOH}\cdot\text{CH}_2\cdot\text{CH}(\text{NH}_2)\cdot\text{COOH}$ by reduction (Salkowski).

It is not improbable that this type of decomposition of the amino-acids may be accompanied by the type of decomposition which is brought about by yeast in presence of sugar and has already been discussed, the characteristic

feature of which is that the amino group is removed with formation of a keto acid, which then undergoes further decomposition.

A second extremely important mode of decomposition of the amino-acids, diamino-acids, &c., during putrefaction, is the simple elimination of carbon dioxide, leading to the formation of bases (decarboxylation):

Many bases have been isolated from putrefying mixtures, and great importance is to be attached to their formation, inasmuch as several of them have a very marked physiological action. The observation that putrefying flesh may contain poisonous basic substances, liable to be confused with the vegetable alkaloids, was made by Selmi (1872), who gave to these bases of animal origin the name ptomaines (πτῶμα, a corpse), and they were then more thoroughly investigated by Brieger. It was at first thought that the poisonous products which result from the action of bacteria on various culture media and on meat, fish, &c., were also members of this class, and the effect of pathogenic bacteria on the living organism was ascribed to the production of these same substances in the system, a view to which the term 'ptomaine-poisoning,' still erroneously applied to case of meat-poisoning, &c., gives expression. It has now however, been found that the characteristic and specific poisons produced by bacteria are probably much more complex in their structure, and belong more probably to the class of proteins than to that of the ptomaines. They are termed toxins or bacterial toxins, and are distinguished as ecotoxins, which pass out of the bacterial cell into the surrounding medium (as do diphtheria toxin and tetanus toxin), and endotoxins, which are retained within the cell, but appear to pass out of it after death (typhoid toxin, &c.).

The origin of many of the simple mono- and di-acid bases which occur in putrefaction can be traced to the corresponding amino acids, among these being isoamylamine derived from leucine, phenylethylamine derived from phenylalanine, *p*-hydroxyphenylethylamine derived from tyrosine, and β -iminazolyethylamine

from histidine, all of which have a very marked effect in raising the blood pressure, or in other ways, and are of physiological importance because they are in all probability formed in the intestine and absorbed (Barger and Walpole, J. physiol. 1909, 38, 343; Barger and Dale, *ibid.* 1910, 41, 19, 499). Bacteria capable of decomposing histidine in this way have actually been isolated from the intestine (Mellanby and Twort, J. Physiol. 1912, 45, 53; Berthelot and Bertrand, Compt. rend. 1912, 154, 1643, 1826). Of the diamino-bases isolated by Brieger may be mentioned ethylenediamine $\text{NH}_2\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{NH}_2$, putrescine or tetramethylenediamine

derived from arginine, cadaverine or pentamethylenediamine derived from lysine (equation *e*).

In addition to these, trimethylamine, choline $\text{CH}_2(\text{OH})\cdot\text{CH}_2\cdot\text{N}(\text{CH}_3)_3\text{OH}$, muscarine

and neurine $\text{CH}_2\cdot\text{CH}\cdot\text{N}(\text{CH}_3)_3\text{OH}$, of which the last two are highly poisonous, all occur, probably derived not from proteins, but from lecithin and its allies, which yield, on hydrolysis, glycerol-phosphoric acid, fatty acids, amino-ethyl alcohol, and choline.

Finally, an invariable product of the action of bacteria on proteins is ammonia, formed either by reduction of amino-acids as explained above, or by their oxidation. This bacterial production of ammonia (ammonification) is a process of fundamental importance in the soil, since, as already described, ammonia serves as the raw material for the production of nitrate. According to Marchal (Chem. Soc. Abstr. 1894, ii. 248), a large number of bacteria are concerned in the process, the most active among them being *B. mycoides*.

In the decomposition of histidine, which contains nitrogen both in the iminazole nucleus and in the side chain, ammonia is produced from both sources by the aerobic action of many bacteria (*B. paratyphosus*, *A* and *B*, *B. faecalis alcaligenes*, *B. pyocyaneus*), whereas *B. vulgaris* (*proteus*) only attacks the side chain (Raistrick, Biochem. J. 1919, 4, 446). Many bacteria of the coli-typhosus group yield with histidine $\text{C}_3\text{H}_5\text{N}_2\cdot\text{CH}_2\cdot\text{CH}(\text{NH}_2)\cdot\text{COOH}$, the unsaturated urocanic acid

formed possibly by direct elimination of NH_2 and H from the side chain (Raistrick, Biochem. J. 1917, 11, 71).

The gases evolved consist of carbon dioxide, hydrogen, and sometimes methane, nitrogen, and sulphuretted hydrogen. Some of the sulphur of the proteins is converted into methylmercaptan (Nencki), and traces of many other sulphur compounds are formed, these being the main cause of the characteristic smell. The phosphorus is chiefly converted into phosphate, the evolution of phosphine alleged by some observers being doubtful.

The organisms which bring about these characteristic changes are very numerous. Usually many different organisms are present, and there seems little doubt that in some cases the various stages of decomposition are effected by different species of bacteria. Reference has already been made to the effect of the presence or absence of air, but this affects not only the chemical changes produced, but also the nature of the bacterial flora. In a free supply of air the organisms are mainly aerobic, whereas in a limited supply anaerobic organisms are chiefly present. Frequently the surface of the putrefying mass is occupied by aerobic organisms, and these use up the oxygen, and provide suitable conditions for the development of anaerobes at a lower stratum. It appears also that the primary proteins are directly attacked and digested by one group of organisms, those which produce an ecto-proteoclastic enzyme, whilst a second group possessing insoluble endo-proteoclastic enzymes, is only able to decompose the simpler products formed by this hydrolysis.

Of the actual organisms which are usually present there may be mentioned *B. vulgaris*

(L. and N.) (formerly known as *proteus*), *B. fluorescens liquefaciens*, *B. mesentericus* (L. and N.), all of which attack and digest albumins. *B. sporogenes* (Metchnikoff) and *B. histolyticus* (Weinberg and Séguin), which have been found in infected wounds, both attack proteins with the production of large amounts of amino-acids, whilst the latter forms both gas and volatile acids from meat (Wolf and Harris, J. Path. Bact. 1907, 21, 386; 1918, 22, 1). The organism formerly known as *B. putrificus* (Bienstock) and regarded as one of the most characteristic putrefactive organisms is probably a mixture of the two sporing anaerobes, *B. sporogenes* (Metch.) and *B. coehlearius* (Douglas, Fleming and Colebrook). Belonging to the second group, which only decompose simpler proteins, are *B. coli communis* and its allies, the characteristic bacilli of the large intestine, many of which produce indole and indole-acetic acid, *B. prodigiosus* (Flügge), *Streptococcus pyogenes* (Rosenbach), &c. In any particular case the flora is largely conditioned by the exact nature of the putrefying material, so that meat, fish, milk, eggs, &c., all have their characteristic organisms and modes of decomposition.

FERMENTATIONS PRODUCED BY MOULDS.

A number of moulds, especially belonging to the families *Aspergillaceæ* and *Mucoraceæ*, are distinguished by producing definite chemical changes of a fermentative character, some of them by the secretion of soluble enzymes, and others by means of endoenzymes.

Alcoholic fermentation. The power of producing alcoholic fermentation is common to a large number of the *Mucoraceæ*, but is only possessed to any considerable extent by a single species of the *Aspergillaceæ*. *Allescheria Gayoni* (Saccardo and Sydow = *Eurotiosis Gayoni*, Cost.) appears to be capable of producing a typical alcoholic fermentation of glucose, levulose, maltose, and lactose, producing as much as 8 p.c. of alcohol in the medium, and forming glycerol and succinic acid in a similar manner to yeast.

The alcoholic fermentation produced by many species of *Mucor* has long been a subject of interest. When the mycelium of *M. racemosus* (Fres.), for example, is submerged in a nutrient medium containing sugar, alcoholic fermentation occurs, and at the same time the mycelium breaks up into spherical cells, which continue to grow by budding, and have hence been termed spherical yeast. The opinion has been held at various times that these cells were true yeasts, and moreover that all yeast had a similar origin. The first statement has now been definitely disproved, and no satisfactory evidence exists in favour of the second. It was further thought that when growing in the normal manner on the surface of the liquid, the mucor had only the power of oxidising the glucose, but that when submerged and thus deprived of a free supply of air, it became able to ferment it (Pasteur). It has, however, been established by the work of Wehmer (Centr. Bakt. Par. ii. 1905, 14, 556, 15, 8) and Kostytschev (*ibid.* 1904, 13, 490) that the mould produces just as much alcohol in presence of a free supply of air as when submerged, and that the commencement of alcoholic fermentation and the production of

spherical yeast cells are not causally connected. A very large number of species of *Mucor* and *Rhizopus* have been carefully examined as to their power of producing alcohol and fermenting the polysaccharides (see Wehmer, article in Lafar, Technische Mykologie, iv. 517).

Production of diastase. Some species of these two families produce such large amounts of diastatic enzyme that they have been employed both industrially and domestically for the saccharification of starch, and a considerable number, if not all of them, produce a certain amount of this enzyme.

Mucor rouxii (Calm.), Wehmer (*Amylomyces rouxii*), was isolated by Calmette from Chinese yeast, and is employed in pure culture for converting the starch in a sterilised distillery wash into sugar, which is then fermented by a pure culture of yeast and distilled. (See Chapman, Cantor Lectures, 1921.)

Aspergillus cryze (Ahlburg), Cohn, has long been employed in Japan for the preparation of saké from rice, and of the soya sauce from the soya bean. The diastase of this organism, known as takadiastase, acts on starch much more energetically than malt diastase.

The oxalic acid fermentation. A very remarkable instance of oxidative fermentation is afforded by *Aspergillus niger* (van Tieghem) (*Sterigmatocystis nigræ*), which converts glucose into oxalic acid. When this mould is grown on a nutrient solution containing glucose at 15°–20°, free oxalic acid is produced, the acidity increases up to a maximum, and then gradually diminishes and finally disappears. If, however, calcium carbonate or an alkaline phosphate be added, the oxalic acid accumulates, either as insoluble calcium oxalate or as an acid oxalate. In this way, for example, 1.5 grams glucose yielded 1.05 grams of oxalic acid in the form of calcium oxalate, whereas in the absence of chalk the maximum amount was 0.298 gram. The complete conversion of all the carbon of the glucose into oxalic acid would yield about 2.25 grams, so that the yield is approximately 50 p.c., the remainder of the glucose being presumably used for the needs of the organism (Wehmer, Ber. Bot. 1891, 9, 223, 163; Bot. Zeit. 1891, 49, 233; Annalen, 1892, 269, 383). As regards the mechanism of this action, Raistrick and Clark (Biochem. J. 1919, 14, 329) have found that oxalic acid is freely produced by this organism from succinic, fumaric, malic, and tartaric acids, and from acetic acid, but not from monobasic acids containing four atoms of carbon, from three-carbon acids or from glycollic, glyoxylic, or formic acids. They conclude that the oxalic acid is in part produced by oxidation of acetic acid formed from the sugar with intermediate production first of β , δ -diketoadipic acid

which then yields acetic acid and oxalacetic acids $\text{COOH}\cdot\text{CH} : \text{C}(\text{OH})\cdot\text{COOH}$, the latter of which undergoes hydrolysis to oxalic and acetic acids. Many species of *Penicillium* produce small amounts of oxalic acid, and one of them, *P. oxalicum* (Thom), which occurs on mouldy corn, gives yields almost equal to those obtained from *A. niger*, producing the acid readily from both glucose and starch (Currie and Thom, J. Biol. Chem. 1915, 22, 287).

The citric acid fermentation. Whereas *Aspergillus niger* produces oxalic acid from glucose, other members of the *Aspergillaceæ*, *Citromyces Pfefferianus* and *C. Glaher*, described by Wehmer; and *C. citricus*, *C. tartaricus*, and *C. oxalicus*, described by Mazé and Perrier (Compt. rend. 1904, 139, 311; Ann. Inst. Pasteur, 1904, 18, 553), convert this sugar into citric acid. According to Currie, however (J. Biol. Chem. 1917, 31, 15), citric acid is also formed by *A. niger*, and is in this case to be regarded as an intermediate stage in the formation of oxalic acid, which is readily produced by this organism from citric acid. Wehmer states that as in the case of oxalic acid, the citric acid is further oxidised if it be allowed to remain in the free state in the presence of the organisms, but accumulates when it is converted into a salt by the addition of calcium carbonate. Currie, however, using *A. niger*, has found that the best yield of citric acid is obtained by growing the mould in an acid solution ($\text{P}_\text{H}=3.4\text{--}3.5$) containing ammonium nitrate as the source of nitrogen. Under these circumstances the production of citric acid may amount to 66 p.c. of the saccharose employed, the acidity of the solution increasing until a P_H of 1.46 is reached. In presence of calcium carbonate about half the sugar can be converted into citric acid; thus, Buchner and Wüstenfeld (Biochem. Zeitsch. 1909, 17, 395), working with *C. citricus*, found that the maximum amount of citric acid produced amounted to 56 p.c. of the sugar. A large amount of carbon dioxide was simultaneously evolved, corresponding in various experiments to the oxidation of 48–77 p.c. of the sugar, the citric acid in the same experiments amounting to 33–38 p.c. of the sugar, and the new growth of mould to 5–31 p.c. of the sugar. The characteristic formation of citric acid could not be obtained with press juice nor with acetone preparations of the mycelium. Citric acid is also formed from glycerol and from alcohol, as well as in small quantities *in vacuo* from the mycelium of the mould alone (Mazé and Perrier).

Mazé and Perrier regard the citric acid as a product of catabolism of the cell substance, induced by lack of nitrogen, and not as a true product of the oxidation of sugar; whereas Buchner and Wüstenfeld ascribe its formation to a process analogous to the production of parasaccharic acid

from lactose by milk of lime (Kiliani).

In their action on sugar and allied compounds the moulds differ very decidedly from the bacteria. The production of lactic, acetic, butyric, and formic acids, and the evolution of hydrogen and carbon dioxide, which are characteristic of so many bacterial actions, are not observed among the moulds. On the other hand, the latter are often capable of producing alcoholic fermentation, are richly endowed with the various hydrolytic enzymes, and, in some cases, produce compounds, which, like malic, oxalic, and citric acids, are characteristic of the higher plants.

Many other interesting chemical changes brought about by moulds have been observed, among which may be mentioned the production of fumaric acid from glucose and fructose by

Rhizopus nigricans (Ehrlich, Ber. 1911, 44, 3737), and the conversion of cinnamic acid into styrene by *A. niger* (Herzog and Ripke, Zeitsch. physiol. Chem. 1908, 57, 43).

Decomposition of amino-acids. The amino-acids are very readily oxidised by many moulds, both by living cultures and by the killed cells after treatment with acetone. In some cases the action is selective, only the naturally-occurring modification being attacked (Herzog and Meier, Zeitsch. physiol. Chem. 1908, 57, 35; Pringsheim, *ibid.* 1910, 65, 96).

Ehrlich has, however, observed (Ber. 1911, 44, 888) that in presence of sugar many fungi convert the amino-acids into the corresponding hydroxy-acids $R \cdot CH(NH_2) \cdot COOH \rightarrow R \cdot CH(OH) \cdot COOH$ and many amines into the corresponding alcohols (Ehrlich and Pistschimuka, Ber. 1912, 45, 1006). He has in this way, by the use of *Oidium lactis* (which can readily be isolated from sour milk or cheese), been able to prepare the optically active hydroxy-acids corresponding with tyrosine, phenylalanine, and tryptophan, which had not previously been obtained. Some fungi (e.g. *Monilia candida*) not only form the hydroxy-acid, but also act in a similar manner to yeast and convert a portion of the amino-acid into an alcohol by elimination of ammonia and carbon dioxide.

Urea, uric acid, and hippuric acid are hydrolysed by many moulds, the active agent being an enzyme present in the filtrates from cultures of the organisms (Kossowicz, Zeitsch. Gärungsphysiol. 1912, 1, 60, 121, 137; 2, 51).

Authorities.—A very copious literature now exists on the subjects of fermentation, enzyme action, and chemical action of bacteria. The chief works consulted in the preparation of the foregoing article, in addition to the original papers, are:

Lafar, Technische Mykologie (Gustav Fischer, Jena), 4 vols., vol. v. in progress.

Oppenheimer, Die Fermente und Ihre Wirkungen, 3 vols. (Leipzig, F. C. W. Vogel, 1909–10).

A. H.

FERNANDINITE. A hydrous calcium vanadyl vanadate $CaO \cdot V_2O_4 \cdot 5V_2O_5 \cdot 14H_2O$, forming compact masses of a dull-green colour or minutely crystallised in rectangular plates. It dissolves readily in acids to a green solution, and sufficiently in cold water to give a yellow solution. It occurs as an alteration product of patronite at Minasragra in Peru. L. J. S.

FERONIA GUM v. GUMS.

FERONUCLIN. Trade name for dry yeast extract.

FERRATES v. IRON.

FERRATOGEN or **FERRINOL.** Syn. for iron nucleinate.

FERRIC ACETATE v. ACETIC ACID.

FERRIC SALTS v. IRON.

FERRICHTHOL. Trade name for an ichthyl preparation of iron.

FERRITE. This term has unfortunately several different meanings. To the chemist it implies a salt in which ferric oxide plays the part of an acid, for example, barium ferrite $BaFe_2O_4$. In a mineralogical sense it was first applied by H. Vogelsang, in 1872, to an amorphous iron hydroxide, of unknown composition, which, as red and yellow particles, is present in many partially decomposed igneous rocks. In this sense the term is much used by certain petrologists for the patches of indefinite ferruginous alteration products seen under the microscope in thin sections of rocks. The same name has also been applied to ferruginous pseudomorphs after olivine occurring in the doleritic rocks of the neighbourhood of Glasgow (M. F. Heddle, Min. Mag. 1882, 1887). It has also been much used by metallographers, following H. M. Howe (The Metallurgy of Steel, 1890), for pure metallic iron, which, together with iron carbide, &c., forms one of the microscopic constituents of iron and steel. Later, the same name was applied by V. I. Vernadsky, in his Russian Treatise on Mineralogy (Petrograd, 1908), to native iron, for example, the terrestrial iron from Uifak on Disco Island, Greenland. L. J. S.

FERRITE (v. *supra*) the name given to the carbon-free constituent of steels. Usually it is nearly pure iron, but in special steels it may be an alloy of iron with silicon, chromium, tungsten, &c. Ferrite exists in three forms: α -iron, stable up to 760° ; β -iron, stable between 760° and 900° ; and γ -iron, stable above 900° . Of these, γ -iron is the hardest (Howe, Metallographist, 1898, i. 259). The freezing-point of ferrite is 1505° (Carpenter, J. Iron and Steel Institute, 1908, iii. 290; Saklatwalla, *ibid.* ii. 92).

Under the microscope ferrite is characterised by its softness, and the cubic structure revealed by deep etching with acids or cupric ammonium chloride (Andrews, Engineering, 1895, 88; Stead, J. Iron and Steel Institute, 1898, i. 145).

FERRITUNGSTITE v. TUNGSTITE.

FERROCHROME, **FERROMANGANESE,** **FERROSILICON,** **FERROTITANIUM,** **FERTUNGSTEN,** **FERROVANADIUM** v. IRON.

FERROCYANIDES v. CYANIDES.

FERROPYRINE (*Ferripyrene*). Trade name for antipyrine ferric chloride. Obtained by the interaction of antipyrine and ferric chloride in aqueous solution. Used as an hæmostatic and astringent.

FERROTYPE v. PHOTOGRAPHY.

FERROUS ACETATE v. ACETIC ACID.

FERTILISERS or **MANURES.** Either of these terms might properly be applied to any material added to the soil for the purpose of increasing its fertility, and, in this sense, would be extended to include lime, chalk, marl, and even clay and sand. In common practice, however, the term 'manure' or 'fertiliser' is restricted to materials the main function of which is to convey directly to the soil some constituent or constituents of plant food, to the exclusion of those of which the fertilising action is mainly indirect, consisting in the improvement of the physical condition of the soil or the

development of its inherent or natural chemical resources. The chief constituents of plant food which are naturally taken up from the soil are nitrogen, phosphorus, sulphur, potassium, calcium, magnesium, and iron, together with the less important constituents silicon, chlorine, and sodium. A manure or fertiliser, in the sense in which the term is ordinarily used, will always contain one or more of these substances.

Apart from calcium—the supply of which is necessary in special cases only—nitrogen, phosphorus, and potassium are by far the most important constituents to be applied as manure, as they are those in which the soil is most generally deficient.

In an efficient fertiliser the constituents must be in a condition suitable for immediate assimilation by the plant, or must be capable of speedily acquiring this condition after mixing with the soil. Manures or fertilisers are sometimes classified as 'natural' and 'artificial', but the dividing line is not always easily drawn. In the present article we shall briefly consider the principal substances employed as manures or fertilisers, passing on to some observations as to the general relative utility of some of them, and shall then refer to the special methods employed for their analysis.

Farmyard manure. Farmyard manure and stable manure are composed of litter mixed with the excreta of animals. The litter in farmyards is usually straw, but this has been to a large and increasing extent superseded in stables by dried and shredded peat moss. In some parts of the country bracken is used for litter, and in hop districts hop-bine is thus worked up into manure. The composition of the manure depends initially to some extent on the nature of the litter, but to a greater extent on the length of time the litter has been in use, the number and kind of animals littered on it, and the quantity and quality of the food consumed by them. Its final value—that is to say, its value at the time of its application to the land—is also largely governed by the mode of 'making,' and the mode and duration of storage. Its valuable effect on the soil may be said to be twofold. In virtue of the large quantity of bulky organic or carbonaceous matter that it contains, it improves the physical condition of the soil, making 'heavy' soils more 'open,' and 'light' soils more retentive. At the same time, it returns to the land the mineral matter and much of the nitrogen previously removed from it in the form of straw, as well as much of the nitrogen and most of the phosphoric acid and potash derived from home-grown fodder consumed during its production, reinforced by similar matter derived from the simultaneous consumption of additional purchased food.

The proportion of the nitrogen and manurially available 'mineral' matters absorbed and retained by animals from their food depends upon their age, condition, and other circumstances. Thus, a young growing steer, or a cow in milk, will assimilate more nitrogen and phosphates, and consequently void less in the form of faeces and urine, than will a fattening ox, which has already built up its frame and principal nitrogenous tissues, and is increasing

its weight mainly by the production of fat. Thus the quantity of nitrogen voided in faeces and urine might vary from more than 95 p.c. of the nitrogen consumed in the food to as little as 75 p.c. The proportion of phosphoric acid and potash voided will be greater. Obviously, in the case of horses, which only spend a portion of their time in the stable, only a fraction of the excreta will be mingled with the litter; and so also in the case of cattle which are turned out for a part of their time. It is manifestly only the stall-fed or yard-fed animal which contributes the whole of the nitrogen, phosphates, and potash which it voids to the actual manure heap.

Unfortunately for the farmer, the fertilising matter thus initially contributed to the manure is by no means all ultimately available for utilisation. Continual losses occur. These are at their highest in an open farmyard exposed to the weather, where more or less loss of the valuable soluble constituents of the manure is always going on by mere drainage, and where there is the greatest facility for the evaporation of ammonia. They are at their lowest where the animals are fed in close boxes, in which the litter is trodden down compactly in watertight pits; but even here there is constant loss by reason of fermentative action, not only through evaporation of ammonia, but also by the reduction of ammonia and other easily decomposable nitrogenous compounds into free nitrogen. The losses that thus occur have been studied by numerous investigators, including Lawes and Gilbert, A. Voelcker, J. A. Voelcker, Hall, Maercker, and Schneidewind, Holdefeiss, Müntz and Girard, Wood, Russell, and numerous others. The general result has been to show that, even under the best conditions of ordinary production, the loss of nitrogen may be expected to amount to about 15 p.c. by the time the manure is taken out of the boxes, while in shallow stalls or yards it may amount to 30 or 40 p.c. Further loss of nitrogen takes place after the manure is heaped or stacked for 'ripening,' or for preservation until it is convenient to transfer it to the land. It is probable that, even with fairly good management, the ultimate loss of nitrogen may amount on the average to 50 p.c. of the initial quantity. Under bad management, especially with open yards and free drainage, it is probably often much greater.

Various plans have been adopted or suggested for checking the loss, such as the use of gypsum or superphosphate sprinkled in the manure during its accumulation, to absorb ammonia; or of kainit, which checks fermentation. In any case the manure should be heaped as compactly as possible, with layers of earth in it, and the heap should be covered with earth. It has been demonstrated that the greatest percentage loss of nitrogen unfortunately occurs in the manure that is initially richest, namely, that produced by animals liberally fed on highly nitrogenous food.

It is obviously difficult to give an average composition for so variable a substance as farmyard manure, but broadly it may be said to consist of:

Water	about 75 p.c.
Organic and volatile matter	22 "
Mineral matter (exclusive of earth)	2½-3 "

But, as the water may vary from perhaps as little as 65 p.c. to over 80 p.c., the quantity of organic matter is liable to considerable inverse variation. The proportion of nitrogen is usually from about 0.45 to 0.65 p.c., that of potash from about 0.4 to 0.8 p.c., and that of phosphoric acid from about 0.2 to about 0.4 p.c.

Hall gives the following tables illustrating the general composition of farmyard manure, and also showing the influence of feeding on the nitrogen contents of the manure:—

COMPOSITION OF FARMYARD MANURE FROM VARIOUS SOURCES (HALL).

	Water	Nitro- gen	Phos- phoric acid	Potash
	p.c.	p.c.	p.c.	p.c.
1. Fresh long straw manure	66.17	0.544	0.318	0.673
2. No. 1 after rotting	75.4	0.597	0.454	0.491
3. Very old and short, from a mushroom bed	53.14	0.80	6.63	0.67
4. Fresh	75.0	0.39	0.18	0.45
5. Rotten } French data {	75.0	0.50	0.26	0.53
6. Very old	79.0	0.53	0.30	0.50
7. Rothamsted average	76.0	0.64	0.23	0.32
8. Fresh liquid manure	98.02	0.044	0.051	0.355

Straw manure will contain more potash than peat moss manure, but the latter contains more nitrogen. Stable manure is 'hotter'—that is to say, ferments more rapidly—than farmyard manure proper. Very large quantities are purchased from town stables by market gardeners and other farmers within easy carriage of cities. This largely consists of litter that a farmer would regard as only half used, owing to the necessity for the prompt clearing of town stables; and it is necessarily poor in soluble nitrogen compared with farmyard manure. Analyses by Dyer (tabulated by Hall) (see next column) illustrate the composition of specimens of such manure, made both with straw and with peat moss, fresh and after some months' storage in heap on the farm of the purchaser.

In addition to its 'mineral' constituents (phosphates, potash salts, &c.), well-made farmyard manure contains enough available nitrogen in the form of ammonia compounds and easily nitrifiable organic matters to enable it to begin to act as plant food immediately; while it has at the same time a reserve of

COMPOSITION OF LONDON STABLE MANURE (DYER—TABULATED BY HALL).

	From peat moss	From straw	From mixed peat moss and straw				
			Fresh		After storage		
			1	2	1	2	3

insoluble matter, partially decomposed organic matter which yields up nitrogen more slowly and gradually, the effect of much of which is realised only in subsequent seasons.

The duration of the action of farmyard manure largely depends upon the nature of the soil. In some 'open,' 'hot,' gravelly soils, farmyard manure is used up with remarkable rapidity. On other soils, its action may be spread over a considerable number of years; but in such cases its fertilising effect, especially on arable land, diminishes to an increasing extent each year, until, under the circumstances of ordinary farming, it becomes imperceptible. There are, however, experimental plots at Rothamsted, where, under circumstances peculiarly favourable to its operation, the effects of early dressings of farmyard manure are still evident after the lapse of 40 or 50 years.

The valuation of the unexhausted effect of farmyard manure in relation to the feeding stuffs consumed in producing it, is an important matter in the application of the Agricultural Holdings Act. This subject is fully discussed by Hall and Voelcker in a paper 'On the Valuation of the Unexhausted Manure obtained by the Consumption of Foods by Stock,' in the Journal of the Royal Agricultural Society of England, 1913, vol. 74 (also republished as a separate pamphlet by John Murray, of Albemarle Street, London, W.). In this paper the original valuation tables of Lawes and Gilbert were revised in the light of later investigation, and, with occasional revision to fit market prices, have been adopted by the Central Association of Tenant Right Valuers.

The general chemistry of farmyard manure has been well treated by Hall in his work on Fertilisers and Manures (Murray), and more fully recently by Russell and Richards (Journal Agric. Science, vol. viii. p. 495, 1917).

Peruvian guano. Guano was originally introduced into England from Peru in 1839, and for many years it occupied the first place among concentrated fertilisers. The original rich deposits have been for a long time exhausted, but considerable importations of Peruvian guano are still made, chiefly from recent deposits. Guano is formed from the excrement and carcasses of sea-fowl. The fresh excrements are highly nitrogenous, and consist chiefly of uric acid and calcium phosphate. If the climate is hot and dry, the excrements are quickly desiccated and the nitrogenous matter protected. These conditions exist on the rainless coast of

Peru. In a moist climate the nitrogenous matter is quickly converted into ammonia and dissipated by evaporation or drainage, a phosphatic guano practically destitute of nitrogen remaining. The main supply of Peruvian guano for 30 years was from the Chincha Islands, which yielded, in all, from what we may call the original deposits, about 10,000,000 tons. This guano was a dry, excellent fertiliser, containing from 13 to 14 p.c. of nitrogen, and from 13 to 14 p.c. of phosphoric acid. On its exhaustion, about the year 1868, guano was shipped from the Guanape and Macabi Islands. This was a damp guano containing from 9 to 11 p.c. of nitrogen, and about 12-14 p.c. of phosphoric acid. This was succeeded by importations, still from old deposits, from the Ballestas Islands and the islands of Lobos de Afuera, and deposits on the mainland at Pabellon de Pica, Punta de Lobos, and Huaniillos. Many of these deposits were of low nitrogenous content, but very rich in phosphates, while some possessed very much the character of the original Chincha guano. In more recent years shipments have been coming in from new deposits formed on the original islands, which have again become 'guaniferous,' the birds being now specially preserved with a view to the constant renewal of the deposits and the consequent maintenance of the output. These deposits of fresh guano are highly nitrogenous, and would be much richer in percentage composition but for the fact that a good deal of sand is sometimes unavoidably mixed with them.

The nitrogen in Peruvian guano is partly in the form of ammonia salts and partly in organic

combination; and in some cases small quantities of nitrate are also present. The main part of the phosphoric acid is in the form of finely divided calcium phosphate, some of the phosphoric acid also being in combination with ammonium, sodium, or potassium. Some of the phosphoric acid, therefore, is immediately soluble in water, while even that which is insoluble is readily attacked by weak acids and rapidly available as plant food. There is also present an appreciable quantity of potash salts. Guano is, therefore, an extremely valuable manure, and has always commanded relatively higher prices than most other concentrated fertilisers. Having regard to the great variation in the composition of different cargoes, it has been for many years the practice of the chief importers to prepare a mixed or 'equalised' Peruvian guano, containing a fixed percentage of nitrogen, for the sake of those users who wish for guano of constant composition; but the guano is also on sale in its unmixed or natural condition, at prices varying *pro rata* with its composition. It may be added that dissolved Peruvian guano, which was introduced by Messrs. Ohlendorff in 1864, and is still manufactured by their successors, the Anglo-Continental Guano Works, is Peruvian guano treated with sulphuric acid to fix the ammonia and render the phosphate nearly all soluble in water. It is a large article of manufacture, and is sold containing definite percentages of nitrogen and soluble phosphate.

Examples of analyses of Peruvian guano of different grades from several of the islands given below, are historically interesting.

Besides Peruvian guano, the only other nitrogenous bird guanos of commercial importance have been obtained from Patagonia and from the Ichaboe Islands off the coast of Africa. Ichaboe guano, being from fresh deposits, is rich in nitrogen, of which it contains from 9 to 14 p.c. Its general composition is similar to that of Peruvian guano of similar grade. An appreciable proportion of the nitrogen, however, is in the form of feathers.

Seaweed. This is largely used in some localities near the sea. When quite fresh, seaweed contains about 80 p.c. of water. Its composition varies a good deal. The nitrogen may be 1-3 p.c. of the dry matter. The average percentage of potash in 20 analyses of *Fucus* and

Laminaria was 3 p.c., and of phosphoric acid 0.5 p.c. of the dry matter. The proportion of nitrogen and potash in fresh seaweed is thus very similar to that in farmyard manure, while the phosphoric acid is deficient.

Fish manure or fish guano. Whole fish are employed as manure in places near the sea. Way found in fresh sprats 63.7 p.c. water, 1.94 p.c. nitrogen, and 2.1 p.c. ash, including 0.43 potash and 0.90 phosphoric acid.

Fish manure, or 'fish guano,' as it is called, is made on a considerable scale from various kinds of fish refuse. The Norwegian fish guano is prepared from cod. Herrings, sprats, menhaden, and other oily fish are boiled and pressed for the sake of their oil, and the residue is dried,

powdered, and sold as fish guano. This manufacture is carried on in various places on the east coast of England and Scotland. It is also carried on to a large extent in London, the raw material being the fish offal of the metropolis, which, for the most part, is simply dried and ground. The principal value of fish guano lies in its nitrogen, which may vary from as little as 6 or 7 p.c., to as much as 10 or 11 p.c. according to the particular kind of fish or fish offal from which it is made, and the presence or absence of much salt or other impurities. There is also a good deal of calcium phosphate, which usually varies inversely with the nitrogen, and may range from as little as 6 or 7 p.c. up to 18 or 20 p.c. The potash is inconsiderable. The following analyses represent different qualities of fish guano:—

The practical value of the manure depends to some extent on the quantity of oil present, the smaller the quantity of oil the more readily does the manure decompose in the soil.

Phosphatic guanos. The ancient deposits of guano occurring in climates in which rain is frequent have lost almost the whole of their nitrogenous matter; they are, when free from sand or rock, of value as phosphatic manures, but have been chiefly used for the manufacture of high-class superphosphates. Some of these guanos have been considerably altered by the action of water and other natural chemical agents. One common result of this action is the formation of 'crusts,' consisting largely of calcium phosphate containing considerably less calcium than tricalcium phosphate, and therefore of special value as manure. Gypsum is also present in some cases to a considerable extent.

The principal places from which phosphatic guanos have been obtained are various islands in the West Indies and in the Pacific Ocean. Those which more particularly retained some of the distinctive characters of guanos are now for the most part used up. More deposits are still occasionally discovered, but in many cases these deposits have become so metamorphosed that they have almost passed the border line between 'guano' and 'mineral phosphate,' which is sometimes not easily drawn. At all events, their function is not that of manure, but of a raw material for its manufacture, and for practical purposes they may be placed with mineral phosphates, to be considered presently.

Ammonium sulphate (commercially called sulphate of ammonia) usually contains from about 95 to 97 p.c. of the pure salt, containing 20–20.5 p.c. of nitrogen, equivalent to from 24 to 25 p.c. of ammonia.

Sodium nitrate (commercially called nitrate of soda) is refined from the crude native deposits (known as caliche), found in the rainless areas of Chile. Good commercial sodium nitrate contains about 95 p.c. of sodium nitrate or 15.6 p.c. of nitrogen (equivalent to 19 p.c. of ammonium). The impurities are moisture, sodium chloride, sodium and magnesium sulphates, small quantities of iodates and sometimes of potassium perchlorate, while in some makes sodium nitrate is partially replaced by potassium nitrate.

Potassium nitrate, or saltpetre, is sometimes used as a source of both nitrogen and potash, but chiefly in India, where it is a native product.

Calcium nitrate has recently been introduced as a fertiliser. Its chief interest at present lies in the fact that it is manufactured from nitric acid produced from the direct combination of atmospheric nitrogen and oxygen in the flaming electric arc. Its production is said to be already considerable, but from an economical standpoint it will assume larger importance in the future, when the present abundant sources of naturally formed nitrate come to an end. As put on the market at present, it contains about 13 p.c. of nitrogen (equivalent to about 15.8 p.c. of ammonium). Its chief fault in its present form is its extreme deliquescence, which makes it necessary to sow it directly the air-tight drums in which it is sent out are opened.

Calcium cyanamide is also a fertiliser made from the nitrogen of atmospheric air: which is passed through coarsely ground heated calcium carbide. The resulting mass contains a large proportion of calcium cyanamide, and contains about 18–20 p.c. of nitrogen. In moist earth it decomposes, yielding ammonia, according to the reaction $\text{CaCN}_2 + 3\text{H}_2\text{O} = 2\text{NH}_3 + \text{CaCO}_3$; but it is probable that other influences than mere moisture—connected probably with the microbic life of the soil—play a part in the production of ammonia. As calcium carbide is a product of the electric furnace, calcium cyanamide, like calcium nitrate, needs electric power for its production. For its manufacture *v. NITROGEN, ATMOSPHERIC, UTILIZATION OF*. It is put on the market under the name of 'kalk-stickstoff' on the Continent, or 'nitrolim' in England.

Some forms of calcium cyanamide, especially of a granulated type made by using excess of lime, contain considerable quantities of dicyandiamide, the action of which appears to be directly deleterious to some crops and to tend to inhibit nitrification in the soil (Voelcker, J. Roy. Agric. Soc. 1917; also Cowie, J. Agric. Sci. 1919, vol. 9, part 2).

Oilcakes. Cheap or damaged oilcakes, or cakes unfit for food (as castor), are employed to a considerable extent as manure, and more particularly the residual meals obtained as by-products in the extraction of oil by spirituous solvents from rape seeds, castor-oil seed, and numerous other oil seeds. They are in large request for hop manuring, and for general use on light soils, on which the farmer prefers a less rapidly active form of nitrogen than is furnished by guano, sodium nitrate, or ammonium sulphate. They will contain 4–7 p.c. of nitrogen, 1.5–3.0 p.c. phosphoric anhydride, and 1–2 p.c. potash.

Hoof and horn. The powdered horn obtained in making combs and other articles is

used to a considerable extent by manure manufacturers; it is extremely rich in nitrogen, containing about 15 p.c.

Dried blood. This is a very valuable manure, its nitrogenous matter becoming readily available to the crop after mixing with the soil. Perfectly dry blood will contain about 15 p.c. nitrogen and 4 p.c. ash, of which one-half is common salt. The commercial article contains from about 11 p.c. to about 13 p.c. of nitrogen. It is in growing demand for direct application to the soil, but the greater part both of the dried blood manufactured here and of that imported from South America is purchased by the manure makers and incorporated in compound fertilisers.

Meat meal, meat guano. The residue from the manufacture of meat extract is exported as manure from South America, and from Queensland and New Zealand. The composition varies much, chiefly according to the proportion of bone ground up with the meat. The nitrogenous samples may contain 11–13 p.c. nitrogen, and 0.6–3.0 p.c. phosphoric anhydride. The phosphatic samples may contain 6–7 p.c. nitrogen, and 14–17 p.c. phosphoric anhydride.

Shoddy and wool waste. These are useful nitrogenous manures, but much less active than those previously enumerated, being only slowly decomposed in the soil. They are less used than formerly, except for hops and market gardening, owing to the cheapness of ammonium salts. Pure dry wool and hair would contain about 17 p.c. nitrogen, and 2 p.c. ash. The percentage of nitrogen in ordinary shoddy varies from 5 to 8, the general average being about 7. Shoddy is apt to contain a good deal of water; the other impurities are cotton, oil, and mineral dust.

Leather. The percentage of nitrogen is 4–6. This is the least active form of nitrogenous matter used as manure; but there are various manufacturing processes—such as treatment with acids or with steam under high pressure—whereby the character of the leather as such is more or less destroyed, the result being a fine powder capable of undergoing more rapid decomposition, and having, in some cases, a large proportion of actually soluble nitrogen.

Soot. House soot is used by farmers as a top dressing for spring corn. Good soot contains about 4 p.c. of nitrogen or nearly 5 p.c. of ammonia (say 20 p.c. of ammonium sulphate), in which form the nitrogen largely exists, but it often contains an admixture of ashes, and consequently varies a good deal.

Bones. These are seldom used in their fresh state; they have generally been first steamed to extract the fat. A more perfect method of extracting the fat by means of benzene has been introduced (J. Soc. Chem. Ind. 1884, 375, 490, 575), but not much employed. Less nitrogenous matter is removed from the bone when benzene is used. A third form of bone is that left after extracting the greater part of the gelatinous matter by boiling under pressure. The analyses in next column illustrate the composition of bone manures.

Bones are either applied to the land directly as crushed bones, or as bone-dust or bone-flour; or they are employed for the manufacture of 'dissolved bone.' The soft parts of bone are

more nitrogenous than the hard parts. Bone-flour is a fine powder, prepared from highly steamed bones.

Bone ash. This is imported from South America. It was formerly much used for preparing high-class superphosphates, but is now less employed, owing to the abundance of cheaper phosphates. Pure ox bone ash will contain nearly 40 p.c. phosphoric acid. The commercial article is usually sold on a basis of 75 p.c. tricalcium phosphate.

Basic slag. By the process patented by Thomas (1877–79), the phosphorus is removed from pig-iron. The melted iron is placed in a Bessemer converter lined with lime, a large dose of lime is added, and the blast applied. At the high temperature reached, the impurities in the iron are oxidised by the air introduced, the phosphorus becomes phosphorus pentoxide and unites with the lime. A slag is formed containing about 40–50 p.c. lime, varying quantities of magnesia, alumina, iron oxide, manganese oxide, silica, and phosphoric acid equivalent to from 20 to 50 p.c. of tricalcium phosphate. The process has been adopted to a very large extent, and basic slag is now an important product of the iron and steel industry. It has been estimated that at the present time (1910) 300,000 tons are annually produced in Great Britain alone, and the continental production is very heavy.

For several years, however, the slag was regarded as valueless, the large amount of iron present leading agricultural chemists to believe that the phosphoric anhydride would not prove available to plants, while the ferrous oxide would probably be injurious. It is now known that the phosphoric anhydride in the slag is almost wholly combined with calcium, and that this calcium phosphate is easily disintegrated and rendered soluble in the soil, and that no ill effects arise from the presence of the ferrous oxide. Tetracalcium phosphate has been regarded as the combination in which most of the phosphorus occurs (Hilgenstock, Dingl. poly. J. 250, 330; Otto, Zeitsch. Chem. 11, 255; Bücking u. Zinck, Stahl u. Eisen, 7, 245); but it is probable that the phosphate has more nearly the composition $(\text{CaO})_5, \text{P}_2\text{O}_5, \text{SiO}_2$ (Hall). About 1.5 p.c. of the total phosphorus exists as iron phosphide, which is changed into phosphate in the soil (Jensch, Zeitsch. Chem. 10, 820).

The phosphate in the slag is not soluble in water; it is dissolved to a considerable extent by a solution of ammonium citrate, and when the slag is finely ground about 80 p.c. of it should dissolve in a 2 p.c. solution of citric acid.

Much basic slag is also now produced in the open hearth process. This is of lower grade of phosphorus content and, of low citric acid solubility owing to the use of calcium fluoride as a flux.

Field experiments with finely ground untreated slag commenced in 1882, and it was found to produce an excellent effect. The Germans were the first to realise the importance of the new manure, and they succeeded in purchasing in advance a large proportion of the English make.

To be effective the slag must be very finely ground; at least 80 p.c. of it should pass through a sieve having 100 meshes to the linear inch. The grinding requires special machinery. It is advisable, according to Horn (*J. Soc. Chem. Ind.* 1886, 242), to break first under stamps, to further reduce between rollers, then to separate pieces of iron by passing over slanting sieves, and finally to grind between millstones.

According to Wagner's trials, 2 parts of phosphoric acid in powdered slag (of which 80 p.c. passed a sieve with meshes 0.2 mm. diameter) are equal in manuring power to 1 part of soluble phosphoric acid in superphosphate; the effect will, however, vary in different soils.

Basic slag is especially valuable on moorland soils rich in organic matter and on clay soils deficient in lime on which the continuous use of superphosphate is undesirable. It has proved especially valuable on pastureland.

Precipitated phosphate. Phosphatic minerals which are unsuitable for the manufacture of superphosphate, either from their poverty in phosphate or from the presence of an objectionable amount of iron oxide or alumina, are sometimes treated with acid, the calcium phosphate dissolved out, and then recovered by precipitation. If the addition of the neutralising base is stopped while the solution is still acid, the precipitate will consist chiefly of dicalcium phosphate.

The phosphoric anhydride in precipitated phosphate stands next in value to that existing as monocalcium phosphate. Commercial dicalcium phosphate may contain as much as 40 p.c. P_2O_5 ; it is thus a very concentrated manure, and especially suitable for use where manure must be conveyed a long distance. Owing to the introduction of basic slag, however, it is now scarcely worth while to manufacture precipitated phosphate except as a by-product. It is thus prepared incidentally to the manufacture of gelatin from bones. The bones are treated with cold hydrochloric acid, which dissolves out the phosphate, leaving the chondrin or gelatinoid matter undissolved. The phosphate is then recovered from the acid solution by precipitation with milk of lime.

Superphosphate. The phosphates previously mentioned may be applied directly to the soil with good effect, if in the condition of fine powder. Natural mineral phosphatic deposits are, however, too hard and insoluble to be economically used in this manner; these are treated with sulphuric acid, and converted into superphosphates.

The treatment of bone with sulphuric acid was originally recommended by Liebig. The treatment of mineral phosphates with sulphuric acid originated with Lawes, who took out a patent for this process in 1842, and founded a manufacture which has since reached enormous dimensions.

Superphosphate in the United Kingdom is always sold on the basis of its percentage of what is called 'soluble phosphate.' This means the quantity of tricalcium phosphate which has been rendered soluble. The phosphoric acid (P_2O_5) soluble in water is determined and calculated into its equivalent percentage of $Ca_3P_2O_8$, this being called 'soluble phosphate.' On the continent of Europe the solubility is, on the other hand, calculated as 'soluble phosphoric acid,' i.e. P_2O_5 dissolved by water. The method of determination will be described later on.

Phosphatic Materials used.

Superphosphate was prepared by Lawes in the first instance from spent animal charcoal; Suffolk (Tertiary) coprolite and Estremadura phosphorite were also early employed. The Suffolk coprolite was for 15 years the principal material made use of. The far superior Cambridge (Greensand) coprolite then became for many years the chief material, but is now scarcely, if ever, used, other phosphates being much cheaper. Deposits rich in calcium phosphate have been found all over the world; many of these have been exhausted, and others given up as of inferior quality, or as being at present prices too expensive to work. We shall give some account both of some of those which have become matters of history, or the use of which is at present in abeyance from the effect of competition, as well as of those which are at present in use. The estimates given of the quantities of the various phosphates recently mined or raised are taken from a paper read at the International Congress of Applied Chemistry, in 1909, by Hermann Voss, who estimated the total output of raw phosphate in 1908 at the enormous quantity of 4,824,000 tons. This would represent in all something like $8\frac{1}{2}$ million tons of superphosphate.

South Carolina or Charleston phosphate. This is apparently a converted Eocene marl. It occurs in rough masses, largely perforated by boring mollusca, and associated with fossil bones and teeth. It is classed as 'land' and 'river' phosphate; the latter is obtained by dredging the Bull, Coosaw, and Stono rivers. This phosphate came first into use in 1867, and soon became the chief material for the manufacture of superphosphate. The quantity exported to the United Kingdom in 1887 was 165,275 tons (principally river phosphate); in the same year 430,549 tons were used in the United States. There are three grades, containing phosphoric acid equal to 50-52, 55-56, and 58-60 p.c. tricalcium phosphate; they differ simply in the proportion of silicious matter present. South Carolina phosphate, though not rich enough for the preparation of high-class superphosphates, is an admirable material for the production of an ordinary superphosphate, containing, according to the quality of the phosphate used, from 11 to 14 p.c. soluble phosphoric

acid, or, in commercial language, 24–30 p.c. soluble phosphate. Owing to the discovery of other deposits and to the local demand for this particular phosphate in the United States, it has at present practically ceased to be imported into England. The quantity of phosphate raised in 1908 in South Carolina and Tennessee is estimated by Voss at 800,000 tons.

Belgian and Somme phosphate. In the north of France (departments Somme and Pas de Calais) and in the adjoining districts of Belgium there exists an enormous deposit of a friable phosphatic rock, 'craie grise,' extending over seven million acres. This deposit lies on ordinary white chalk; it consists of yellowish grains embedded in a chalky matrix. The rock contains 20–30 p.c. of calcium phosphate, occurring in the crystalline grains above mentioned. In the upper layer of this deposit are pockets, chiefly developed in France, which contain a sand far richer in phosphate and poorer in carbonate than the underlying rock, the proportion of phosphate in this sand being 50–80 p.c. The sand has probably been formed from the original rock by the action of water. This phosphatic sand is known as 'Somme phosphate.'

The Belgian phosphatic rock is generally of low quality. By washing and blowing, a material containing 40–45 p.c. calcium phosphate is produced. Many schemes have been tried for removing the calcium carbonate, and thus raising the value of the material; none has yet become a commercial success. Belgian phosphate is used with other phosphates as a diluent; the carbonate it contains produces much gypsum when acted on by the sulphuric acid, and considerably improves the porosity and dryness of the manure. The export from Belgium to the United Kingdom is considerable.

One practical advantage possessed by the Belgian and Somme phosphates is that they require no grinding. Somme phosphate as imported goes entirely through a sieve of 60 wires to the inch. The output of Belgian phosphate in 1908 was estimated at 150,000 tons, and of Somme and other French phosphate at 350,000 tons.

Phosphorites. Large deposits of apatite, or of phosphates having an apatite character, occur in many places; those most worked have been the Estremadura, the Canadian, and the Norwegian. These, however, are not now brought to this country, and have for the present ceased to be worked.

1. *Estremadura phosphorite.*—An immense deposit occurs in Cáceres. In composition it is a fluor-apatite, but mixed with much quartz, and with more or less calcium carbonate. There are three qualities, containing about 50, 60, and 70 p.c. tricalcium phosphate. The calcium carbonate varies from 6 to 16 p.c. The exports were in former years very large, amounting sometimes to 60,000 tons per annum.

2. *Canadian phosphorite.*—This is much richer than the Estremadura phosphorite, containing 70–80 p.c. tricalcium phosphate. The lower qualities contain much mica. The amount formerly exported to the United Kingdom was considerable.

Caribbean phosphates. Under this head we group the rock phosphates found on many of

the West India Islands, some of which are often classed as phosphatic guanos.

1. *Aruba.*—This is one of the Dutch islands. The phosphate is of high quality, containing 75–80 p.c. tricalcium phosphate, but the imports now are small. The total quantity raised in 1908 is estimated at 30,000 tons.

2. *Curaçao.*—Another Dutch island. This, which is now being largely worked, is one of the finest phosphates available, containing about 85 p.c. tricalcium phosphate. With this phosphate, superphosphate may be made containing 44–45 p.c. soluble phosphate (20–20½ p.c. soluble P_2O_5).

3. *Sombrero.*—This valuable deposit is nearly exhausted. It contains 70–78 p.c. tricalcium phosphate.

4. *Monk and St. Martin's Islands.*—Both deposits are now exhausted; the former was of very high quality.

5. *Navassa.*—The deposit on this island has a well-marked pisolitic structure. The phosphoric anhydride is equivalent to 60–70 p.c. tricalcium phosphate. The use of Navassa phosphate is limited by the considerable amount of alumina and ferric oxide present, which makes it unsuitable for the preparation of high-class superphosphates.

6. *Redonda and Alta Vela.*—The phosphates of these islands consist chiefly of aluminium phosphate. They are quite unsuitable for the manufacture of superphosphate. They have been dissolved in sulphuric acid, and the alumina separated as alum. It has also been found possible to obtain a large proportion of the phosphoric acid as sodium phosphate by heating with sodium chloride in superheated steam, or by firing with sodium sulphate and carbon (J. Soc. Chem. Ind. 1886, 570).

Bordeaux phosphate. Raised in the departments of Lot and Tarn-et-Garonne. This is now little used in England, as it is not rich in phosphate, and contains a good deal of ferric oxide and alumina.

Nassau or Lahn phosphate. This is still used locally, but the exports to this country have ceased. It varies much in composition; the higher qualities are suitable for the manufacture of superphosphate, but the lower qualities contain much iron. This phosphate is remarkable as containing a distinct amount of iodine.

Coprolites. The phosphatic nodules commonly known as coprolites, found in England, are scarcely used now, cheaper phosphates being available. The Cambridge (Upper Greensand) coprolite was the best of the English sorts; it contained 55–60 p.c. tricalcium phosphate, without an admixture of ingredients prejudicial to the production of soluble phosphate. The Suffolk coprolite (Tertiary) contains less phosphate (55 p.c.), and more ferric oxide. The Bedfordshire coprolite (Lower Greensand) is still more inferior, the ferric oxide being present in increased proportion.

In France there are considerable deposits of coprolite in the Upper Greensand in the departments of Pas de Calais, Meuse, and Ardennes; those from Pas de Calais are shipped to England from Boulogne. These coprolites generally contain a low proportion of phosphate, and much silicious matter.

Florida phosphate. Extensive deposits of

high-grade phosphate have been opened up during recent years in the State of Florida. The phosphate is of two kinds, namely, 'hard rock' phosphate and 'pebble' phosphate. The rock phosphate commonly contains from 78 to 80 p.c. of tricalcium phosphate, and the pebble phosphate about 70-74 p.c. There is, however, also a high-grade pebble phosphate containing from 78 to 79 p.c. of tricalcium phosphate. These phosphates are very widely used in superphosphate. According to the estimates of Voss, 600,000 tons of Florida 'hard rock' phosphate and 900,000 tons of Florida 'pebble' phosphate were raised during 1908.

African phosphate. An extensive range of phosphate deposits is now worked on or near the northern coast of Africa, known in commerce as Algerian, Tunisian, Tocqueville, Gafsa and Egyptian phosphates. These are soft, powdery, or friable minerals, containing for the most part comparatively little silicious matter, but a large proportion of calcium carbonate. The proportion of tricalcium phosphate is commonly somewhere near 60 p.c., varying from about 59 p.c. to nearly 64 p.c. The quantities of North African phosphates mined in 1908 were estimated by Voss at over 1,500,000 tons. Some of them are now prepared in a finely ground state for direct application to the soil.

Christmas Island phosphate. This is a deposit found on Christmas Island—an island lying in the Indian Ocean south of Java. It contains about 87 p.c. of tricalcium phosphate, and makes excellent superphosphate. At present the output is said to be largely consumed in the manufacture of superphosphate in Japan.

Pacific phosphate. Valuable deposits of similar high-grade phosphates, containing 86 or 87 p.c. of tricalcium phosphate, accompanied by very little ferric oxide or alumina and practically no silica, have been discovered in recent years on certain islands in the Pacific Ocean lying to the north-east of Australia. The principal deposits at present worked are those of Ocean Island and Nauru Island, but deposits have also been found on the islands of Makatea, Tahiti, and Angaur. Much of the phosphate

raised on these islands is consumed for superphosphate making in Australia, New Zealand, and Japan. These phosphates in a finely ground state are also now sold for direct application to the soil.

Manufacture of superphosphate. The raw phosphate is first reduced to an extremely fine powder. Considerable improvements have now been effected both in the economy of the grinding and in the degree of fineness attained. If the material is in large lumps, it is first reduced by means of a crusher, and is then transferred to a suitable mill. The Kent mill is largely used for this purpose, and is worked in conjunction with a screen and elevator. The finer the powder obtained, the more complete will be the decomposition by the sulphuric acid. For first-class work the powder should pass through a sieve of 80 wires to the inch. In view of the stringency of modern factory legislation, a dust-collecting plant of some sort, such as the Beth filter, is usually considered necessary in the part of the works devoted to milling.

It has been assumed in some text-books that the reaction in superphosphate making is simply:

This is true as regards the major portion of the phosphate rendered soluble. But in practice, as was first pointed out by Ruffe (J. Soc. Chem. Ind. 1887, 327), the reaction, as regards an appreciable portion of the phosphate, almost invariably proceeds further, thus:

so that a water solution of superphosphate contains a major proportion of $\text{CaH}_4\text{P}_2\text{O}_8$, with a minor proportion of free phosphoric acid H_3PO_4 . Indeed, unless there is a fair proportion of the latter, the proportion of 'soluble' phosphate is unstable, owing to liability to reversion by subsequent interaction between the dissolved phosphate and that which was originally left undissolved. Thus well-made superphosphate, when freshly made, often contains as much as from 6 to 10 p.c. of H_3PO_4 , and sometimes more.

In the first stage of the reaction, phosphoric acid alone is probably produced, and this afterwards reacts on the remaining undecomposed phosphate. The proportion of free phosphoric acid in the resulting manure is greater when strong sulphuric acid has been employed, the total soluble phosphoric acid being, at the same time, diminished. When superphosphates are dried at 100° , a loss of soluble phosphoric acid also occurs, and this loss becomes much greater when a higher temperature is employed (Ruffe). Monocalcium phosphate can, in fact, exist only when in union with water.

A further reaction which is of great practical moment to the manufacturer of superphosphate is the disappearance of soluble phosphate by keeping. The regenerated insoluble phosphate is known as 'reverted phosphate.' This deterioration during storage is not observed in the case of well-made superphosphate prepared from finely ground mineral phosphate containing no appreciable quantity of iron or aluminium, but it is observed when ferric oxide or alumina is present.

So long as superphosphate is valued on the basis of its contents in soluble phosphate, ferruginous and aluminous phosphates will be avoided by the manufacturer. On the Continent, however, and in the United States, reverted phosphate has a considerable money value, and mineral phosphates containing iron and aluminium consequently find employment.

The sulphuric acid employed is usually pyrites-made chamber acid of 1.55 to 1.60 sp.gr. Weak acid is essential, as the dryness of the superphosphate depends largely upon sufficient water being present for the crystallisation of the calcium sulphate ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) formed by the reaction. It follows that, when much calcium carbonate is present in the phosphate, weaker acid will be required than when but little calcium carbonate is present. When calcium fluoride is present in considerable quantity, and very little or no calcium carbonate (as in apatite), acid stronger even than 1.60 sp.gr. is necessary, as calcium fluoride is not so readily decomposed as calcium carbonate.

The proportion of sulphuric acid to be used depends, of course, upon the composition of the phosphatic material. Theoretically, 100 of tricalcium phosphate will require 94 of sulphuric acid of sp.gr. 1.60 (55 p.c. SO_3), or 100 of sulphuric acid of sp.gr. 1.55 (51.5 p.c. SO_3), if monocalcium phosphate is to be produced. The proportion of sulphuric acid used in practice is usually as large as can be employed without endangering the dryness of the product. It is generally somewhat in excess of that needed to produce monocalcium phosphate, but is considerably below that required to yield only phosphoric acid. For South Carolina river phosphate, the ordinary proportion is 95 p.c. of sulphuric acid of sp.gr. 1.57.

The excess of lime present in the material (as carbonate or fluoride) is a principal factor in determining the quantity of sulphuric acid to be employed: 100 of lime will require 260 of acid sp.gr. 1.6 or 277 of acid sp.gr. 1.55 to produce calcium sulphate. At the foot of the table previously given will be found the excess of lime (over that required to form tricalcium phosphate) present in each of the mineral phosphates

commonly employed. Phosphates containing a considerable excess of lime will yield a poorer superphosphate than their percentage of phosphoric acid would seem to warrant, owing to the large proportion of sulphuric acid which they require.

To prepare a 'mineral superphosphate,' the only ingredients are the powdered phosphate and sulphuric acid. When turnip manures, or other manures containing a little nitrogen, are prepared, crushed bones, powdered hoof and horn, shoddy, or ammonium salts, are added when the ingredients are mixed. Mixed superphosphates, formerly called 'dissolved bones,' are usually prepared from a mixture of mineral phosphate, bone, and some concentrated nitrogenous matter.

Owing to the requirements of the Fertilisers and Feeding Stuffs Act, however, such mixtures are now sold as 'dissolved bone compounds,' the term 'dissolved bone' or 'vitriolised bone' being restricted to fertilisers made from pure bone and acid only. Usually, in such cases, only from one-half to two-thirds of the phosphate is actually soluble in water, but much of the remainder is in the readily assimilable form of dicalcium dihydrogen phosphate. If enough acid were used to dissolve all the phosphate, the product would be too pasty for sowing.

The mixer in which the reaction takes place stands on a platform, over an empty chamber, variously known as the 'bin,' 'den,' or 'pit.' It consists of a cylinder, sometimes nearly horizontal, sometimes vertical, furnished in the centre with a revolving shaft, carrying arms set on screw-wise. Into this mixer the charge of weighed 'dust' is emptied, bag by bag, while, at the same time, a measured quantity of sulphuric acid is run in from a tank. When the charge is completed, agitation is continued for two minutes; a valve is then opened, and the whole contents of the mixer (about 16 cwt.) allowed to fall into the pit below. Ten charges can be easily worked in one hour. The pit below is built of brick or concrete on three sides, the fourth side consists of a wooden hoarding which is taken down when the pit is being emptied. A pit will hold from 80 to 140 tons. The fluid material which enters the pit rapidly reaches a temperature considerably exceeding 100° , and then becomes solid. In a few hours it is ready to be excavated.

Formerly the excavation of the superphosphate was accomplished by the simple means of digging it out by the aid of pickaxes. At the present time, however, manual labour is being gradually superseded by the use of mechanical appliances, many patents for inventions for doing this part of the work having been taken out. Among these, one of the best known is the superphosphate excavator of Dr. A. Keller, of the Anglo-Continental Guano Works of London, Hamburg, Antwerp, and Düsseldorf, which is now in successful use in various parts of the world. This machine consists of an arm extending from a staging, which latter travels upon metals laid in front of the pit; the arm is furnished with travelling knives and scrapers, and it revolves on a pivot around the staging as a centre, so that it can be swung in and out of the pit and be made to reach to the extreme back part of it. When the

knives and scrapers are set in motion, the superphosphate is scraped forward and dropped on to a conveyor traversing the front of the pit, whence it can be elevated and conveyed to the part of the works where it is required to be stored. The machine is so constructed that the arm is made to move from left to right and *vice versa*, and lower itself automatically as the superphosphate is removed.

The gases given off during the reaction, both from the mixer and pit, are of a particularly unpleasant description, especially when the phosphate contains fluorides. Both mixer and pit are provided with flues in connection with a fan, by which all the gases are removed; these are purified in a scrubber, and then conducted to a tall chimney.

Well-made superphosphate is a porous mass, the cavities being due to imprisoned gas. It is usual to break up the lumps at the time of manufacture by passing it through a rotary screen, and to further grind and screen it after storing and before delivery. If mixed manures are to be made, the other ingredients are added while passing through the disintegrator.

By adding ammonium sulphate or other nitrogenous material, with or without potash salts, 'corn,' 'grass,' 'mangel,' and 'potato' manures are produced. Sodium nitrate cannot safely be added to superphosphate unless the latter is very dry; if this precaution is neglected, free nitric acid is produced, the manure bags are destroyed, and serious mischief may occur. To employ ammonium sulphate and sodium nitrate together is still more objectionable, as ammonium nitrate is formed, and even when it does not suffer decomposition it ruins the manure by its deliquescence.

Ordinary superphosphate is made from a mixture of phosphates, and contains 26 p.c. of dissolved phosphate (=11.9 p.c. P_2O_5) and 2-3 p.c. of undissolved phosphate. The turnip manures containing bone have generally rather less of dissolved phosphate, more of undissolved, and nearly 1 p.c. of nitrogen. Special manures of greater strength are also prepared. From high-class phosphate, superphosphate containing 30-31 p.c. dissolved phosphate (13.7-14.2 P_2O_5) may be obtained. High-grade Florida rock will yield superphosphate containing 38-39 p.c. dissolved phosphate (17.4-17.9 P_2O_5). From Ocean Island and Christmas Island phosphates, superphosphate with 44-45 p.c. dissolved phosphate (20.2-20.6 P_2O_5) may be prepared.

Far richer superphosphates are obtained by the process patented by Packard (Eng. Pats. 6176, 6750, 6752). Superphosphate, prepared so as to be rich in free phosphoric acid, is extracted with water, the solution evaporated to sp.gr. 1.125-1.300, and sufficient calcium phosphate, carbonate, or hydroxide added to leave one-third of the phosphoric acid in the free state. The solution is then filtered, and the filtrate evaporated to dryness. The product contains about 40 p.c. of soluble phosphoric acid, equal to 87 p.c. of so-called 'soluble phosphate.' This superphosphate has a special value where manure has to be conveyed a long distance.

There is a large export trade in English-made superphosphate.

Gypsum. This has in most cases a very small value as a manure. Where superphos-

phate is employed, it is applied in this manure. Massive gypsum is imported from the South of France. It was formerly used as a diluent in making the lower-class of superphosphates, but its place is now taken by Belgian phosphate. It is an excellent drier for mixing with damp manure.

Lime, chalk, and marl. These can hardly be classed as artificial manures, as they are not generally applied as plant foods, but for the sake of the considerable amelioration of the soil which they effect.

Potassium salts. These will be found described under their own head.

THE RELATIVE VALUE OF MANURES.

We have described as briefly as possible the various nitrogenous and phosphatic manures at present used. The important question remains, Have the nitrogen and phosphoric acid the same value in all these manures? and, if not, what is the difference of value? This question may be considered from (1) a trade point of view, viz. by calculating from the market price of various manures what is the money value of their chief constituents. If the prices given for manures were determined by an accurate knowledge of their effect in the field, these prices would really show us their average relative value. As a fact, market prices do generally indicate, though sometimes very imperfectly, the relative manuring value of different manures. The matter may also be considered from (2) the data afforded by actual investigation. In this case, we soon find that the number of available investigations is insufficient, and that the relative value of the same manures differs more or less with differences in the soil, crop, and season. Certain points, however, are fairly well established.

Nitrates are, in a large majority of cases, the most active, and therefore the most valuable, form of nitrogen. Comparisons between sodium nitrate and ammonium salts, containing similar amounts of nitrogen, have been made for many years at Rothamsted, and also at Woburn. With cereal crops the nitrate, on an average, yields distinctly more corn and considerably more straw than the ammonia. The produce by the nitrate is most in excess in dry seasons; in a wet season the ammonia may be superior. On pasture, the relative superiority of the nitrate is about the same as with cereals. With potatoes, ammonia, apparently, is equal to nitrate. With mangel-wurzel, or sugar beet, the nitrate is far superior. A good result with ammonium salts is much more dependent on the presence of abundance of phosphates and potash in the soil than is the case with nitrates. Nitrates and ammonium salts, in favourable circumstances, give all their effect in the first year of their application.

Cyanamide, under favourable conditions, gives results similar to those obtained from a corresponding quantity of ammonium sulphate, but its action depends upon its time of application and upon suitable weather, and probably upon the texture and composition of the soil, as well as on biological considerations. It is best used after admixture with superphosphate, though it has the incidental effect of 'precipitating' soluble phosphate. It is not a pleasant

substance to handle in its raw condition, and, if sown alone, it should be sown by means of a mechanical distributor.

The effect of organic nitrogenous manures differs in different soils. In a clay soil, bones decompose so slowly as to be of little value. Organic manures, as shoddy, oilcake, bones, and farmyard manure, yield only a small portion of their nitrogen to the crop during the first year, and several years will elapse before the supply is exhausted. The continued use of such manures increases the proportion of nitrogen in the soil. The proportion of the nitrogen in the manure that is recovered in the crop is frequently smaller than that obtained under favourable circumstances in one season from the application of sodium nitrate, the slowly acting manures being, in the case of arable land, subject to an annual loss of nitrogen as nitrates by drainage. Organic nitrogenous manures are more active in proportion as they are finely divided, and when applied to a well-aerated soil. They are best applied in autumn, while nitrates and ammonium salts should be applied in spring.

Pot culture experiments have been made by Wagner on various nitrogenous manures. If the crop yield obtained from sodium nitrate be represented by 100, the relative efficacy of a like quantity of nitrogen supplied in other fertilisers proved to be as follows:—

Sodium nitrate . . .	100
Ammonium salts . . .	94
Peruvian guano . . .	87
Green plants . . .	77
Horn meal . . .	74
Dried blood . . .	73
Castor cake . . .	73
Wool-dust . . .	26
Cow manure . . .	22
Leather meal . . .	16

But it does not necessarily follow that these figures represent the relative value of the fertiliser in all the varied conditions of practical farming. This subject is being investigated by field trials at Rothamsted.

The relative value of different forms of phosphates has been a subject of much controversy. Some mineral phosphates (as apatite) having been found almost useless as manure, it was too hastily concluded that (with the exception of bone and guano phosphates), only phosphates soluble in water were effective. It has been maintained that very fine grinding will render any phosphate as available as soluble phosphate.

In considering the subject we should bear in mind that the phosphates in the soil, on which plants feed, are not soluble in water, drainage waters being free from phosphoric acid. Soluble phosphate when applied to a fertile soil is quickly precipitated, and is generally finally converted into a hydrated ferric or aluminium phosphate. The practically insoluble phosphates of the soil are dissolved by the acid sap of the root hairs immediately before absorption by a crop or by the carbonic-acid-laden water of the soil.

One great advantage possessed by a phosphate soluble in water consists in its diffusibility. When rain falls after an application of superphosphate, the phosphoric acid is distributed in the soil more perfectly than can be achieved by any other mode of application, and consequently

a greater number of root hairs may come in contact with it. Superphosphate is thus more immediately effective than any other form of phosphate. The superiority of superphosphate is, however, not shown in the case of some soils very poor in lime, and in which any additional supply of acid matter is hurtful to the plant; in such cases an assimilable undissolved phosphate may produce a better result.

In view of this, an article known as 'basic superphosphate' is, on the suggestion of Mr. John Hughes, sent out by various manufacturers. It consists of superphosphate neutralised by admixture with sufficient lime to convert the originally soluble phosphate into 'precipitated' or 'reverted' phosphate.

On such soils (poor in lime), basic slag, Peruvian guano, or fine bone meal, also find an appropriate place.

Numerous experiments have been made regarding the assimilability of mineral phosphates when finely ground. It appears that apatites and other crystalline phosphates not disintegrated in the soil, have a very small effect as manure even when finely ground. The small crystalline grains of the Somme phosphate lie in this category. The majority of mineral phosphates are, however, effective as manure when very finely ground, but to a different extent on different soils. The conditions favourable to the use of undissolved phosphates are presence of humus and absence of lime. On the moor soils of Germany, where such conditions prevail, basic slag has had its greatest success. A calcareous soil is the one most unsuitable for the use of undissolved phosphates, calcium carbonate offering a great resistance to the solution of calcium phosphate (Chem. Soc. Trans. 1866, 313).

It is generally admitted that precipitated dicalcium phosphate is nearly equal in effect to soluble phosphate. Phosphates that are soluble in ammonium citrate (including the reverted phosphate of superphosphate) may be safely regarded as assimilable by plants; in America they are regarded as of about equal value with water-soluble phosphate; that they are so always is certainly open to doubt. Phosphates that are insoluble in ammonium citrate are often effective as manure. Ammonium citrate gives thus no safe distinction between assimilable and non-assimilable phosphates, though it affords a useful approximate means of determining 'reverted' phosphate in superphosphate.

As a measure of ready availability in basic slag, a 2 p.c. solution of citric acid has now superseded ammonium citrate.

SPECIAL METHODS OF ANALYSIS.

The enormous quantity of artificial manures bought and sold upon the results of analysis has led to great attention being paid to the question of accurate and speedy analytical methods. To enter into a discussion of all the methods which have been suggested, or even of those which have been 'officially' recognised by the associations of agricultural analysts in different countries, is here impossible.

In the analysis of fertilisers, the object is sometimes merely the determination of a definite fact, such as the percentage of total nitrogen or the percentage of total phosphoric

acid. In such cases there are divers processes serving to arrive at the same results. Sometimes, however, the analysis is needed for such a purpose as the determinations of 'soluble' phosphate. Here much depends upon the interpretation of the word 'soluble,' since solubility depends not merely on the nature of the solvent, but upon its proportion to the material acted upon and the mode and duration of its application. It is therefore necessary to define 'solubility' before determining it. Unfortunately, different interpretations of solubility have been in vogue in different countries, causing occasional confusion in international trade, but recent efforts to arrive at international agreement have been attended with some measure of success.

ANALYSIS OF RAW MINERAL PHOSPHATES

Determination of phosphoric acid. The phosphoric acid in mineral phosphates may be accurately determined either by the use of molybdic acid or by what is sometimes called the citric-oxalic-magnesium process, without the intervention of molybdic acid.

There are several modifications of the molybdate process which give fairly accurate and therefore concordant results in the hands of careful workers. Their one common disadvantage is that the quantity of sample represented in the portion of solution finally worked upon is necessarily smaller than in the alternative procedure, and consequently any errors due to inaccuracy of calibration of flasks or pipettes or to lack of exactness in using them, are correspondingly multiplied; and the same observation obviously attaches to errors incidental to the washing of precipitates, the efficiency of filters, and the operations of weighing. There is cogent reason for supposing that many disagreements sometimes attributed to the use of alternative processes are due to insufficient appreciation of some of these sources of error, or to the non-observance of the precautions necessary to avoid them. Considerations of the pecuniary cost of molybdic acid sometimes afford a temptation to operate on far too small a scale, and this temptation should be resisted. Thus, many continental analysts were for years content to operate on as little as 0.2 gram of raw phosphate. In such a case, a single milligram of magnesium pyrophosphate (the form in which the phosphate is weighed) is equivalent to approximately 0.7 p.c. of tricalcium phosphate—a grave consideration in the case of large cargoes, the price of which is exactly adjusted to the results of analysis, even to the second place of decimals.

Two modifications of the molybdic process as applied to the analysis of raw mineral phosphates may be given, the first being that of G. Jörgensen, who has devoted much time and attention to the matter, the other that communicated by Dr. M. Ullmann, on behalf of the Verein Deutscher Dunger-Fabrikanten, to the International Congress of Applied Chemistry in London in 1909. Jörgensen's process was originally published in Denmark, but an account of it, communicated by himself, is published in the Analyst, 1909, 34, 392. As there are some differences of detail between the processes, both of which yield accurate results,

they may be given side by side. It will be seen that Jörgensen operates finally on a quantity corresponding to 1 gram of the original material, whilst in Ullmann's process the quantity is halved. 1 gram can, however, be equally well taken by doubling the quantity of reagents.

Reagents used.

	Solvent.	
Jörgensen.	Ullmann.	
Nitric acid of sp.gr. 1.21.	Aqua regia (3 parts hydrochloric acid of sp.gr. 1.12, and 1 part nitric acid of sp.gr. 1.2).	

Molybdic Solution.

100 grams of ammonium molybdate are dissolved in 280 c.c. of ammonia of sp.gr. 0.97, and 300 c.c. of this solution poured with vigorous shaking into 700 c.c. of nitric acid of sp.gr. 1.21, the mixture being allowed to stand for 24 hours.

150 grams of ammonium molybdate are dissolved in 500 c.c. of water. This solution and a separate solution of 400 grams of ammonium nitrate are mixed and made up to 1 litre. The mixture is poured into 1 litre of nitric acid of sp.gr. 1.2, and allowed to stand for 12 hours at 60°, or for 24 hours at the ordinary temperature.

Wash Fluid for Molybdic Precipitate.

40 grams of ammonium nitrate and 10 grams of nitric acid per litre. The author prepares this by mixing 90 c.c. of nitric acid of sp.gr. 1.4 with about 1500 c.c. of water, adding 80 c.c. of ammonia of sp.gr. 0.91 and making up to 2 litres.

32 grams of nitric acid of sp.gr. 1.2 and 50 grams of ammonium nitrate, made up to 1 litre.

Magnesia Mixture.

50 grams of pure crystallised magnesium chloride and 150 grams of pure ammonium chloride, dissolved and made up to 1 litre.

50 grams of pure crystallised magnesium chloride and 150 grams of pure ammonium chloride, dissolved and made up to 1 litre.

Wash Fluid for Ammonium-Magnesium Precipitate.

Ammonia solution containing 2½ p.c. NH₃. (This may be made by diluting 100 parts of ammonia of sp.gr. 0.91 with water to 1 litre.)

Ammonia solution containing 2½ p.c. NH₃.

Method of Jörgensen. Five grams of the mineral phosphate are dissolved in 20 c.c. of nitric acid in a 250 c.c. flask. After gentle boiling for 15 minutes, the contents of the flask are cooled, made up to 250 c.c., and filtered. To 50 c.c. of the filtrate (=1 gram of the phosphate)

in a beaker-flask, 165 c.c. of the molybdc solution are added, and the flask and its contents placed in a water-bath at a temperature of 50° for 10 minutes, with occasional stirring. After cooling and standing, the supernatant liquid is poured through a filter and the precipitate is washed 10 times by decantation with the acid ammonium nitrate solution, about 20 c.c. being used for each washing. The filtrate should be tested with more molybdc solution to see that the precipitation is complete. The washed precipitate is dissolved in 100 c.c. of $2\frac{1}{2}$ p.c. ammonia solution, and filtered, if necessary, through the filter which served for its separation, the filter being washed 8 times with ammonia solution, until the final volume is about 180 c.c. The beaker-flask is covered with a clock-glass, the contents brought just to boiling-point, and 30 to 35 c.c. of the magnesia mixture added drop by drop from a burette, the whole being well stirred and allowed to cool with frequent stirring as long as it remains. If the precipitate is not compact and crystalline, the stirring during this time should be continuous. After standing for at least 4 hours, the precipitate is filtered off, using a platinum (Gooch) crucible packed with spongy platinum, and washed with the $2\frac{1}{2}$ p.c. ammonia solution until free from chlorides, and once with alcohol. It is then dried, heated (at first gently), and then ignited strongly, cooled, and weighed as $Mg_2P_2O_7$.

Method of Ullmann. To 5 grams of the phosphate in a 500 c.c. flask, 50 c.c. of *aqua regia* are added, the whole being evaporated nearly to the consistency of syrup for the elimination of silica. The residue, after setting to an approximately solid mass, is taken up with 10 c.c. of nitric acid (of sp.gr. 1.2) and 50 c.c. of water, boiled, cooled, made up to 500 c.c. with water, and filtered. 50 c.c. of the filtrate ($=0.5$ gram of the phosphate) are treated with an excess of molybdc solution (at least 100 c.c. for every 0.1 gram of P_2O_5), and digested in a water-bath at 50° for 1 hour. After sufficient standing, the supernatant liquid is poured through a small close filter, and the precipitate washed repeatedly by decantation until free from calcium. At least five washings with 20 c.c. each time are recommended. The filtrate should be tested with molybdc solution to see that the precipitation has been complete. The precipitate is dissolved with from 80 to 100 c.c. of the $2\frac{1}{2}$ p.c. ammonia solution, and filtered through the same filter which served for its separation. The filter should then be washed five or six times with hot water, until the total volume of the solution is from 130 to 150 c.c. The solution is warmed to 60° or 80° , and immediately precipitated with 20 c.c. (or a sufficiency) of the neutral magnesia mixture, added drop by drop with constant stirring. After at least 4 hours' standing, followed by half an hour's stirring, the precipitate is allowed to rest, filtered, and washed with $2\frac{1}{2}$ p.c. ammonia solution until the washings are free from chlorine. The precipitate is dried, gently heated, ignited to constancy, and weighed as $Mg_2P_2O_7$.

CITRIC-OXALIC-MAGNESIUM PROCESS.

The phosphoric acid (and incidentally the lime) may be correctly determined in the following way. Two grams of the mineral

phosphate are treated with 25 c.c. of strong hydrochloric acid in a beaker covered with a clock-glass to avoid loss by spraying. After a few minutes' warming, the clock-glass is washed back into the beaker and removed, the beaker being placed in a water-bath and the contents evaporated to dryness. This results in the elimination from solution of not only silica, but of fluorine compounds, the removal of which is essential to the accuracy of the process. Mere evaporation to dryness with a small quantity of hydrochloric acid is insufficient to ensure this removal. It is necessary to use at least the large quantity of acid specified (25 c.c.), so that its evaporation may extend over several hours. (The non-observance of this precaution is a fruitful source of error, resulting in the subsequent formation of magnesium fluosilicate and consequent over-estimation of phosphoric acid.) The dry residue is taken up with 5 or 10 c.c. of hydrochloric acid and about 20 c.c. of water, and warmed. The silica, together with pyrites or other insoluble matters, is filtered off and thoroughly washed. To the filtrate and washings (measuring about 150 c.c.), 4 grams of powdered citric acid are added and 3 to 4 grams of powdered ammonium oxalate. The solution is heated nearly to boiling, and rendered just alkaline with dilute ammonia (sp.gr. about 0.970) and excess of acetic acid is immediately added and the liquid is boiled for a few moments. The calcium oxalate is immediately filtered off and washed several times with boiling water, dried, and ignited over a yellow argand flame, and weighed as $CaCO_3$. The precipitate contains all the calcium. It may contain very minute quantities of ferric oxide, aluminium oxide, or manganese oxide, and a minute quantity of phosphoric acid. On this account the precipitate, after being weighed, is dissolved in dilute hydrochloric acid, the solution being boiled and treated with a slight excess of recently diluted ammonia. The small precipitate which forms is filtered through a small filter, washed, and re-dissolved in a little dilute acid, the solution being boiled and again treated with a slight excess of ammonia. The precipitate is washed, ignited, and weighed. If this small precipitate weighs only 5 or 6 milligrams or less (as is usually the case in the hands of a practised worker), it may be assumed that the precipitate contains P_2O_5 equal to half its own weight of $Mg_2P_2O_7$, this assumption being based on the analysis of a large number of such precipitates. But if, owing to unskilful work or to any peculiarity in the mineral under investigation, the quantity is greater, the little precipitate may be re-dissolved in hydrochloric acid, with the addition of about 0.1 gram of citric acid, and its solution added to the original filtrate from the calcium oxalate precipitate.

This filtrate is made strongly ammoniacal and the phosphoric acid precipitated by the gradual addition of magnesium mixture, a large excess being finally added. The gradual addition and vigorous stirring are both necessary to ensure that the precipitate comes down in a compact crystalline form. The whole bulk at this stage will be about 350 c.c. After 2 to 3 hours, during which the liquid is frequently stirred—or after standing, if more convenient, over-night—the greater part of the liquid is

decanted off through a close filter, leaving about 40 c.c. of it in the beaker with the precipitate. The filter is washed with dilute hydrochloric acid, the washings being used to redissolve the precipitate in the beaker. After complete re-solution, the contents of the beaker are rendered ammoniacal by slowly dropping in dilute ammonia with vigorous stirring until the precipitate assumes as before a dense crystalline form. Excess of ammonia solution (sp.gr. 0.880), equal to about one-fifth or one-sixth of the bulk of the liquid, is added and the whole allowed to stand with occasional vigorous stirring for at least one hour. The precipitate is then filtered, washed well with ammonia (sp.gr. 0.970), dried, ignited, and weighed as $Mg_2P_2O_7$.

The re-solution and second precipitation of the ammonium magnesium phosphate is an essential feature of the process, since in the first precipitation small quantities of magnesium oxalate are usually formed. The non-observance of this precaution has been a frequent source of 'high' results.

The presence of ammonium citrate and ammonium oxalate results in the retention in solution of a minute quantity of P_2O_5 . In earlier days it was usual to precipitate the ammonium magnesium phosphate, in a flocculent form, by the sudden addition of ammonia and magnesium mixture, and under these circumstances (*see*, for example, the original directions of Fresenius) a very substantial correction was necessary for solubility of the precipitate. Crystalline precipitation, however, reduces this to a minimum, and the accurate determination by molybdic acid of the phosphoric acid in the evaporated and ignited filtrates obtained in a large number of analyses of numerous grades and varieties of phosphate indicates that, if the process be carried out as here described, the quantity of P_2O_5 which escapes precipitation corresponds to an average of approximately 0.0025 gram of $Mg_2P_2O_7$, which quantity must be added to the weight of $Mg_2P_2O_7$ obtained, together with half the weight of the small ammonia precipitate (obtained from the calcium oxalate precipitate), unless this was redissolved into the main filtrate (*see* above).

If the precautions herein set forth are observed, the results will be identical with those obtainable by the accurate working of the molybdic process as defined by Jörgensen or by Ullmann.

DIRECT MAGNESIUM PRECIPITATION WITHOUT REMOVAL OF CALCIUM.

This process consists in adding to the acid solution of the phosphate a large excess of citric acid, sufficient to prevent calcium precipitation, and of ammonia, and in the direct precipitation of the phosphoric acid by magnesium mixture, without re-solution. This process (with certain precautions) answers well for basic slag (*see* later), and in some hands appears to give good results with mineral phosphates. It does not, however, answer equally well for all phosphates, and the result, even when accurate, owes its success to a balance of positive and negative errors, since the precipitate finally weighed does not consist of pure $Mg_2P_2O_7$, as is assumed to be the case. For rough work, as in phosphate prospecting, when an error of 0.5 p.c. or so is

of no moment, it is excellent, being expeditious and involving a minimum of trouble. It is essential that silica should be eliminated by preliminary evaporation of the acid solution to dryness as in the preceding section.

DETERMINATION OF FERRIC OXIDE AND ALUMINA IN MINERAL PHOSPHATES.

The solvent used should be hydrochloric acid rather than *aqua regia*. The latter is sometimes recommended. For many phosphates it is perhaps immaterial which solvent is used. But some phosphates (such as American river pebble phosphates) contain much pyrites. If *aqua regia* is used, this is dissolved and included as ferric oxide—which is misleading, seeing that pyrites is not attacked by the sulphuric acid used in superphosphate making, and is consequently non-injurious. It should, therefore, be eliminated with the silica, as is the case if hydrochloric acid be used as the solvent.

There are two methods in use which accurately determine ferric oxide and alumina.

ACETATE METHOD.

Two grams of phosphate are treated with strong hydrochloric acid. The solution is evaporated to dryness and the residue redissolved in acid and water and filtered from the silicious residue. The filtrate is oxidised by addition of bromine water until orange coloured, nearly neutralised with ammonia, cooled and precipitated with a good excess of ammonium acetate solution containing an excess of acetic acid. After standing some hours, the precipitate is filtered off and washed with hot water.

The bulky precipitate contains all the ferric oxide and alumina (as phosphates), together with a varying quantity of calcium phosphate. It is dried, ignited, and weighed. It is then dissolved in a very small quantity of hydrochloric acid and about 1 gram of citric acid and 0.5 gram of ammonium oxalate added, slight excess of ammonia, and then excess of acetic acid. After simmering gently for half an hour the calcium oxalate is filtered off, ignited, and weighed as carbonate. The phosphoric acid is then determined, exactly as in the citric-oxalic-magnesium method of phosphate analysis already described—except that the operation is conducted all through in solutions of very small bulk. The sum of the lime and phosphoric acid deducted from the weight of the ammonium acetate precipitate will give the ferric oxide and alumina. The iron is determined by precipitating the total filtrates and washings from the precipitation and reprecipitation of the ammonium magnesium phosphate with ammonium sulphide. If allowed to stand for an hour or two at a temperature of about 80°C., the precipitate settles well, and may be rapidly filtered, washed with hot water to which a little ammonia and ammonium sulphide are added, ignited strongly and weighed as Fe_2O_3 . The alumina is obtained by difference. The method is tedious, but accurate.

MODIFIED GLASER METHOD.

The following method, modified from that of Glaser (which originally, but incorrectly, assumed a constancy of composition of the precipitate of mixed phosphates) is somewhat shorter, and

gives results identical with those obtained by the method just described.

Four grams of the phosphate are treated with about 25 c.c. of strong hydrochloric acid and evaporated to dryness. The residue is taken up with 10 c.c. of strong sulphuric acid, about an equal bulk of water being cautiously added. After digestion in a water-bath for about $\frac{1}{2}$ hour, the cake of calcium sulphate is well broken up by stirring with a glass rod, and the whole contents of the beaker are washed into a 200 c.c. flask with ordinary strong alcohol (methylated spirit), and allowed to remain for an hour with frequent shaking. The contents are then made up (with spirit) to 200 c.c., again well shaken and filtered rapidly. Of the clear filtrate, 100 c.c. (=2 grams of the sample) are evaporated in a glass or porcelain basin until the residue fumes and begins to 'char,' when it is washed with a little hot water into a beaker and mixed with sufficient bromine water to make it strongly orange-coloured. After standing for half an hour, the liquid is heated nearly to boiling and precipitated with slight excess of ammonia, kept in a water-bath for half an hour, and made slightly acid with acetic acid. The precipitate (which, under these conditions, contains only phosphoric acid, ferric oxide, and alumina) is filtered off, washed with a slightly ammoniacal 20 p.c. solution of ammonium nitrate, dried, ignited, and weighed. It is then dissolved in a little hydrochloric acid, 1 gram of citric acid is added to the solution, which is then made ammoniacal, and the phosphoric acid determined by precipitation with magnesium mixture. The total bulk of fluid should be kept within about 100 c.c. In this case, the precipitate of ammonium magnesium phosphate does not need re-solution and re-precipitation, seeing that no oxalate is present. The iron is precipitated from the filtrate with ammonium sulphide, as in the preceding process, and the alumina is arrived at by difference.

LASNE PROCESS FOR DIRECT DETERMINATION OF ALUMINA.

Objection has been sometimes raised to the fact that, while in the processes already described, ferric oxide is determined directly, alumina, on the other hand, is taken by difference. The following process, as described by H. Lasne, affords a correct method for the direct determination of alumina. It has been frequently tested by the writer of this article, in whose experience it gives results substantially identical with those obtained by the two differential methods already quoted. In either case, whether a direct or an indirect method be used, success depends upon delicacy of manipulation and strict attention to the details prescribed.

Five grams of phosphate are treated with hydrochloric acid, the solution being evaporated to dryness, taken up with 60 c.c. of 10 p.c. hydrochloric acid, and digested at about 100°C. for 1 hour. The solution is diluted to 500 c.c., and filtered, 125 c.c. being taken for the determination of alumina. Five grams of caustic soda (free from silica and alumina) and 1 gram of sodium phosphate are dissolved in 20 c.c. of distilled water in a nickel basin. Into this solution the 125 c.c. of phosphate solution are

poured, with constant stirring, and kept for about an hour at a temperature of about 100°C., with occasional stirring, preferably with a nickel spatula. The liquid is cooled, and made up to 250 c.c. in a glass flask. The contents are filtered, and 200 c.c. of the filtrate (=1 gram of the phosphate sample) mixed with 30 c.c. of a solution of ammonium chloride (125 grams per litre), sufficient hydrochloric acid being added to dissolve such precipitate as is formed. Ammonia is then added in very slight excess. After boiling for 5 minutes, the precipitate is filtered off, washed slightly once with water, and re-dissolved through the filter into the original beaker with a little 10 p.c. hydrochloric acid, the filter being washed with water five or six times. The solution is treated with $3\frac{1}{2}$ c.c. of a solution of pure ammonium phosphate (10 grams per 100 c.c.), and ammonia added till a permanent precipitate is formed, and then sufficient dilute hydrochloric acid to again dissolve the precipitate. The fluid is diluted to 250 c.c., when 10 c.c. of a solution of ammonium hyposulphite (15 grams per 100 c.c.) are poured in. After half an hour's boiling, five drops of a saturated solution of sodium acetate are added, and, after 5 minutes' further boiling, the precipitate is filtered off and washed seven or eight times with water. The precipitate, which is granular and not gelatinous, is ignited to constancy, and assumed to have the composition of pure aluminium phosphate. Its weight multiplied by 0.418 gives the alumina in 1 gram of the sample.

ANALYSIS OF SUPERPHOSPHATE, DISSOLVED BONES, &c.

'Moisture' is conventionally determined by simply drying to constancy at 100°C. The result should, in such cases, be stated as 'moisture' (*i.e.* loss at 100°C.), because the figure obtained is not moisture in the true sense, since it includes a varying quantity of water of hydration. True moisture can only be determined by drying to constancy *in vacuo* over sulphuric acid. The result in that case should be stated as 'true moisture' (*i.e.* loss *in vacuo*).

DETERMINATION OF SOLUBLE PHOSPHATE.

Formerly in England, and still in America, solubility was determined by fractional exhaustion with successive small quantities of cold water (with or without a final exhaustion with hot water). On the continent of Europe it has long been usual to dissolve in a large bulk of water at one operation. The former method usually extracted somewhat more phosphoric acid than the latter, since some interaction occurs on dilution between the dissolved phosphoric acid and the 'insoluble' phosphate. As this depends upon the chemical composition of the original phosphate, and also on the degree of dilution, the differences in the results obtained by the two methods of extraction are variable—being sometimes negligible, but occasionally serious.

The following method of extraction of soluble phosphate, adopted at a meeting of the International Congress of Applied Chemistry, is now usually adopted in England, and is the method officially laid down in 1908 by the

Board of Agriculture for use under the Fertilisers and Feeding Stuffs Act:—

'In the case of superphosphates, dissolved bones and similar substances, 20 grams of the sample shall be continuously agitated for 30 minutes in a litre flask with 800 c.c. of water. The flask shall then be filled to the mark, and again shaken, and the contents shall be filtered.'

The mode of determination of phosphate in the water solution thus obtained is officially prescribed as follows:—

'50 c.c. of the filtrate shall be boiled with 20 c.c. of concentrated nitric acid, and the phosphoric acid shall be determined by the molybdate method prescribed below.'

OFFICIAL MOLYBDATE METHOD (BOARD OF AGRICULTURE, 1908).

'To the solution, which should preferably contain from 0.1 to 0.2 gram of phosphoric oxide (P_2O_5), 100 to 150 c.c. of molybdic acid solution prepared as described below, or an excess of such solution, i.e. more than is sufficient to precipitate all the phosphoric oxide present in the solution, shall be added, and the vessel containing the solution shall be placed in a water-bath maintained at 70° for 15 minutes, or until the solution has reached 70°. It shall then be taken out of the bath and allowed to cool, and the solution shall be filtered, the phospho-molybdate precipitate being washed several times by decantation, and finally on the paper with 1 p.c. nitric acid solution. The filtrate and washings shall be mixed with more molybdic acid solution and allowed to stand for some time in a warm place in order to ascertain that the whole of the phosphoric oxide has been precipitated.

'The phospho-molybdate precipitate shall be dissolved in cold 2 p.c. ammonia solution, prepared as described below, and about 100 c.c. of the ammonia solution shall be used for the solution and washings. 15 to 20 c.c. of magnesia mixture prepared as described below, or an excess of such mixture, i.e. more than sufficient to precipitate all the phosphoric oxide present, shall then be added drop by drop, with constant stirring. After standing at least 2 hours with occasional stirring, the precipitate shall be filtered off, washed with 2 p.c. ammonia solution, dried, and finally weighed as magnesium pyrophosphate. The filtrate and washings shall be tested by the addition of more magnesia mixture.

'(e) *Preparation of molybdic acid solution.*

'The molybdic acid solution shall be prepared as follows:—

'125 grams of molybdic acid and 100 c.c. of water shall be placed in a litre flask, and the molybdic acid shall be dissolved by the addition, while the flask is shaken, of 300 c.c. of 8 p.c. ammonia solution, prepared as described below. 400 grams of ammonium nitrate shall be added, the solution shall be made up to the mark with water, and the whole added to 1 litre of nitric acid (sp.gr. 1.19). The solution shall be maintained at about 35° for 24 hours and then filtered.

'(f) *Preparation of magnesia mixture.*

'The magnesia mixture shall be prepared as follows:—

'110 grams of crystallised magnesium chloride and 140 grams of ammonium chloride shall be dissolved in 1300 c.c. of water. This solution shall be mixed with 700 c.c. of 8 p.c. ammonia solution, and the whole shall be allowed to stand for not less than three days and shall be then filtered.

'(g) *Preparation of the ammonia solutions.*

'The 8 p.c. ammonia solution shall be prepared as follows:—

'One volume of ammonia solution of sp.gr. 0.880 shall be mixed with three volumes of water. This solution shall then be adjusted by the addition thereto of more strong ammonia solution or water as required until the sp.gr. of the solution is 0.967.

'The 2 p.c. ammonia solution shall be prepared as follows:—

'One volume of 8 p.c. ammonia solution shall be mixed with three volumes of water.'

The soluble phosphate may be determined equally well by applying to 100 c.c. of the water extract, obtained by the official method of extraction (=2 grams of the original superphosphate) the oxalic-citric-magnesium process as described for raw mineral phosphates, omitting the evaporation to dryness; but in disputed cases in which litigation may arise, the molybdate method should be used.

Both 'soluble phosphate' and 'insoluble phosphate' in England are always stated in terms of tricalcium phosphate. On the Continent, it is usual to state them in terms of P_2O_5 , with or without a statement of the equivalent $Ca_3P_2O_8$. The 'insoluble' phosphate is estimated by determining the 'total' phosphate and deducting from it the soluble phosphate.

DETERMINATION OF TOTAL PHOSPHATE IN FERTILISERS.

This may, in most cases, be carried out by the methods already described for the analysis of raw mineral phosphates, materials containing much organic matter being first incinerated.

The official method prescribed in England under the Fertilisers and Feeding Stuffs Act, however, which should be adhered to in disputed cases, is the molybdate method, already described under soluble phosphate.

The official prescription of the Board of Agriculture for determination of total phosphate in fertilisers is as follows:—

'A weighed portion of the sample, in which portion, if necessary, the organic matter has been destroyed by ignition and the silica removed by appropriate means, shall be dissolved in nitric acid and boiled, the solution being made up to a definite bulk. The phosphoric acid shall be determined in an aliquot part of the solution by the molybdate method prescribed' (see above).

REVERTED PHOSPHATE.

The 'reverted' phosphate in superphosphate may be determined as follows: 2 grams of the sample are stirred up in a beaker with successive quantities of 50 c.c. of water, each portion, after settling, being decanted off through a filter. The water-soluble phosphate having been thus approximately removed, the matter on the filter is washed back into the beaker with a little water, and the undissolved matter is treated

with either neutral or ammoniacal ammonium citrate solution. In America, neutral citrate is used, made by dissolving 185 grams of citric acid, neutralising with ammonia (using alcoholic solution of coralline as indicator), and making up to 1 litre. In France, a strongly ammoniacal solution is used, made by dissolving 400 grams in 1 litre of ammonia of sp.gr. 0.920.

In the American method, the water-insoluble residue referred to is digested with 100 c.c. of (neutral) citrate solution for half an hour with frequent shaking. In the French method, it is digested with 100 c.c. of (ammoniacal) solution for 12 hours, agitating occasionally during the first hour.

The matter undissolved by the citrate solution is filtered off, washed, ignited, and dissolved in hydrochloric or nitric acid and the phosphoric acid determined in it. The difference between water-soluble phosphate and total phosphate gives the insoluble (including reverted) phosphate. The difference between this and the phosphate undissolved by citrate solution is taken as 'reverted' phosphate.

ANALYSIS OF BASIC SLAG.

In the analysis of basic slag, it is now usual to determine (a) the percentage of 'fine meal,' (b) the percentage of total phosphoric acid, and (c) the percentage of phosphoric acid soluble in a 2 p.c. solution of citric acid.

Fine meal.—This is determined by sifting a given weight of the sample through a sieve made of brass gauze, having approximately 10,000 apertures per square inch, of the make known as 'Amandus Kahl, No. 100 E, Hamburg,' and weighing the residue.

As the size of the apertures depends upon the gauge of the wire, the use of any other make or pattern of gauge is a possible source of discrepancy. In well-ground slag from 80 to 90 p.c. should pass through the sieve. This is called the percentage of 'Fine meal.'

The total phosphoric acid may be determined as in mineral phosphates or as in other fertilisers.

An excellent method for slag, however, giving (by an admitted balance of errors) results identical with those of the molybdc process, is as follows: Treat 2 grams of the slag with strong hydrochloric acid and evaporate to dryness. Take up with 15 c.c. of hydrochloric acid and 25 c.c. of water, adding 20 grams of powdered citric acid. The silica is filtered off and washed, and the filtrate and washings (measuring about 170 c.c.) are cooled, a large excess of magnesium mixture is added and about 50 c.c. of strong ammonia. The liquid is stirred continuously for 15 or 20 minutes by aid of a mechanical stirrer, and allowed to stand with occasional stirring for 2 hours. The precipitate is filtered off, dried, ignited, and weighed as $Mg_2P_2O_7$.

N.B.—This process is largely in use on the Continent, without observance of the initial precaution of evaporating the acid solution to dryness to remove soluble silica. If the slag be merely digested with acid and the liquid filtered and precipitated without having been evaporated to dryness, the results may be seriously in excess of the truth. This has been pointed out by several investigators, but is not yet well recognised.

The phosphate soluble in 2 p.c. solution of citric acid is determined, according to the method prescribed in the official directions of the Board of Agriculture:—

'Phosphate soluble in 2 p.c. citric acid solution.

'5 grams of the sample shall be transferred to a stoppered bottle of about 1 litre capacity. 10 grams of pure crystallised citric acid shall be dissolved in water, the volume shall be made up to 500 c.c., and the solution shall be added to the weighed portion of the sample in the bottle. To lessen the possibility of caking, the portion of the sample in the bottle may be moistened with 5 c.c. of alcohol or methylated spirit before the citric acid solution is added; and in that case the volume of the citric acid solution shall be 495 c.c. instead of 500 c.c. The bottle shall be at once fitted into a mechanical shaking apparatus, and shall be continuously agitated during 30 minutes. The solution shall then be filtered through a large "folded" filter, the whole of the liquid being poured on the paper at once. If not clear, the filtrate shall be again poured through the same paper.

'50 c.c. of the filtrate shall be taken and the phosphoric acid shall be determined by the molybdate method prescribed.'

It may be added that 100 c.c. of the solution (=1 gram of sample) can be used equally well for the molybdate determination.

The phosphate in the citric acid solution of the slag is frequently estimated by direct precipitation with magnesium mixture after adding a large excess of ammonium citrate. The results, however, are inaccurate (being too high) unless the citric acid solution of the slag is first evaporated to dryness with hydrochloric acid to eliminate soluble silica. If this precaution be taken, the results compare well with those of the molybdate process—which, on the whole, is quicker, and therefore preferable.

ANALYSIS OF POTASH SALTS.

Some commercial potash salts are of complex constitution, others are approximately simple salts. The methods of determining such constituents as calcium, magnesium, chlorine, &c., do not differ from those ordinarily employed in inorganic analysis, but the essential determination, namely, that of potash, may be described. Broadly speaking, two methods are in use, namely, the perchloric acid method and the platinum chloride method. The perchloric acid method was formerly but little used in this country, but owing to the great increase in the cost of platinum-chloride has now come into wide use, and ranks with the platinum chloride method as "official" in England.

The following are the details of the method for determining potash in potash salts and in fertilizers officially prescribed in England in 1918 for use under the Fertilisers and Feeding Stuffs Act:—

'DETERMINATION OF POTASH.

'(a) *Muriate of potash free from sulphates.*

'A weighed portion of the sample (about 5 grams in the case of concentrated muriate of potash or 10 grams in the case of low-grade muriate) shall be dissolved in water, the solution shall be filtered if necessary and made up

to 500 c.c. The potash shall be determined in 50 c.c. of the solution either by the platinum chloride method, or by the perchloric acid method, prescribed below in clauses (e) and (f) of this paragraph.

'(b) Salts of potash containing sulphates.'

A weighed portion of the sample (about 5 grams in the case of concentrated sulphate of potash or 10 grams in the case of kainit or other low-grade salts) shall be boiled with 20 c.c. of hydrochloric acid and 300 c.c. of water in a half-litre flask. Barium chloride solution shall be cautiously added, drop by drop, to the boiling solution until the sulphuric acid is completely precipitated. Any slight excess of barium shall be removed by the addition of the least possible excess of dilute sulphuric acid. The liquid (without filtration) shall be cooled and made up to 500 c.c. and filtered. 50 c.c. of the filtrate shall be taken and evaporated to dryness, and shall then be moistened with concentrated hydrochloric acid, again evaporated to dryness, treated with a little dilute hydrochloric acid and filtered if necessary. The potash shall be determined in the filtrate either by the platinum chloride method, or by the perchloric acid method, prescribed below in clauses (e) and (f) of this paragraph. If the solution contains phosphates, iron, manganese, or other substances that would interfere with the determination of potash, the method prescribed in clause (c) of this paragraph is to be used instead of the method prescribed in clause (b).

(In calculating the results, international atomic weights are used, including Seubert's atomic weight for platinum, which, in the international table for 1911, is given as 195.2.)

'(c) Potash in flue-dust.'

Ten grams of the sample shall be gently ignited in order to char organic matter, if present, and shall then be boiled with 300 c.c. of water. 10 c.c. of concentrated hydrochloric acid shall be added slowly so as not to check the boiling, which is to be continued for a further 10 minutes after the addition of the last portions of acid. The liquid shall be filtered into a half-litre flask and raised to the boiling-point; and to the boiling liquid powdered barium hydroxide is to be added until there is slight excess. The liquid shall then be cooled, made up to 500 c.c., and filtered. Of the filtrate, 250 c.c. shall be treated with ammonia solution and excess of ammonium carbonate, and, while boiling, with a little powdered ammonium oxalate. It shall then be cooled, made up to 500 c.c. and filtered. Of the filtrate, 50 c.c. or 100 c.c., according to the amount of potash expected, shall be evaporated in a porcelain dish to dryness. If desired, nitric acid may be added during the evaporation after free ammonia has been driven off. The residue is to be heated gently over a low flame until all ammonium salts are expelled, the temperature being carefully kept below that of low redness. The residue shall be moistened with concentrated hydrochloric acid, evaporated to dryness, treated with dilute hydrochloric acid, filtered, and the potash deter-

mined in the filtrate either by the platinum chloride method or by the perchloric acid method, prescribed below in clauses (e) and (f) of this paragraph.

'(d) Potash in guanos and mixed fertilisers.'

Ten grams of the sample shall be gently ignited in order to char organic matter, if present, and shall then be heated for 10 minutes with 10 c.c. of concentrated hydrochloric acid, and finally boiled with 300 c.c. of water. The liquid shall be filtered into a half-litre flask, raised to the boiling-point, and a slight excess of powdered barium hydrate shall be added. The contents of the flask shall be cooled, made up to 500 c.c. and filtered. Of the filtrate, 250 c.c. shall be treated with ammonia solution and excess of ammonium carbonate, and then, while boiling, with a little powdered ammonium oxalate, cooled, made up to 500 c.c., and filtered. Of the filtrate, 100 c.c. are to be evaporated in a porcelain dish to dryness. If desired, nitric acid may be added during the evaporation after free ammonia has been driven off. The residue is to be heated gently over a low flame, till salts are expelled, the temperature being carefully kept below that of low redness. The residue shall be moistened with concentrated hydrochloric acid, evaporated to dryness, treated with dilute hydrochloric acid, and filtered. The potash shall be determined in the filtrate either by the platinum chloride method, or by the perchloric acid method, prescribed below in clauses (e) and (f) of this paragraph.

'(e) Platinum chloride method.'

To the solution obtained as above described in clauses (a), (b), (c), or (d) of this paragraph a few drops of hydrochloric acid shall be added, if none is present, and also 10 c.c. or 20 c.c. (according to whether the portion weighed was 5 grams or 10 grams) of a solution of platinum chloride containing 10 grams of platinum per 100 c.c. After evaporation to a syrupy consistency on a water-bath, the contents of the basin shall be allowed to cool and shall then be treated with alcohol of sp.gr. 0.864, being washed by decantation until the alcohol is colourless. The washings shall be passed through a weighed or counterpoised filter paper, on which the precipitate shall be finally collected, washed with alcohol as above, dried at 100°, and weighed.

The precipitate is to be regarded as K_2PtCl_6 , and is to be calculated to its equivalent as K_2O .

'(f) Perchloric acid method.'

To the solution obtained as above described in clauses (a), (b), (c), or (d) of this paragraph and placed in a small glass or porcelain basin, 7 c.c., or 12 c.c. (according to whether the portion weighed was 5 grams or 10 grams), of a 20 p.c. solution of perchloric acid (sp.gr. 1.125) shall be added. The basin shall be placed on a hot plate or sand-bath and the contents evaporated until white fumes are copiously evolved. The precipitate shall be re-dissolved in hot water, a few drops of perchloric acid solution added, and the whole concentrated again to the fuming stage. After cooling, the residue in the basin shall be thoroughly stirred with 20 c.c. of alcohol

of specific gravity 0·816 to 0·812 (95 to 96 p.c. of alcohol by volume). The precipitate shall be allowed to settle, and the clear liquid shall be poured through a weighed or counterpoised filter paper, or through a gouch crucible, draining the precipitate as completely as possible from the liquid before adding the washing solution. The precipitate shall be washed by decantation with alcohol (as above) saturated with potassium perchlorate at the temperature at which it is used, pouring the washings through the paper or gouch crucible on which the whole of the precipitate is finally collected, dried at 100°C., and weighed.

The precipitate is to be regarded as KClO_4 , and is to be calculated to its equivalent as K_2O .

DETERMINATION OF NITROGEN IN FERTILISERS.

Nitrogen was formerly determined by the soda-lime combustion process which was modified by Ruffe (Chem. Soc. Trans. 1881, 87), so as to be also applicable to mixtures containing nitrates by means of introducing into the soda lime an admixture of sodium thiosulphate. The soda-lime process has now, however, been almost universally superseded by Kjeldahl's moist sulphuric acid combustion process, modified and improved by the successive labours of many investigators. In its present form it is one of the most accurate and reliable processes at the disposal of the analyst. It cannot be more clearly or concisely described than by quoting the directions laid down for its use in connection with the Fertilisers and Feeding Stuffs Act in the official regulations of the Board of Agriculture (1908):—

'The presence or absence of nitrates must first be ascertained.

'Nitrogen in absence of nitrates.

'A weighed portion of the sample shall be transferred to a Kjeldahl digestion flask; 10 grams of potassium sulphate and 25 c.c. of concentrated sulphuric acid shall be added, and the flask shall be heated until a clear liquid, colourless, or of light straw colour, is obtained. The operation may be accelerated by the addition of a small crystal of copper sulphate or a globule of mercury to the liquid in the digestion flask.

'The quantity of ammonia shall be determined by distillation into standard acid after liberation with alkali, and, where mercury has been used, with the addition also of sodium or potassium sulphide solution.

'Nitrogen in mixed fertilisers when nitrates are present.

'A weighed portion of the sample shall be transferred to a Kjeldahl digestion flask; 30 c.c. of concentrated sulphuric acid, containing 1 gram of salicylic acid, shall be added, and the flask shall be shaken so as to mix its contents without delay. The shaking shall be continued at intervals during 10 minutes, the flask being kept cool, and then 5 grams of sodium thiosulphate and 10 grams of potassium sulphate shall be added. The flask shall be heated until the contents are colourless or nearly so. Copper sulphate or mercury may be used as above described.

'The quantity of ammonia shall be determined as above prescribed.'

The quantity of material operated upon will vary according to its nature. In the case of materials rich in nitrogen, from 1 gram to 1·5 grams may be operated upon. On the other hand, in the case of materials composed chiefly of inorganic matter, and containing only small quantities of nitrogen—like low quality dissolved bone compounds—as much as 5 or 6 grams may be conveniently operated upon. It is usually convenient to make two simultaneous experiments on different quantities of the material, such as 1 gram and 1·5 grams, or 1·5 grams and 2 grams. The larger the quantity of material that can be satisfactorily dealt with, the less, obviously, is the multiplication of experimental error. Duplicate results, in careful hands, should differ by no more than a few units in the second place of decimals, when expressed as percentage of nitrogen in the material under examination.

It is pointed out in the regulations that all the materials used in either of the methods described must be examined as to their freedom from nitrogen, by means of a control experiment carried out under similar conditions with the same quantities of the reagents which are employed in the actual analysis, 1 gram of pure sugar being substituted for the weighed portion of the sample. The quantity of standard acid neutralised in the control experiment—which should be small if the materials are good—must be deducted from the total quantity of acid found to have been neutralised in the distillation of the sample. The observance of this precaution is of vital importance, seeing that small quantities of nitrogen compounds are frequently found even in sulphuric acid sold as pure for analysis; while traces of nitrates or nitrites may be present in sodium hydroxide.

In the above described modification of the Kjeldahl process for mixtures containing nitrates—due originally to Jodlbauer—phenol may be used, if desired, in place of salicylic acid, and 1 gram of zinc-dust may be used in place of the 5 grams of sodium thiosulphate. Zinc-dust, like the other materials, may contain traces of nitrogen, and must be carefully examined by being included with the other materials in a 'blank' experiment.

In the case of ammonium sulphate or other material containing nitrogen in the form of ammonium salts only (other than ammonium nitrate), the nitrogen may be determined by simple distillation with alkali.

Determination of nitrogen in sodium nitrate or in saltpetre. This may be carried out by several methods. One of the most convenient is the Ulsch method, which in the regulations of the Board of Agriculture is described as follows:—

'One gram of the sample shall be placed in a half-litre Erlenmeyer flask with 50 c.c. of water. 10 grams of reduced iron and 20 c.c. of sulphuric acid of 1·35 sp.gr. shall be added. The flask shall be closed with a rubber stopper provided with a thistle tube, the head of which shall be half filled with glass beads. The liquid shall be boiled for 5 minutes, and the flask shall then be removed from the flame, any liquid that may have accumulated among the beads being rinsed back with water into the flask. The solution shall be boiled for 3 minutes more, and the beads again washed

with a little water. The quantity of ammonia shall then be determined as above prescribed. (See *Nitrogen in absence of nitrates*.)

'In cases in which the proportion of nitrates is small, a larger quantity of the sample shall be taken.'

General observations as to preparing samples for analysis. In the case of all samples, whether of fertilisers or of raw materials for use in their manufacture, it is obviously important to obtain a thoroughly representative portion for analysis. To this end it is usual, in the case of powdered fertilisers in dry or moderately dry condition, to pass the sample through a sieve, the perforations of which are about 1 mm. in diameter, pulverising the portions at first retained on the sieve—either in a mortar or, better, in a suitable mill—until they pass through. Adventitious materials which cannot be conveniently crushed, such as fragments of metal sometimes found in basic slag, must be removed and weighed, and subsequently allowed for in calculating the results of the analysis. Some materials, like shoddy, wool waste, or hair, cannot be powdered, but as a rule they can be passed through a shredding machine; or, if this is not possible, they must be finely cut up by hand. Some moist fertilisers do not admit of being passed through a sieve, and in dealing with these the analyst must use his discretion as to the best mode of obtaining an average sample. Crystalline or saline materials, like ammonium sulphate, potassium chloride, kainit, or sodium nitrate, are best prepared by mixing and rapidly grinding in a stoneware mortar, the portion reserved for analysis being especially finely ground. In the case of many moist materials, especially fibrous materials like shoddy wool waste, or rough fish guano, moisture is inevitably lost during the preparation of the sample. It is therefore necessary to separately determine the moisture in a large average portion of the original material before proceeding to pulverise the remainder. The moisture must also be determined in the fine material as prepared for analysis, and the results of the analysis recalculated so as to represent the percentages present in the sample in its original moist condition. In the case of raw mineral phosphates, it is usual to determine the moisture in a rough sample separately taken for this purpose, and to conduct the rest of the analysis on a separately prepared fine portion, after drying the latter at 100°—the results being returned on the dry basis, with a simple statement at the foot of the analysis of the percentage of moisture in the rough sample. But in the case of almost all other materials, the results of the analysis are returned as percentages of the material in its original moist condition. B. D.

FERULIC ACID. *m. Methoxy-p-hydroxycinnamic acid* $C_6H_5 \begin{cases} \text{CH:CH}\cdot\text{CO}_2\text{H} & (1) \\ \text{OCH}_3 & (3). \text{ Occurs} \\ \text{OH} & (4) \end{cases}$

in asafœtida resin (Hlasiwetz and Barth, *Annalen*, 138, 64); in opopanax (Tschirch and Knitt, *Arch. Pharm.* 1899, 256), and in the resin of the black fir (Bamberger, *Monatsh.* 12, 441). The alcoholic extract of asafœtida resin is precipitated with lead acetate, and the precipitate, consisting of lead ferulate, is decomposed with sulphuric acid. It has been prepared arti-

ficially by means of Perkin's reaction by heating together vanillin, acetic anhydride, and dry sodium acetate, and decomposing the acetylferulic acid thus formed with potash (Tiemann and Nagai, *Ber.* 1878, 647); also by treating the methyl ether of *p*-amino-*m*-coumaric acid with sodium nitrite and decomposing the diazo-compound thus produced with water (Ulrich, *J.* 1885, 2093; *cf.* D. R. P. 32914; *Frdl.* i. 588). Rhombic needles, melting at 168°-169°, almost insoluble in cold water, readily soluble in alcohol, less soluble in ether (Tiemann and Nagai, *Ber.* 1876, 416). The solution gives with lead acetate a yellow flocculent precipitate, with ferric chloride a yellowish-brown precipitate, reduces silver nitrate and Barreswil's (Fehling's) solution on warming. Fusion with caustic potash converts it into acetic and protocatechuic acids. Sodium amalgam reduces it to hydroferulic acid $C_{10}H_{12}O_4$.

FETTBOL *v.* **BOLE.**

FIBRIN *v.* **BLOOD** AND **PROTEINS.**

FIBRINOGEN *v.* **BLOOD** AND **PROTEINS.**

FIBROLYSIN. Trade name for a combination of thiosinamine and sodium salicylate.

FICHELITE. A hydrocarbon $C_{18}H_{32}$, found as white or yellowish platy crystals and crystalline crusts in the crevices of lignified pine wood in peat-bogs. The monoclinic crystals, both natural crystals and those obtained by recrystallising the material from alcohol or benzene, are interesting on account of their hemimorphic development, there being, as in crystals of cane-sugar and tartaric acid, no plane of symmetry. Sp.gr. 1.01; m.p. 46°; b.p. 355.2°; specific rotation in solution in chloroform $[\alpha]_D^{20} = +18.08^\circ$. Analysis gives:

C 86.79, H 13.02 p.c.; the vapour density is 8.6; and the molecular weight, determined by the cryoscopic method in benzene, 254.2. It has a high degree of stability, and can be distilled over red-hot lead oxide without decomposition; derivatives are consequently difficult to obtain. Oxidation with chromic acid in an acetic acid solution yields two acids, the silver salts of which are $C_{15}H_{20}O_6Ag_2$ and $C_3H_5O_3Ag$. On distillation under 270 mm. pressure the bulk goes over at 290°-295° as a nearly colourless, viscous liquid with a splendid blue-violet fluorescence; this is dehydrofichtelite $C_{18}H_{30}$. Localities where fichtelite has been found are Redwitz and several other places in the Fichtel Mountains in northern Bavaria, Kolbermoor near Rosenheim in southern Bavaria, Borkovic and other places in Bohemia, Handforth in Cheshire, Shielding in Ross-shire, &c. For a review of the literature, see A. Schmidt, *Centralbl. Min.* 1901, 519; F. Plzák and V. Rosický, *Zeitsch. Kryst. Min.* 1908, xlv. 332; A. Rosati, *ibid.* 1912, i. 126. L. J. S.

FICOCERYLIC ACID $C_{15}H_{25}COOH$, m.p. 57°, is obtained from the wax of the wild fig-tree.

FIG. *Ficus carica* (Linn.). Many varieties are known, varying greatly in size of fruit—from 6 or 7 grams to 80 grams each—the average weight of the fresh ripe fruit being about 35 grams.

According to Colby (Reports of the Agric. Exp. Stat. California, 1892-1894), the average of 41 analyses of different varieties is—

Water	Sugar	Protein	Ash
78.9	15.6	1.4	0.6

The juice, amounting on the average to about 76 p.c. of the whole, contained 20.7 p.c. of sugar and 0.12 p.c. of free acid expressed as sulphur trioxide.

Ballard (Rev. intern. falsif. 1900, 13, 92) found more water, less nitrogenous matter, and in addition about 0.28 p.c. fat, and 1.5 p.c. crude fibre.

Colby found the ash to have the following composition (mean of 3 analyses):—

K ₂ O	Na ₂ O	MgO	CaO	Mn ₃ O ₄	Al ₂ O ₃ & Fe ₂ O ₃	P ₂ O ₅	SO ₃	SiO ₂	Cl
55.8	2.4	5.6	11.2	0.2	2.2	12.8	3.9	4.3	2.0

Figs are eaten in the fresh, ripe state in districts where they are grown, but, for export, they are largely dried. The following is the average composition of dried figs (König):—

Water	Protein	Sugar	Free acid (as Malic acid)	Other carbo-hydrates	Fibre	Ash
28.8	3.6	51.4	0.7	1.3	5.3	6.2
2.7						

The seeds of dried figs, according to Balland (*l.c.*), contain—

Water	Protein	Fat	Carbohydrates	Fibre	Ash
7.7	12.0	24.6	23.4	29.8	2.5

Hotter (Zeitsch. Nahrungsm.-Unters. Hygiene u. Waarenk. 1895, 9, 1) found, in dried figs from Smyrna, 0.0015 p.c. of boric acid. Wittmann (Zeitsch. landw. Versuchs Oesterreich, 1901, 4, 131) found 0.83 p.c. pentosans in fresh, 3.8 p.c. in dried figs.

According to analyses by Paladino (Biochem. Zeitsch. 1910, 24, 263), the following represents the composition of green and dried figs :—

	Water	Protein	Fat	Sugar	Cellulose	Mucilage, etc.	Ash
Green figs, pulp	80.0	0.7	0.3	16.2	1.3	0.8	0.7
" " skin	86.0	(?)	0.1	5.4	5.8	2.7	(?)
Dried figs .	57.0	4.1	2.2	26.0	8.0	0.2	2.5

It thus appears that the proportion of water in dried figs varies greatly.

When figs are moistened with warm water containing tartaric acid, they speedily ferment and yield a wine. This is largely made in Algeria, and is used for adulterating grape wine. When fig wine is evaporated to a syrup and allowed to cool, it solidifies, after 24 hours, to a crystalline mass consisting chiefly of mannitol, but containing glycerol and small quantities of sugar and organic acids. Mannitol is present in fig wine to the extent of 6 or 8 grams per litre, whilst in grape wine its amount does not exceed a few decigrams per litre. This fact may be used to detect fig wine as an adulterant of grape wine (Cables, Compt. rend. 1891, 122, 811).

The stems and branches of plants of the genus *Ficus* yield a viscid, milky juice containing caoutchouc or resinous substances resembling caoutchouc. *F. elastica* (Roxb.) is the species from which the largest proportion of this substance is obtainable. H. I.

FIG WAX *v.* WAXES.

FILBERT. The seed of *Corylus Avellana* (Linn.). The kernels have the following average composition (König):—

Water	Protein	Fat	Soluble Carbohydrates	Crude fibre	Ash
7.1	17.4	62.6	7.2	3.2	2.5

VOL. III.—T.

These were evidently in the dried condition; as usually eaten for dessert filberts contain much more water. The essential oil of the leaves was examined by Haensel (Chem. Zentr. 1909, i. 1476), who found it present to the extent of 0.04 p.c. It is light brown in colour, solidifies at about 30°, contain 18 p.c. of palmitic acid, and a paraffin hydrocarbon melting at 49°. It had an acid value 60.4, ester value 24.6, and its sp.gr. (in the super-cooled liquid condition) was 0.8844 at 25°.

H. I.

FILICIC ACID *v.* FILIX MAS.

FILITANNIC ACID *n.* **FILIX MAS** and

TANNINS.

FILIX MAS (B.P.), *Aspidium* (U.S.P.). Male fern; *Rhizoma filicis*. (*Racine de fougère mâle*, Fr.; *Farnwurz*, Ger.) The rhizome of male fern, *Aspidium filix mas* (Swartz), has been a favourite anthelminthic medicine since the times of Theophrastus, Dioscorides, Pliny, and Galen. (For botanical characters, *v.* Woodville (Med. Bot. 271), Moore and Lindley (Ferns of Great Britain, 14-17), and Benth. A. Trim. 300.)

The early chemical investigations of the rhizome (see Pereira, Mat. Med. 3rd ed. 2, 959, and Poulsson, Arch. exp. Path. Pharm., 1891, 29, 1) show that, besides the constituents common to plants, it contains a peculiar *green fixed oil, tannin*, and a crystalline compound, first analysed by Luck (J. 1851, 558) and named by him *filicic acid*. These constituents are all found in the ethereal extract or 'oil of male fern,' in which form alone the drug is made use of in medicine.

The green fixed oil is composed, according to Katz (Arch. Pharm. 236, 655) of the glycerides of oleic, palmitic, and cerotic acids, the chief constituent being triolein. The tannin, *filiciannic* or *filicitannic acid*, is, according to Malin (Annalen, 143, 276), a glucoside; Wollenweber (Arch. Pharm. 1906, 244, 466) gives it the formula $C_{41}H_{44}O_{24}N_2H_2O$ (?). Its aqueous solution froths.

Filicic acid $C_{35}H_{42}O_{13}$ or $C_{35}H_{40}O_{13}$ is an amorphous colourless powder, melting at about 125° , and physiologically active. In boiling ethereal solution it is converted to its lactone *filicin* $C_{35}H_{40}O_{12}$ (Poulsson, *l.c.*), or $C_{35}H_{38}O_{12}$ (Boehm). This anhydride is inert and forms small yellow, rhombic leaflets, m.p. 184.5° . It is insoluble in water, hardly soluble in cold alcohol, readily in hot. By careful treatment with alkali it can be retransformed to the active acid (Poulsson). An insight into the constitution of filicic acid has been obtained by Boehm, who has isolated a number of other crystalline substances from fern extracts, and has made by far the most important contributions to our knowledge of the subject (Arch. exp. Path. Pharm. 1897, 38, 35; Annalen, 1898, 301, 171; 1899, 307, 249; 1901, 318, 230, 245, 253; 1903, 329, 269, 310, 338). All the substances isolated by Boehm appear to be either methylated phloroglucinylpropyl ketones, or to consist of two or three such ketone nuclei joined together by one or two methylene groups.

Aspidinol $C_{12}H_{16}O_4$, bright yellow crystals, m.p. 156° – 161° , is the simplest of these substances. On boiling with zinc-dust and sodium

hydroxide it is decomposed to methylphloroglucinolmonomethyl ether and *n*-butyric acid. It probably has the constitution—

Filicin (filicic acid), on the other hand, is the most complex, and consists of three such ketone nuclei, joined by two other carbon atoms. On boiling for a short time with zinc-dust and sodium hydroxide it yields, amongst other products, 'filicinic acid butanone,' m.p. 95°–97°, which is isomeric with aspidinol, and has the constitution—

or one tautomeric with it.

By more prolonged boiling it breaks up into *n*-butyric acid and *gem*-dimethylphloroglucinol (filicinic acid). The latter substance gives, on oxidation, dimethylmalonic acid.

The other substances isolated by Boehm are composed of two ketone nuclei joined by one methylene group.

Albaspidin $\text{C}_{25}\text{H}_{32}\text{O}_8$, needles, m.p. 148°, consists of two filicinic acid butanone residues, and can be synthesised from this ketone by means of formaldehyde, whence the constitution:

Phloraspin $\text{C}_{33}\text{H}_{40}\text{O}_8$, colourless needles, m.p. 211°, is similarly built up of methylphloroglucinol-*n*-butanone, and the methyl ether of phloroglucinol-*n*-butanone, two isomeric ketones $\text{C}_{11}\text{H}_{14}\text{O}_4$, lower homologues of those already referred to.

Flavaspidic acid $\text{C}_{24}\text{H}_{32}\text{O}_8$ exists in two modifications, melting at 92° and 156°, and appears to have on one side a four-membered ring—

By boiling hydriodic acid it is reduced to a xanthene derivative—

With the exception of filicic acid, all the above substances occur also in the rhizome of *Aspidium spinulosum* (Swartz), in which the filicic acid is replaced by *aspidin* $\text{C}_{25}\text{H}_{32}\text{O}_8$, m.p. 124°–5° (=polystichin, Poulsson, Arch. exp. Path. Pharm. 1898, 41, 246). As the latter fern is often confused with *A. filix mas*, the commercial extracts of male fern may contain aspidin as well. The substance may be recognised in the crude extract by crystallisation (Hausmann, Arch. Pharm. 1899, 237, 544;

Hausmann and Boehm, Annalen, 1903, 329, 321). Aspidin has most probably the constitution—

being built up of aspidinol and filicinic acid butanone. On reduction with hydriodic acid the same xanthene derivative is formed as is obtained from flavaspidic acid.

Most of the above substances are physiologically active on tape worms and other lower animals (Boehm; Straub, Arch. exp. Path. Pharm. 1902, 48, 1); the simplest one having any degree of activity is filicinic acid butanone; lower degradation products are inactive. It is difficult to attribute the anthelmintic action to any one substance in particular, but, according to Kraft (Arch. Pharm. 1904, 242, 489), this action is primarily due to yet another substance, *filmarone*, more complex than any isolated by Boehm. Kraft states that good extracts of male fern contain 3·5 p.c. filicic acid, 2·5 p.c. flavaspidic acid, 0·05 p.c. albaspidin, 0·1 p.c. aspidinol, 0·1 p.c. flavaspidin (probably identical with phloraspin of Boehm), and 5 p.c. *filmarone*. The last substance, $\text{C}_{41}\text{H}_{54}\text{O}_{16}$, is an amorphous brownish-yellow acid, melting at about 60°, and consisting of four different phloroglucinyl ketones. Boiling with zinc-dust and sodium hydroxide decomposes it into filicic acid, aspidinol, and various other substances. Whether *filmarone* is a chemical individual is not clear, but it seems to have met with a certain measure of clinical success.

For cases of poisoning by fern extracts, see Poulsson (Arch. exp. Path. Pharm. 1891, 29, 1); for detection of filicic acid in such cases, see Bocchi (Chem. Zentr. 1896, ii. 1137). G. B.

FILMARONE v. FILIX MAS.

FILROLYSIN. A mixed solution of allylthiourea (thiosinamine) and sodium salicylate. Used in the treatment of lupus and in softening scar-tissue.

FILTER-PAPER. The high-grade filter-paper used by the chemist for analytical work is usually made from cellulose obtained from flax or cotton, mostly in the form of waste material as yarn fabric or rags. Cotton cellulose is preferred owing to its low hydrating power, as compared with linen cellulose, under the action of 'beating,' resulting in what is termed a 'free' pulp, imparting 'bulk' or softness to the paper on which its efficiency as a filtering medium largely depends.

The filter-paper used in analysis, or for chemical work in general, should be as free as possible from inorganic matter. Lime and other inorganic impurities may be introduced into the pulp by the water used, or by the chemical operations in the paper-mill, such as bleaching. Iron and copper may be present from want of care in sorting the material employed. Silica and alumina may be owing to the presence of kaolin in the rags. The organic impurities consist mainly of starch, oil, and resinous matter—the last due to the natural presence of resin in the cotton fibre. The starch arises principally from the dressing in the

rag material, and is largely removed by the treatment with boiling alkali and subsequent washing to which the rags are subjected. The small amount left in the pulp has the effect of 'sizing,' and thereby impairs the absorbing power and filtering speed of the paper. The amount of oil left in good filter-paper is usually not greater than 0.07 or 0.08 p.c. (Bevan and Bacon, Analyst, 1916, 159).

According to McBride and Scherrer (J. Amer. Chem. Soc. 1917, 39, 928), filter-paper frequently contains reducing substances which are extracted by the solutions passed through the paper, and which cause the filtrate to decolorize dilute permanganate solution, such as $\frac{N}{50}$ or $\frac{N}{100}$, especially when the titration is made on the heated liquid, whereby a relatively considerable error may be caused. The experiments indicated that the main bulk of the reducing matter is extracted by the first portion of the reagent passed through, and that if the filter be washed with 25 c.c. of the reagent before use, filtration and titration may be carried out, even on the heated liquid, without sensible error.

FILTER PUMPS. The filter pump is generally some form of dynamic air pump. Sprengel, in 1865 (Chem. Soc. Trans. 18, 9), showed how a very perfect vacuum could be obtained by the fall of mercury or other liquids, and Bunsen, in 1868 (Annalen, 148, 277), showed how the difference of pressure so obtained could be utilised in greatly improving the ordinary process of filtration.

This application has given a name to all these instruments, though they are applicable to nearly all the purposes for which any ordinary air pump or aspirator might be used. Many of them, with a continuous supply of falling liquid or of steam or other gas, under pressure, are almost automatic in their working, and far more convenient than any piston air pump.

The pumps used in laboratories are of three kinds:

1. Barometer or weight pumps.
2. Momentum or pulsation pumps.
3. Injection or pressure pumps.

1. Barometer pumps. Of these there are two varieties, the statical or Geissler pump, and the dynamic or Sprengel pump.

The Geissler pump was invented about 1855 by Geissler, and in it air is exhausted by the alternate emptying and filling with mercury of a vessel forming the upper part of a barometric column. It is simply an application of the Torricellian vacuum. Geissler used this pump in the production of his vacuum tubes, and since his time it has been modified and improved by many inventors: Töpler (Dingl. poly. J. 1862, 423), also Poggendorf, Mitscherlich, Pfleger, Joule, and others.

The Sprengel pump, in its simplest form, is a plain tube of small but uniform bore, and of a length rather greater than that of the barometric column of the liquid used in it. It is furnished with a side tube near its upper extremity. The continuous falling of the liquid, generally mercury or water, produces the exhaustive effect, which is slow at first, but can be made to give a more perfect vacuum than is possible by any other means. The improvements of the Sprengel pump have been chiefly towards quickening its

action, and have been described by McLeod, Swan and Stearn, Gimingham, Weinhold, and others. Crookes' experiments on the radio-meter and radiant matter were rendered possible by the use of the Sprengel pump, and in the manufacture of incandescent electric-lighting lamps these barometric pumps have had a considerable industrial application. The Sprengel pump, worked by water, was that used by Bunsen in his improved mode of filtration, and this application—the most important to the chemist—gave rise to the many inventions described below in this article.

2. The momentum or pulsation pump. This was described by Jagn, in 1872 (Pogg. Ann. 148, 317). It consists of a plain tube of moderate length, with side tube near the upper end. In action, the soft indiarubber tube connecting the apparatus with the water supply (of a very moderate fall or pressure) is ingeniously made to act as a valve by which the water is alternately admitted and shut off. We have thus an action similar to that of the hydraulic ram, in which the momentum of a column of liquid comes into play. In the ram, water is raised in front by the momentum; in this pump, air is pulled in behind. Modifications of the Jagn pump have been described by Thorpe (Phil. Mag. 1872, 249), also by Foote, Linnemann, and O. Witt. As these pumps are intermittent in their action, they work more slowly than others which are continuous, and have been superseded by them.

3. Injector or pressure pumps. These consist of tubes of various forms, but generally furnished with a jet or narrow neck in front of a wider neck or expanding mouthpiece. Any liquid or gas under pressure, such as water or steam, may be used to work them, and in any position.

They are similar in principle and construction to the water pump (Fig. 1) described

FIG. 1.

by James Thomson (B. A. 1852-3) or the Giffard steam injector, patented in 1858. The principle of the injector was, however, partially known long before. Hawksbee, in 1719, found that on blowing through a tube into a small box, the air escaping by another tube opposite the first, the pressure in the box became less than that of the atmosphere; and D. Bernoulli, in 1738, found that water from a higher source flowing towards the wide end of a conical tube could lift water from a lower level through a side tube attached near the narrow part of the conical tube. Between 1830 and 1850, the steam-jet aspirator was used by Carson, G. Stephenson, and others. Clement and Desormes, in 1855 (Ann. Chim. Phys. 36, 69),

showed that a light plate brought near a small orifice in the side of a reservoir of compressed air was attracted, and remained rapidly oscillating near the opening. This effect can be shown by blowing between the fingers against a piece of paper, or by blowing between two cards, as described in Weinhold's Physics, 312. All these experiments are examples of the passage of a fluid through an expanding mouthpiece, causing a diminished pressure as compared with that in front, which in each case is that of the atmosphere.

The first injector air pump for laboratory use was that of Christiansen, described in 1872 (Pogg. Ann. 196, 155). In Fig. 2, A is a piece of thick-walled indiarubber tubing, perforated at B by a hot wire, and constricted at C by a ring drawn over the tube. On inserting at B a short piece of bent glass tubing drawn out to a jet, and connecting the top end of A with the water supply under moderate pressure, air is drawn in through the bent tube, and a considerable vacuum obtained.

Other early forms of injectors were described by Lovett (Chem. News, May, 1874, 209) and Casamajor (*ibid.* June 27, 1875, 33); and soon after these dates numerous forms were invented for the use of chemists, dentists, &c.

The experiments of W. Froude (B. A. 1875), though made for a different purpose, afford an excellent explanation of the action of injectors.

Froude showed that water under any head H (Fig. 3), passing through a contracted pipe, does

FIG. 3.

not exert an excess of pressure on the converging surface, which it meets, as is frequently stated, but that the pressure is least at the contracted part, as shown by the levels in the gauge glasses a, b, c, d, e . If the pipe be much contracted, the pressure can be still more reduced, so that if two cisterns, A and B (Fig. 4), be connected by such a

FIG. 4.

contracted pipe, a portion of the pipe at C may be removed without the flow of the liquid being interfered with; the water rising in the cistern B only slightly below its level in A. At F, in the central line of the connecting pipe, the full head of pressure H is exerted, but there is practically

no movement, while at C there is no pressure, but very rapid movement. The pressure and velocity of movement are therefore convertible and complementary, and the differences of pressure at any two points vary as the differences of the squares of the velocities at those points. In any given case the pressure observed, *plus* that which has been lost in producing velocity, is constant and equal to the total head of water H (Figs. 3, 4, 5). If we modify Froude's experiment and cut off the pipe at E (Figs. 4, 5), the pressure at E is simply the general pressure of the atmosphere, and all the pressure due to the head of water in A has been changed into velocity, but the velocity at C must be greater than the velocity at E by as many times as the sectional area of the pipe at C is contained in its area at E. The velocity at C being so much greater than at E, the pressure must be less, and therefore less than that of the atmosphere. The tube G (Fig. 5) may be regarded as a gauge to show the minus pressure, and if this gauge be supplied with mercury, the latter may rise to near the height of the barometer. In place of water or liquid under pressure, air, steam, or any gas under pressure may be used, and injector air pumps worked by steam have been proposed by Lovett, Kochinke, Teclu, and others.

FIG. 5.

Injector air pumps, worked by water, may be classified:

(a) As in Figs. 6, 7, where the water enters by a jet placed over a constricted tube or neck, the air being drawn in on all sides round the jet of water. The ratio of the areas of the jet and neck in this form is generally 1:2, or their respective diameters 1:1.4.

FIG. 6.

FIG. 7.

FIG. 8.

FIG. 9.

(b) As in Fig. 8, where the jet and neck are continuous and the air enters on one side only.

(c) As in Fig. 9, where the general form is similar to (a), but the air enters by a very narrow jet and the water filling the body of the pump enters all round the jet.

These differences in construction are of little importance in the practical working of the

instruments, but by altering the width of the apertures, pumps suited to different pressures can be obtained. Pumps with very narrow apertures work best with small quantities of water at very high pressures, whereas pumps with wider apertures require much more water at a low pressure. As the water passing through these instruments is practically a falling body, on multiplying the weight of water in pounds used per minute by its head or pressure in feet, we obtain in foot-pounds the power required to produce the exhaust in one minute's working of the pump. Compared in this manner, the low-pressure pumps are less efficient than those working at higher pressures.

In using these injectors, care should be taken to have a sufficient and constant water supply. The water tap turned full on should supply in one minute twice to three times the quantity required by the pump in the same time. In towns and large buildings where many persons are using the water at different levels, the pressure is often very variable, and a reservoir of water under pressure is necessary. A simple form devised by the author is a strong iron bottle (or an iron boiler) capable of standing a greater pressure than is likely to be required, say up to or over 100 lbs. per square inch. This bottle A (Fig. 10) has one tube passing to the

FIG. 10.

bottom connected by a T-piece with the water-supply pipe, and it may carry a pressure gauge if desired. The connection with the water tap may be made with lead pipe and soldered joints, or with sound rubber tubing encased in a double thickness of strong canvas sewn over it, the connections being well bound with copper wire. The bottle being air-tight and water-tight under pressure, and full of air when connected with the supply pipe, the air cannot escape, but is compressed by the pressure of the water. Thus at 15, 30, or 45 lbs. pressure the bottle becomes half, two-thirds, or three-fourths full of water, and with a variable pressure in the supply pipe keeps the pressure more constant, and maintains the supply for some time, depending on the size of the bottle or reservoir. Passing from this reservoir, the supply pipe is next led to the pump B, which may be conveniently fixed out of the way on a board against the wall behind the laboratory table. The board carries a barometric gauge to show the vacuum obtained.

Passing from the pump, the water used runs into the sink on the laboratory table, or if desired it may be connected with a box or drum

provided with an overflow at a certain height, so as to give a blast of air under pressure suitable for general blowpipe work. The vacuum tube from the pump is connected by means of the tap C (Fig. 10) with the safety tube D, having a Bunsen valve fitted inside to the end of the vacuum tube, thence with the barometric gauge E and the laboratory vacuum tube G.

Fig. 11 shows in full size the tap C in Fig. 10, which is fitted to the bottom of the safety tube and to the laboratory vacuum tube at each working place on the tables F (Fig. 10). An ordinary good gas tap, which should be specially ground so as to be as air-tight as possible, has the little screw and washer at the bottom of the plug removed and a hole bored from C into the ordinary through hole of the tap, the latter being soldered up at one side at D, so that the hole is from the bottom to one side only, and the plug is then trimmed and reground. A piece of tubing, FF, is then soldered on to the body of the tap and a pointer, E, soldered on to the top of the plug to point which way it is open. When the plug is turned across in the ordinary position of a closed tap, it is closed to both A and B; when the pointer points to A, it is open towards A, and if towards B to B. The tube FF is fitted air-tight by means of a stopper in the bottle H (Fig. 10).

FIG. 11.

By means of these taps (devised by the author in 1883), one pump can do all the exhaustion work in an ordinary laboratory for a number of filtrations going on simultaneously. The pump is connected with a main pipe of soft lead tubing passing along or under the laboratory tables, and at each worker's place is a bottle like H (Fig. 10) fixed below the table, the tube FF from it rising above the table. One end of the tap, say A, is connected with the vacuum main pipe by soldered lead tubing; the other end of the tap is connected by a flexible tube with the filtering apparatus or other vessel to be exhausted.

In using this arrangement, all the vacuum supplied at B must come from the bottle below FF, and not from the main pipe, which is then shut off. When the vacuum is not required at B, the tap is turned towards A to raise the degree of exhaustion in the bottle. As these bottles are of half-gallon or 2.2 litres capacity, a moderate vacuum in one of them (say half to three-quarters the height of the barometer) is sufficient for a filtration on the small scale, and as there are a number of such bottles in the laboratory they form together a vacuum reservoir of some magnitude available at once without waiting. If well fitted, the taps retain the vacuum for several days. A lute made by dissolving indiarubber in vaseline at as low a temperature as possible is of good service for these taps and connections.

The author made a series of comparative tests of the pumps in common use (J. Soc. Chem. Ind. 1887, 64-76). With a supply and pressure of water suited to each pump, and exhausting receivers of the above capacity, 2.2

litres, vacua corresponding to from half to three-quarters of the height of the barometer could generally be obtained in one minute's workings; such vacua are quite sufficient for ordinary filtrations.

As the apparent size of these instruments is somewhat misleading, the quantity of water used is the real test of size; pumps of the same construction but of different sizes would exhaust a receiver at different rates, but in proportion to the water used.

The table on p. 198 gives the results in brief of tests made with the pumps most frequently found in use; first, in exhausting a receiver of 2.2 litres capacity, and second, in blowing air, with the exhaust tube of the pump open to the atmosphere. The results of the first minute's working only are given, though the tests were carried on to 10 minutes. In each case, those pumps which worked best during the first minute continued to so do throughout, and came nearest to the height of the barometer at the end of the exhaustion.

The blowing power of each pump is also a test of its exhaustive power, as in blowing with the pump open to the atmosphere it is practically exhausting an infinitely large receiver.

Of the high-pressure pumps, those of Fischer, Bulk, Knecht, and Muencke's brass pumps give good results, and of the low-pressure pumps, which use more water, those of Arzberger and Zulkowsky, Finkener, and Körting, are good. Alvergriat's glass and brass pumps are intermediate in character, and work well through a considerable range of pressure.

Given abundance of water at sufficient pressure, the pumps which give the most rapid exhaustions are those of Finkener, Körting, Alvergriat, Arzberger, and Zulkowsky; but where economy of water is desired, the high-pressure pumps ought, if possible, to be used. Though considered as machines doing work for the power put into them, none of these injectors is very perfect, yet they are exceedingly convenient, and it will be observed that all those tested give at some particular pressure in one minute's working sufficient vacua for filtrations and similar laboratory work.

In choosing an instrument for laboratory use, one should ascertain the average quantity of water per minute delivered by the fully open water tap and also the average pressure in the closed water pipes. The pump selected should require not more than half the quantity of water delivered by the open tap, and should work well at from half to two-thirds of the pressure in the closed pipes.

In recent years, there has been a great increase in the use of injectors for industrial purposes, including many chemical and mechanical applications.

Generally, the energy applied in injectors gives about 50 p.c. in real effective duty, but their low initial cost, absence of moving parts, and of metallic or corrodible surfaces, and above all the perfect control under which they can be applied and regulated, more than make up for the low percentage of duty. Thus they are ideal machines where ordinary pumps or exhausters are inadmissible, and are excellent as auxiliary agents to more complicated or permanent apparatus for improving the draught in furnaces, the ventilation in mines and workshops, and the

conveyance or transfer of corrosive liquids and gases, and of mixtures of solids and liquids, such as ordinary sewage, and of mixtures of sand and water. The removal of ashes in steamships is most conveniently effected by this means.

Injectors are used to produce a blast for the division or spraying of liquids, as in the burning of liquid or semi-liquid fuels under boilers, the coating of large surfaces by spraying the paint over them, even where they are difficultly accessible. The spraying of water into the leaden chambers in the manufacture of sulphuric acid is found to be more efficient than the admission of steam.

Similarly, the exhaust obtained by injectors worked by air, steam, or water, is applied in the various methods of vacuum cleaning. These applications are well described in the book on *The Transportation of Gases, Liquids, and Solids*, written and published by Oskar Nagel, of New York, 1910.

A convenient circulating pump which may be constructed out of ordinary laboratory materials, and is adapted to maintain a flow of water around most complex apparatus at almost any desired rate, has been contrived by J. S. Morgan (*Chem. Soc. Trans.* 1915, 107, 1710). A simple valve to prevent water from being sucked back into the filtering flask has been described by Hutchinson (*Chem. News*, 1912, 106, 99).

T. F.

FILTRATION is the operation of mechanically separating finely divided solids from their associated liquids by means of porous media.

FIG. 1.

The media used may consist of loose material, such as sand; a compact body, such as biscuit pottery; or woven or felted materials, such as cloth, paper, and felt. It may be remarked, however, that the real filtering medium is often the layers of separated solids, the materials mentioned above only serving as convenient supports. A loose filtering medium is generally adopted where the proportion of liquid is relatively large and the solids of little value. The filter shown in Fig. 1 may be used for cleansing

FIG. 2.

an effluent. Each compartment, *a*, is filled with wood-wool, kieselguhr, or similar material which is replaced when choked. Fig. 2 is a section of

a filter in which the bed, 6-10 inches deep, is formed by means of layers of graded materials, as gravel, sand, coke, limestone, &c. The upper layer of (finest) material is retained in place by a covering of stout wire gauze or perforated metal, when the shovels of the workmen are removing the separated solids. By providing a movable basket with a bottom of gauze which may be lifted by means of a crane, an economy in handling is effected where labour is dear. This filter is intended for vacuum working by connecting the lower pipe opening *a* to a vacuum vessel and pump. The swinging pipe *b* enables the workman to remove rapidly the upper layers of liquid, which may become clear by subsidence. In filters of this type, where the solids are of no value, their removal is often accomplished by stirring the upper layers and running to waste the turbid liquor. The direction of the liquor current is often reversed

for the same purpose. Water supplies are usually filtered through sand filters, and by the addition of a coagulant (to form large aggregations), such as aluminium sulphate, pressure may be used, and the rate of filtration increased from 4 to over 200 vertical inches per hour. The ordinary domestic water filter, in which hollow cylinders of biscuit pottery are used as the filtering medium, is occasionally met with in a large form in chemical factories. To obtain suitable porosity, such filtering devices are made of clay mixed with finely divided combustible materials such as wood, cork, &c., which are burnt off in the process of firing. Filter stones are made on this principle, in which the layers are of varying porosity. For very fine precipitates in acid solutions filters provided with such 'stones' or 'tiles' are most successful, and are far more economical than filter presses using woollen cloths. A

FIG. 3.

common form is shown in Fig. 3, and consists of a lead-lined steel cylinder holding three (one or more) filtering trays, which may be attached to the front cover and moved in and out on rails. The 'tiles' are provided on the underside with grooves or with feet to rest on the floors of the trays, and are cemented in position. Outlet pipes with valves passing through temporary joints on the front or back of the cylinder provide for the discharge of the filtrate.

The trays may be filled with sludge or mother liquor while outside the cylinder, or simple arrangements may be made for the purpose after the admission of compressed air when filtration is proceeding. Sight glasses are sometimes provided for inspection, especially to ensure that washing commences before the cake of precipitate begins to crack. Generally, the operator waits until air appears at an outlet before the valve of that particular tray is closed. The cake is washed in a similar way, and since

there is little diffusion, the amount of washing water required is very small. The rate of filtration through these 'tiles' does not alter after many months of use, and the filtrate is bright from the start.

The simplest filtering apparatus in which a woven fabric is used consists of a frame to which the fabric is secured. A wicker basket is sometimes used, and this arrangement is most convenient where the cake of material is to be folded in the cloth and squeezed in a press for the removal of more liquor. Washed graphite and similar materials are often separated in long and narrow canvas bags tied to spouts in the delivery channel from the washing apparatus. A simple form of vacuum filter, using a woven fabric or a disc of paper as a filtering medium, is shown in Fig. 4. It is made in stoneware, the perforated plate *b* supporting the fabric and the vacuum pump being connected with the nozzle *a*.

Filtration may be carried out in centrifugal

machines which are conveniently driven from below. The rotating basket is provided with a removable cage carrying the filtering cloth, which is bodily removed and replaced at each

will take place fastest at those points where the resistance to the flow of liquor is least, i.e. the porosity of the cake is automatically maintained constant all over, with a result that the washing must also be uniform and efficient.

FIG. 4.

FIG. 5.

operation. Another system by which rapid filtration may be obtained with a small area of filtering surface consists in mounting the filter cloth on a perforated drum, as shown in the diagrammatic section (Fig. 5). The drum revolves about once a minute in a bath of the liquid to be filtered which is maintained at a constant level. The filtrate is removed from the inside of the drum under a vacuum of 10 or 12 inches of mercury, produced by connecting the hollow spindle of the drum with a vacuum vessel and pump. The deposited solids on the surface of the drum are washed by the water jets *b* and finally removed by the scrapers *c*.

A type of filter which is now coming into common use is the vacuum leaf-filter. In this filter a group of flat filtering bags, provided with means to prevent them from collapsing, are surrounded by the liquid to be filtered, and a partial vacuum applied to the interior of the bags or leaves. When cakes of most efficient thickness are formed, either the mother liquor

support the filter cloth and to enable the liquid which has passed through the cloth to leave the press through a channel in the plate. The solid

FIG. 7.

matter is retained in the hollow spaces, and is discharged in cakes by separating the plates. The hollow spaces between the plates are formed either by raised margins on the plates, *Recessed plate type* or *chamber press* (Fig. 7), or by means of distance frames, the width of which determines the thickness of cake formed, *Flush plate and distance frame type* or *frame press* (Fig. 8). The plates and frames are made of material suitable for the liquors to be treated, and may be of cast iron, gun-metal, aluminium, hard lead, wood, &c. Iron plates are sometimes covered with sheet tin, lead, zinc, or ebonite. Chamber presses are to be preferred where the solids do not form a solid cake, or where there is risk of choking the narrow channels leading to the frames of the frame press. The pressure used and the thickness of cake are also determined by the character of the separated solids. With slimy solids, a thin plate and a low pressure are desirable; the cake may be $\frac{1}{2}$ inch thick and the pressure may be that produced by placing the feed tank a few feet above the press. Easily filtered solids may be separated in a frame $\frac{3}{4}$ inches wide at a pressure of over 100 lbs. per square inch. Frames 1 inch wide are used in general work.

Owing to the facility of forming channels through the press from plate to plate by

FIG. 6.

or the group of filtering leaves is moved, and washing water applied. After washing, the cakes may be dislodged from the leaves by a puff of compressed air. It will be realised that, during the formation of the cake, deposition

FIG. 8.

providing holes in each plate in similar positions, many complicated operations may be performed. The liquid treated may be continuously maintained at a suitable temperature by providing channels in each plate for the circulation of a hot or cold fluid. By the provision of rubber diaphragms and water under high pressure, the cakes may be squeezed before removal from the press. Washing the cakes is simply accomplished by feeding the washing water by means of a special channel behind the filtering cloths of alternate plates, and allowing it to leave the press by a channel connected to the remainder of the plates (Fig. 8). As the washing water rises in the cakes, the imprisoned air is allowed to escape by means of air cocks.

The joints between the plates at each of the holes which form a channel through the press, are made by rubber packing rings or by the arrangement of short pieces of rubber pipe so that the internal pressure of the liquid ensures tightness.

Air vessels of ample dimensions should be fitted to pumps feeding filter presses to prevent variations in pressure. Taps are usually provided on each plate for the delivery of the filtrate, so that any plate may be cut out should its effluent become turbid. In starting the filtration, the pressure is applied gradually to build up the filtering layer; with some substances, the filtrate is always turbid for a second or two. In presses where the plates deliver their filtrate into a common channel, small cylindrical filters supported in cages are sometimes provided to stop this action and also, by choking, to automatically stop the delivery of a turbid filtrate through the piercing of any filter cloth. Presses for volatile liquids are usually provided with a cover dipping into an oil or water seal, and connected on occasion with suitable recovery plant.

The materials used as filter cloths are simply well-made strong fabrics—cotton material for most purposes, woollen fabric for dilute acid liquors, and for certain fine work, silk. The filter paper used should be crinkled to admit of its expansion in contact with its supporting fabric. Wire gauze or perforated metal plates are used for some filtrations, a filter bed being first formed by running into the press a pulp of vegetable or mineral fibres.

The rate of filtration and washing is comparable with the flow of liquids through capillary tubes, provided that it is understood that the total area of the passages through the cake is affected by the pressure and by the viscosity of the filtrate or washing liquid.

If washing be carried out at pressures which do not break down the cake, the rate of washing will depend on the filtration pressure, and is directly proportional to the washing pressure, and inversely proportional to the thickness of the cake and the viscosity of the washing liquid. During filtration, however, owing to the pressure affecting the porosity of the cake, the rate is usually proportional to the pressure raised to a power less than unity. An increase in the viscosity of the liquid increases the value of this index. In the case of a coarsely granular or crystalline precipitate, the value of this index may be 0.6, but with fine amorphous material it may not be more than 0.2. With gelatinous

precipitates the effect of pressure on the porosity of the cake is generally so serious, that only enough pressure to ensure the flow of the mother liquor may be used.

With precipitates requiring much washing, it is good practice to filter at a lower pressure than that at which washing is carried out, for not only is the rate of washing increased, but the efficiency of the washing is improved. It will be noticed that in the ordinary filter press the thickness of cake during washing is twice that during filtration, when the mother liquor is delivered in the middle of the cake.

FINE BLUE, GENTIAN BLUE 6B, SPIRIT BLUE, OPAL BLUE, BLEU DE NUIT, BLEU

LUMIERE. The hydrochloride, sulphate, or acetate of triphenylrosaniline and triphenyl-pararosianiline (*v.* **TRIPHENYL-METHANE COLOURING MATTERS**).

FIRE-CLAY. A refractory clay suitable for the manufacture of fire-bricks for furnace-linings, gas-retorts, crucibles, glass-house pots, &c. The qualities required for such goods are that they should retain their size and shape during firing, possess strength and durability, resist high and sudden changes of temperature, and the corrosive action of hot liquids and gases. The attainment of a combination of these qualities best suited to any particular purpose will depend more on the physical characters of the fire-clay than on its chemical composition, and actual trial of samples is desirable rather than detailed analyses. It is, however, essential that the material should consist mainly of aluminium silicate, with only small amounts of alkalis, calcium, iron (especially as pyrites), and titanium, all of which have the effect of lowering the fusibility. The presence of free silica also has the same effect, but to a much less degree. Pure kaolinite ($\text{H}_2\text{Al}_2\text{Si}_2\text{O}_8$, m.p. about 1820°) and quartz (m.p. 1760° , as tridymite) are both highly refractory, but mixtures have a lower melting-point than either, with a minimum of 1630° for 90 p.c. kaolin and 10 p.c. quartz. This is, however, still above the lower limit (about 1600°) usually allowed for a fire-clay. The best fire-clays occurring beneath beds of coal in the English coal-measures contain Al_2O_3 , 20–30 p.c., and SiO_2 , 50–70 p.c. (corresponding to about 3–23 p.c. of free silica). With increasing amount of silica these clays gradually pass into sandstones, which are also used as refractory materials; *e.g.* ganister (*q.v.*) and the so-called Dinas 'clay' from the Vale of Neath in Glamorganshire, containing as much as 98 p.c. of silica. The analyses at top of next column are of fire-clays from: I. Stourbridge in Worcestershire, by C. Tookey (also P_2O_5 , 0.06 p.c.). II. Dowlais in Glamorganshire, by E. Riley. III. Better-bed fire-clay from Bowling in Yorkshire, by J. W. Westmorland (also TiO_2 , 0.87 p.c.). IV. Plastic fire-clay from St. Louis, Missouri, quoted by H. Ries, 1908 (also SO_3 , 0.35). (For a large series of analyses of British and foreign fire-clays, *v.* Percy's Metallurgy: Fuel, 1875, 87.)

The celebrated fire-clay of Stourbridge in Worcestershire is remarkable for the small amount of contraction that it undergoes when fired, the shrinkage of the unrefined clay being in some cases as low as 1 p.c. For the purpose

	I.	II.	III.	IV.
SiO_2	65.10	67.12	68.12	57.62

of reducing shrinkage, fire-clay is often mixed with 'grog,' *i.e.* burnt fire-clay, which has also the effect of giving sufficient porosity to the fire-bricks to enable them to withstand sudden changes of temperature. A greater degree of porosity, with correspondingly less strength, required in the fire-bricks of household stoves, is often produced by mixing sawdust with the clay.

A fire-clay occurring in the millstone-grit series at Glenboig in Lanarkshire, has been examined by J. W. Gregory and D. P. McDonald (Proc. Roy. Soc. Edinburgh, 1910, xxx. 348, 374), who find that the fine-grained clay substance forming the bulk of the material is present as minute rounded granules about 0.001 mm. in diameter; this is amorphous and not crystalline, and is referable to the mineral species halloysite rather than to kaolinite. Embedded in it are abundant grains of quartz, some grains of feldspar, and minute crystals of a rhombohedral carbonate referred to sideropileite (a variety of chalybite).

L. J. S.

FIRE EXTINCTION AND PREVENTION.

Combustion, as it exists in ordinary cases of fire, is due to the rapid combination of the burning material with the oxygen of the air at temperatures above the ignition-point, and it may be extinguished either by lowering the temperature of the burning mass below the point necessary for the continuance of the combustion, or by cutting off the access of air, and so depriving the combustion of the oxygen which is essential for its support.

The usual method adopted for extinguishing a fire is to pour on to the blazing material a large volume of water, and this acts partly by rendering heat latent in its evaporation, and so cooling down the burning mass, and partly by the steam generated driving back the air and so giving time for the cooling action to take effect.

The force with which the water is thrown upon the burning body also produces a considerable effect by sweeping the flame from the surface and so extinguishing the burning gaseous products.

Although, in round figures, 1 lb. of well-dried wood on combustion will convert about 5 lbs. of water into steam, yet in the early stages of a fire it is only the surface of the wood that is burning, so that the 5 lbs. of water will have a useful effect over a considerable surface, whilst

the steam generated occupies a volume about 1700 times that of the water used.

In the use of water, a certain amount of discretion is necessary, as otherwise undesired results may follow. For instance, in a big warehouse fire, the lower portion soon becomes a mass of red-hot carbonaceous matter, and if water is recklessly played into this, the water is almost instantly turned into steam, which is decomposed in passing through the surrounding red-hot carbon, forming a mixture of hydrogen and carbon monoxide, known as 'water gas.' This gas is inflammable, and by its combustion adds to the general blaze, whilst, if it escapes being ignited, it may collect under ceilings and roofs, where, mixing with air, it forms a highly explosive mixture liable to be ignited by any chance flame or spark.

If, however, the water is directed on to the top of the mass, the carbonaceous matter is cooled downwards, so that the steam evolved does not pass through the glowing carbon, and there is thus the minimum generation of inflammable products.

A fire can also be extinguished by practically smothering it by cutting off the supply of air, and although this is rarely practicable, yet the closing of all doors and windows, by reducing the quantity of air available, checks the combustion.

Water is useless for the extinction of burning oils and spirits, as these, being lighter than water, float on the surface and continue to burn. The best way of treating a fire of this kind is to throw on it sawdust, sand, or earth or anything that will serve to keep the air away, and so cause the flame to die out.

Sawdust is more efficient than sand, as it floats on the burning liquid. For the extinction of small petrol fires, such as may occur in a garage, the British Fire Prevention Committee recommend the use of a mixture of sawdust, 1 bushel (about 12 lbs.), with 10 lbs. of sodium bicarbonate. The sawdust floats on the burning liquid, smothering the fire, and the action is materially assisted by the carbon dioxide given off by the bicarbonate. A mixture patented in the U.S. as 'Foamite' consists of acid sulphate of alumina and bicarbonate of soda, the latter being mixed with a licorice decoction. The two solutions are run simultaneously into a mixing tank, and thence flow to the fire. Another foaming mixture is produced from solutions of sodium hydroxide (caustic soda) and ordinary alum. The separate liquids are kept ready for use at many stores and garages.

Attempts have been made to employ certain gases which are unable to support combustion, and which can be obtained commercially at a fairly cheap rate, but the advantages of this method are very doubtful, as, unless the whole of the surrounding air can be replaced by an atmosphere of the extinguishing gas, little good results. With a fire well alight in an open space, there is always a strong up-current of hot air and the products of combustion, so that any gas poured on to the fire would be carried upwards out of the area where it would be effective. In certain cases, however, as in confined spaces, this method has its uses. For instance, when a chimney is on fire, the combustion can be stopped by throwing a handful of sulphur on

the fire in the grate. The sulphur burns, forming sulphur dioxide, and this being drawn up the chimney cuts off the supply of air from the burning soot and so extinguishes the fire.

The fact that certain gases and salts will extinguish a fire under certain conditions, has led to a variety of apparatus being designed, which are known under the name of chemical extincteurs, and vary in size from the small hand grenade to the horse-drawn or motor-driven chemical fire engine. Amongst the substances that have been brought into requisition for this purpose are such gases as carbon dioxide, hydrochloric acid gas, and ammonia, none of which supports combustion, and salts, like common salt and borax, tungstates and phosphates of the alkali metals, which form a protective coating on the surface of the combustible material.

Extincteurs may be divided into two classes, those in which carbon dioxide is provided in a liquefied form in a suitable capsule which can be pierced, or the gas generated rapidly from a charge of some carbonate, such as chalk or sodium carbonate, and an acid in the presence of a large volume of water. The pressure created by the evolution of the carbon dioxide in the containing vessel causes the water to dissolve the gas, and at the same time the pressure drives the water holding the gas in solution through the small hose and nozzle on to the fire. The water, as soon as it is subjected to the ordinary atmospheric pressure and heat, gives up the carbon dioxide, which, together with the steam, drives the air away from the burning material, whilst the cooling effect of the water is aided in the extinction by the salts in solution coating the heated mass.

The substances generally employed for the rapid evolution of the carbon dioxide are sodium carbonate and hydrochloric or sulphuric acid. These chemicals must, of course, be kept separate in the extincteur until the moment when the apparatus is brought into action, and there are several devices for securing this end. In some cases, the acid is contained in a thin glass bottle, which is left unsealed, at the top of the apparatus, whilst the carbonate is dissolved in the water. On turning the containing vessel upside down, the acid runs out of the bottle and mingles with the carbonate solution, causing immediate evolution of the gas. In other forms, the acid is in a sealed bottle, which is broken either by the release of a leaden weight inside the extincteur or by a blow on a plunger from outside. In the large forms of extincteur, the acid is contained in a bottle covered by a lead capsule, which can be pierced when necessary by a lever from outside the apparatus.

According to a Memorandum of the British Fire Prevention Committee (Tests on Fire Extinguishers, No. 186), bicarbonate of soda is usually employed, and care must be taken that the normal carbonate is not substituted in appliances designed for the former. The sulphuric acid should be 1.84 sp.gr., and the quantity used should be considerably less than the theoretical amount, so that the discharged liquid shall not be acid. One lb. of bicarbonate requires theoretically 9.3 ozs. of pure sulphuric acid, but the maximum quantity should not exceed 6 ozs. (by weight); smaller quantities

down to 3·5 ozs. (weight) being equally effective. 0·75 lb. of sodium bicarbonate is sufficient for 2 gallons of water. An air space of 15 p.c. should be allowed for expansion of the liquid. The quantity of liquid should not exceed 3 gallons; with this amount the total weight of the extingisher will approximate to 0·5 cwt. Less than 1 gallon of liquid is too small to be of practical value. Dangerous pressures may be set up through the rapid generation of gas, especially if some obstruction at the valve or discharge exists, and several fatal accidents have occurred. The Committee recommend that all extingishers should stand a hydraulic pressure test of 350 lbs. per square inch for 5 minutes, and the same applies to rubber hose. For certain situations it may be necessary to provide against the liquid contents freezing. Such salts as common salt or calcium chloride are employed, and these may set up corrosion of the metal container, solders, &c.

The second class of extingisher contains solutions of chemicals which coat the combustible materials, and in addition some of them employ chemicals which give off extinctive gases when subjected to the heat of the fire.

One of the most effective of the many solutions that can be used for this purpose is a solution of a mixture of sodium sulphide and ammonium chloride in molecular proportions. When this is thrown upon a hot fire, sulphur dioxide and ammonia are set free and smother the combustion, whilst the remaining combustible gets coated with a glaze of common salt.

For small fires and in the earliest stages of a fire in an enclosed space, extingishers have proved very useful, but in the open and with a strong conflagration they are perfectly useless. A fire can rapidly and easily be extinguished if it be attacked within a few minutes of its starting, but in the majority of cases the fire originates during the night or when the place is shut up, so that by the time the outbreak is noticed the fire has gained a firm hold. In order to cope with these cases, numerous automatic devices, such as sprinklers, have been brought forward.

The first form of automatic sprinkler was introduced by Major A. Stewart Harrison, who had the idea of fitting the various rooms to be protected with a system of water pipes furnished at the necessary places with nozzles closed by easily fusible metal plugs. Any serious rise in temperature melted the plugs and started the flow of water through the various jets. Automatic sprinklers have been widely employed, and many different forms of apparatus, based in general on the release of a valve by the melting of strips of fusible alloy, are in use. The alloy commonly employed has the composition: bismuth, 4 parts; lead, 2 parts; tin, 1 part; cadmium, 1 part. Its melting-point is 65°C. (150°F.). Such fusible alloys have also found application in the automatic release of fire-proof doors, shutters, &c.

It is the earlier stages of an outbreak of fire that are the most important from the point of view of ease of extinction, and in order to draw attention as soon as possible to an outbreak of fire in a building, such as a closed warehouse, automatic fire alarms have been devised, which on an undue rise of temperature, complete an

electric circuit and ring a bell at a fixed place some distance away, say, at a fire station. The first forms of automatic fire alarm consisted of thermostats, which were sensitive thermometers, into the bore of which were sealed platinum contacts: as the temperature at the seat of the fire rose, the mercury of the thermostat expanded and completed an electric connection, causing a fire alarm to ring. But these were not certain in action, owing to the surfaces of the mercury and platinum becoming dirty and failing to establish contact, so to obviate this trouble, liquids having a cleansing action were introduced above the surface of the mercury to prevent any amalgamation or oxidation and ensure contact.

Another form of thermostat consists of a closed U-tube containing mercury, above the surface of which in each limb a volatile liquid is confined, and one limb is also surrounded by an insulating sleeve. A sudden rise of temperature will cause the liquid to volatilise more rapidly in the exposed limb, and so drive the mercury downwards: this action opens a closed electric circuit and closes a secondary system, which transmits a signal to any required spot. A differential thermostat is also used in connection with a fixed temperature thermostat, which remains stationary until a definite temperature is attained, and then has a long range for a small increase in temperature. After the first warning call has been given, a further rise in temperature gives a fire call.

Some alarms depend for their action upon the unequal expansion of metals, whilst others rely on the difference in rate of expansion between relatively large and small masses of the same metal; but in all cases, the movement brought about by the sudden rise of temperature is made to complete an electric circuit, and thus give warning at some predetermined place.

Although timber, like all organic substances, is combustible and is burnt away when subjected to a high temperature, yet it can be treated in such a way as to render it fireproof, so that, instead of causing it to burn away, intense heat merely chars it. Various substances have been suggested for this purpose, but many of these so-called 'antipyrènes' have proved unsuitable owing to their injurious effect upon the wood or upon the paints and varnishes used upon it. Common salt was at one time regarded with much favour as a fireproofing material for wood, but its hygroscopic properties ultimately caused its use to be abandoned.

Any substance which is to be used for fireproofing wood must have no deleterious action on the wood or corrode the nails and screws inserted in it, and must also be a stable and non-volatile body, otherwise, although the chemical might do the required work for a short period, if evaporated it would leave the wood as inflammable as before. The compounds, which practical experience has shown to be of use in this direction are ammonium chloride, ammonium phosphate, ammonium sulphate, calcium chloride, magnesium chloride, zinc chloride, zinc sulphate, stannous chloride, alum, borax, boracic acid, and the tungstates.

On a practical scale, the timber is run on a trolley into a large chamber, which is sealed up and then exhausted of air as far as possible. In

this way, all the air and moisture are extracted from the cells of the wood, and, after allowing the wood to remain in the vacuum for some time to complete the extraction, the solution of chemicals is run into the chamber, the whole of the contents being then placed under hydraulic pressure, the amount of which is carefully regulated according to the nature of the wood under treatment, as the pressure required by a dense wood would crush and destroy the cells of a lighter timber. A gauge glass on the chamber shows when the right proportion of liquid has been absorbed, when the wood is removed, drained, and dried at a definite temperature. The temperature to which the wood is subjected for drying purposes has a great effect upon the quality of the final product: too high a temperature will cause the wood to be brittle, but if the correct temperature be employed, the wood dries with all its original qualities unimpaired, but with the added property of non-inflammability.

Wood treated in this way, with mixtures of ammonium phosphate and boric acid, can be worked in just the same way as non-treated wood: it has no injurious effect upon the tools, and will take paints, varnishes, and other decorative material as well as before treatment, whilst nails and screws do not corrode in it.

When wood thus treated is subjected to the action of a flame, charring takes place, as the cellulose of the wood fibre is still left, and under the action of heat is carbonised, but directly the flame is removed the charred mass blackens, and no spreading of the fire takes place. This effect is due to the chemicals used (chiefly ammonium phosphate and boric acid) being forced into the cells of the wood by the course of treatment adopted, and once there it is practically impossible to remove them. Under the influence of heat, the ammonium phosphate decomposes, giving off ammonia and phosphoric acid, the former of which drives any air out of the wood replacing it by a non-combustible gas, whilst the phosphoric acid together with the boric acid coat the cell walls with a glaze, which prevents the access of oxygen from the air to carry on further combustion. V. B. L.

FISCHER'S SALT. *Potassium cobaltinitrite.*

FISETIN, FISETOL *v.* YOUNG FUSTIC.

FISH OILS *v.* OILS AND FATS.

FLAGSTONE. A stratified rock which may be split along the planes of bedding into smooth-faced slabs, suitable for use as paving stones. If the stone is too absorbent, or finely laminated, the surface is apt to flake off by the action of frost. As hardness and durability are essential in a flagstone, sandstones are superior to calcareous or argillaceous rocks. The flaggy sandstones are generally micaceous; and their fissility may be partly due to the presence of mica along definite planes. The best English flagstones are derived from the lower coal-measures, the millstone grit, and the Yoredale rocks. Most of the flags used for paving the streets of London are obtained from the Yorkshire coal-field. The Elland flagstone, which is extensively worked, is a fine-grained micaceous sandstone from the lower coal-measures, or ganister series, extending with persistence through the coal-fields of Yorkshire, Lancashire, and Derbyshire. In Scotland, the lower old red sandstone yields

paving slabs of very large size, the best-known being the dark-grey flagstones of Caithness and the Arbroath pavement of Forfarshire. The celebrated Caithness flagstone is one of the most important economic products of the old red sandstone. It is used locally as a building stone, and for use as stone flooring and stair-cases it has been exported to all parts of the world. The extensive works for Liebig's meat-extract on the River Plate in South America are floored throughout with Caithness flags. The stone is finely laminated, tough and compact, and its cementing material is siliceous, argillaceous, calcareous, and bituminous. The last of these, derived from the vast number of fossil fishes, renders the stone impervious to moisture. Analysis of stone from the Castle Hill quarries at Thurso, Caithness-shire, gave: SiO_2 , 69.45; $\text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3$, 10.50; $\text{K}_2\text{O} + \text{Na}_2\text{O}$, 2.20; CaCO_3 , 10.65; organic matter, 5.79 p.c. Weight per cubic foot, 157 lbs. L. J. S.

FLAKE WHITE. A variety of white lead (*v.* LEAD). The term is also applied to basic bismuth nitrate.

FLAME.

Incandescence of gases. When solids and liquids are heated beyond a certain temperature by an external source of heat, they become luminous, and the intensity of the light emitted increases very rapidly as the temperature is further increased. There is no reason to suppose that gases would behave differently except in degree, for according to the kinetic molecular theory of matter, light should arise from molecular vibrations occasioned by molecular collisions. It is doubtful, however, whether a gas has ever been brought by artifice into what may be called a state of purely thermal glow. The high transparency of gases to light is correlative to a very low emissivity. Iodine vapour, which is an exceptional gas in its absorptive power, does indeed glow when heated in a glass tube even when the walls are considerably below a red heat, but there is reason to believe that this glow is connected with the dissociation and recombination of the atoms in the iodine molecule (see especially Evans, *Astrophys. J.* 32, 1, 1910).

Attempts to heat colourless gases, such as nitrogen, to the glowing-point, have given negative results.

In almost every case, a flame is glowing gas, and in view of the facts just recited we must add the qualification that the glow is the accompaniment of chemical change. It would be possible to refine upon this definition. A 'flame' of pure hydrogen in dustless air is, according to Stas, invisible, the radiation of short-wave length being wholly in the ultra-violet. Again, the glow observed during the decomposition of acetylene in a hot tube may be due wholly to the particles of liberated carbon and in no degree to anything gaseous. But, speaking generally, the basis of flame is a glowing gas, and the exciting cause chemical action. This description would include ordinary hot flames and also flames of the kind called phosphorescent, which may be quite cold in the ordinary sense of the word.

If, then, a chemical change takes place, resulting in the production of gas and the liberation of a quantity of latent chemical energy, a

flame may make its appearance. Experience shows that this only occurs when the amount of energy liberated is very considerable, in other words, flames are only to be expected during the resolution of highly endothermic compounds, like gun-cotton, into gaseous constituents, or during the formation of highly exothermic compound gases from their components, as in the case of carbon dioxide from carbon monoxide and oxygen. In phosphorescent flames, such as that of phosphorus, the energy liberated per gram-molecule of product formed is no less considerable.

Flames produced during the decomposition of single endothermic compounds do not call for any detailed consideration, since, apart from their genesis, they do not present many special features of interest. The case of acetylene is interesting, inasmuch as a flame initiated in a column of the gas at one point is not propagated for more than a short distance, unless the gas is under a pressure of about two atmospheres.

Conditions determining flame. The principles underlying flame phenomena are best considered in the ordinary case where the flame is occasioned by combination between two substances, either single substances or mixtures of substances. Such a case as that of coal gas and air is complicated by the fact that both these substances are mixtures, and it is to be remembered that in the intermingling of such mixtures the diffusive power of each component will assert itself and lead, for the moment, to local variations of condition.

In selecting even one of the simplest cases for the purpose of discussing flame phenomena, it is necessary to premise that there are many factors of which we have at present only an imperfect knowledge, and many doubtless of which we have no conception at all. We may recall, for example, the remarkable discoveries concerning the influence of minute quantities of water vapour upon the initiation and intensity of combustion. The mechanism of what was formerly regarded as so simple a chemical phenomenon—the burning of hydrogen—is full of difficulties. H. B. Dixon, discussing this subject (*Chem. Soc. Trans.* 1910, 97, 661), considers that steam intervenes in the initial action of hydrogen on oxygen at moderate temperatures, but he does not think it necessary for the propagation of a flame once started in the mixture. The mode of action of the steam, which, according to E. W. Morley's calculation, quoted by Bone (*British Association Reports*, 1910), is present to less than the extent of 4 molecules per 1000 million molecules of dried gas, is at present unintelligible.

Notwithstanding Larmor's conclusion about the infrequency of trimolecular collisions in a gas, and the support thereby given to the theoretical and experimental inference of other workers as to the probability of one molecule of hydrogen uniting initially with one molecule of oxygen, Dixon shows that there are great difficulties in maintaining that hydrogen peroxide is the first product formed in a hydrogen flame.

Similar complications present themselves in nearly every case of combustion. The main phenomena of flame can, however, be usefully discussed without entering into minutiae of the chemical transactions involved, and this course will be taken in what follows.

Limits of inflammability. In order that a flame of the common type may be produced, it is necessary to have the combining substances mixed in certain proportions, and to heat a portion of the mixture initially to a certain temperature. The proportions within which self-sustaining flame may be incited are called the *limits of inflammability*, and the temperature at which self-sustaining flame is set up is called the *temperature of ignition*.

When a portion of a stationary inflammable mixture is raised to the temperature of ignition, unless the quantity so heated is very minute, a flame travels through the mixture. The flame may, however, be quenched in the neighbourhood of surfaces of high heat conductivity, as, for example, when it enters narrow tubes or impinges upon a fine metallic meshwork. This is the well-known principle which applies in the miner's safety lamp, the flaming fire-damp and air within the lamp being extinguished in contact with the metallic gauze. The rate at which a flame travels through an inflammable mixture depends, apart from the form and material of the enclosure, on the nature of the gases, on their proportion in the mixture, and on the distance traversed. Formerly, the rates of inflammation of gaseous mixtures were supposed to be very moderate. Thus, for hydrogen and oxygen in the proportions of electrolytic gas, Bunsen gave the rate of propagation of flame as 34 metres per second.

The existence of vastly higher rates was first demonstrated by Berthelot, in the discovery of the 'explosive wave,' and as the result of his researches as well as those of Mallard and Le Chatelier and H. B. Dixon, we now know that in many gaseous mixtures the initial slow rate of inflammation may be succeeded by a rate of explosion or detonation, amounting to between 1500 and 3500 metres per second. If mixtures of this kind be ignited at the end of a long tube, the flame first proceeds with a sensibly uniform velocity for a distance of from 0.25 to 1 metre (period of inflammation); then a vibratory movement ensues, which increases in intensity until finally the explosive wave is set up, and the flame proceeds through the rest of the mixture with the high velocity just described.

In connection with flames, we are concerned only with the rates of inflammation, and these are exhibited for a number of mixtures in the diagram (Fig. 1 taken from Chapman, *Chem. Soc. Trans.* 1921, 119, 1679).

As will be seen from the diagram, the rate of propagation of flame is not necessarily greatest in mixtures containing the combining gases in the proportions just required for complete combination. The flame in a mixture of 40 p.c. of hydrogen and 60 p.c. of air has a higher rate of propagation than one with 28 or 29 p.c. of hydrogen (the stoichiometric proportions). This apparent anomaly is explained when we consider that (1) heat evolution per unit volume of the mixture diminishes as we depart from the stoichiometrical proportions; (2) heat conduction from layer to layer increases in rapidity as the proportion of the highly conducting gas (hydrogen) increases, until (3) this accelerating effect of the gas in excess is balanced by the diminution of heat evolved per unit volume of the mixture.

Temperature of ignition. The temperature of ignition of gaseous mixtures is the temperature

FIG. 1.

to which a portion must be heated to produce self-sustaining flame. The fact that they are usually ignited by a match flame or a spark of high temperature produces the impression that a flame necessarily appears *per saltum*. Experiment and theory teach that the rate of chemical action varies continuously with varying temperature, and if flame is merely an accompaniment of chemical action, it should appear gradually as the temperature is increased. The fraction of combining molecules in a mixture at low temperature might not yield a visible amount of radiation; but as the temperature rose we might expect a glow to appear gradually and to intensify. As the rate of chemical action normally increases very rapidly with increasing temperature, the luminosity need not appear far below the temperature of ignition. To test this view, it is therefore necessary to examine mixtures in that region of temperature. Almost the only case that at once presents itself is that of phosphorus. Phosphorus ignites at about 60°, so that at the ordinary temperature it is within 50° of its temperature of ignition. The fact that its vapour glows at ordinary temperature is the best-known property of phosphorus. The glow diminishes as the temperature is reduced, and disappears at about 7°.

If other combustible substances are examined under corresponding conditions, the vast majority show the same property. All that is necessary is to heat them in admixture with air to a temperature near their igniting-point, when they show all the appearance of 'phosphorescence.'

When phosphorescence begins, the number of molecules combining in a given volume of the gas is small, so that the elevation of temperature of the whole mixture will be small. As the temperature is raised and the phosphorescence

intensifies, a greater rate of combination has set in, and the liberation of heat becomes more perceptible.

The foregoing considerations lead to a tolerably precise characterisation of the temperature of ignition. As heat is supplied at an increasing rate to a gaseous mixture, the rate of combination increases, and if the combination itself produces heat, a point will be eventually reached when this heat will be produced with sufficient speed to compensate the loss due to radiation and conduction. The source of external heat may then be withdrawn and the burning will continue. The temperature required to induce this condition is the temperature of ignition. It may be well illustrated by causing the vapour of carbon disulphide to issue from a tube at the mouth of which is a ring of platinum wire that can be gradually heated by an electric current. A phosphorescent flame appears below the temperature of ignition. If the current through the platinum ring be diminished, the flame disappears; if it be raised, the flame increases in intensity until a certain temperature is attained when self-sustaining combustion ensues and accessory heat from the platinum ring is no longer necessary.

The following table of ignition temperatures is taken from a paper by Dixon and Coward (Chem. Soc. Trans. 1909, 95, 514):—

THE IGNITION TEMPERATURES OF GASES.

	Ignition temperature			
	In oxygen		In air	
	Between	Mean	Between	Mean
Hydrogen	580°-590°	585°	580°-590°	585°
Carbon monoxide (moist)	637°-658°	650°	644°-658°	651°
Cyanogen	803°-818°	811°	850°-862°	856°
Ethylene	500°-519°	510°	542°-547°	543°
Acetylene	416°-440°	428°	406°-440°	429°
Hydrogen sulphide	220°-235°	227°	346°-379°	364°
Methane	556°-700°	—	650°-750°	—
Ethane	520°-630°	—	520°-630°	—
Propane	490°-570°	—	—	—
Ammonia	700°-860°	—	—	—

The gases were separately heated to the same temperature and then allowed to meet, and in this way certain difficulties attending earlier methods of determining ignition temperatures were overcome. Another method of determining temperatures of ignition employed by Falk (J. Amer. Chem. Soc. 28, 1517; 29, 1536) and modified by Dixon (Chem. Soc. Trans. 1910, 97, 674), consists in compressing the gaseous mixture under practically adiabatic conditions, and so heating it to the point of inflammation.

Types of flame. A stationary flame with complete combustion may be produced by igniting an inflammable mixture as it issues into a neutral atmosphere, or by allowing one of the combining gases to issue from an orifice into an atmosphere of the other, and igniting the self-made mixture at the orifice. A third method is to have one gas in excess in the mixture and to allow it to issue into an atmosphere containing the other. All these conditions are found in

practice, and they merge into each other. Let us consider the case of a flame of carbon monoxide in air, which lends itself readily to experimental demonstration. (See Fig. 2.)

If undiluted carbon monoxide be sent from a cylindrical tube under a gentle pressure, the flame which is formed is a simple hollow cone of blue light resting upon the orifice of the tube (a). If the tube be made of a material of high heat conductivity, there is a perceptible gap of

FIG. 2.

extinction between the end of the tube and the superimposed flame. The genesis of the cone is easy to understand. The escaping gas makes its own mixture with air, and so the stream is burned through from the outside as it ascends. The current of gas, moreover, issues with a greater velocity in the axis of the tube than at the sides, where it is impeded by friction against the walls, and the unburned gas in the middle is also heated as it ascends through the burning walls. All these factors promote the conical form of the flame. The form of a carbon monoxide flame issuing from any other kind of orifice can be predicted from similar considerations. Of course, when the velocity of issue increases, the case is complicated by the turbulent motion of the gas.

Let us now consider the effect of adding some air to the carbon monoxide before it issues from the orifice. Air added in this way is often called *primary* air, and the additional air taken from the atmosphere round the orifice to complete the combustion is called *secondary* air. A small quantity of primary air produces a noticeable effect upon the flame. The cone diminishes in height, and seems to have a lining of brighter blue (b). With a little more air, the lining is seen to be a second cone within the first, and consequently with a gentler slope. The individuality of this inner cone becomes apparent when the proportion of primary air mixed with the issuing gas is sufficient to bring the mixture well within the limits of 'inflammability' (c). The mixture is, indeed, inflaming downwards, but as the rate of propagation does not exceed the upward velocity of the gas stream, the inner cone of flame cannot travel against the gas stream. With more air, however, a greater rate of inflammation ensues, and eventually the inner

cone, after becoming more and more squat, enters the tube and travels against the gas stream, first as a flat disc and then as a convex surface with the bulge downwards (d). Throughout all these changes, the second or outer cone is maintained at the orifice of the tube by the combustion in the external air of the carbon monoxide remaining in excess of what the primary air suffices to oxidise in the inner cone or disc. It loses in brilliance owing to its dilution with the carbon dioxide and nitrogen which come up from the inner cone. If the primary air supply be further increased, the outer cone will eventually disappear altogether, for a point is reached when the oxidation can be completed by the primary air (e). This, however, is not the end point, for an excess of primary air, just like a defect, diminishes the rate of inflammation, and consequently when this rate has been reduced below the velocity of outflow of the gaseous mixture, the single (inner) cone of flame will rise again to the orifice of the tube and remain there. It is to be noted that now the flame consists of only one film of burning gas. The film is still conical, in virtue of the greater axial velocity in the stream of gas, but it has considerable thickness, and its lower boundary is also a conical surface (f). There is need of a term to distinguish a flame of gas which is burning continuously throughout the whole or nearly the whole space included by its external surface, from one which is burning in thin films and whose external surface includes chiefly unburned gas. The word 'solid' is sometimes used in this connection, but a 'solid carbon monoxide flame' is obviously a contradiction in terms. Perhaps one might speak of a *volume* flame as distinguished from a *film* flame.

The last stage to be described in the development of the carbon monoxide air flame is reached when the excess of primary air brings the mixture near to the limits of inflammability, or, precisely speaking, when the rate of inflammation of the mixture is reduced below the velocity of the slow-moving part of the ascending gas mixture adjacent to the walls of the tube. The flame then gets detached from the orifice, rises, and disappears.

The various phases are shown diagrammatically in Fig. 2.

In Fig. 2 (e) the inner cone, which has retreated, is shown as being arrested at the orifice of the narrow tube through which the mixed gases are led into the wider one. The arrest is due to the fact that the velocity of efflux through the narrow tube exceeds in all cases, for the present example, the velocity of inflammation of the mixture. Mention may here be made of a piece of apparatus used by Smithells (Chem. Soc. Trans. 1892, 61, 204), known as the flame separator, as it depends for its action on the principle just referred to. The separator, Fig. 3, consists of two cylindrical tubes of different diameter, made preferably of fireproof glass, one of which slides within the other through an india-rubber collar. A brass candle adapter attached to the inner tube keeps the inner tube coaxial with the outer one. Mixtures of an inflammable gas and air can be admitted through the lower end of the narrow tube by attaching a T-piece, or more simply by attaching it to a Bunsen burner. In all cases, a two-coned flame can be obtained,

and if the proportion of the gases is suitably adjusted for a velocity of inflammation intermediate between the upward velocity of the mixture in the wide tube and that in the narrow one, the inner cone will descend in the wide tube and come to rest at the orifice of the narrower one. If the outer cone be now slid down, a two-coned flame rests on the orifice of the narrow tube. The practical value of the appliance depends on the fact that it permits of the aspiration of the interconal gases in a pure state, and in this way it has been of assistance in the study of the progress of combustion in complex gases.

FIG. 3.

Flame temperatures. The principles developed in the discussion of the carbon monoxide air flame are applicable to all flames. We may now apply them in connection with the question of flame temperature.

In speaking of the temperature of flame it is necessary to specify exactly what is meant by the term. Most flames are composed of thin films, and their external surface encloses a large quantity of unburned gas. We might speak of the temperature of such a flame as meaning the average thermal state of the burning films and the included gas. This, however, is not the custom. The temperature attainable by the combustion of gas usually means the temperature which would be indicated by a thermometric instrument wholly immersed in the region of combustion. It is obviously very difficult to make such measurements in thin films of flame; in volume flames, produced by burning ready-made mixtures of combustible gas and air it is more practicable to measure the temperature experimentally. Flame temperatures have been measured chiefly (1) by exploding gaseous mixtures and calculating the temperature from the increase of pressure; (2) by means of thermo-couples, especially the platinum platinum-rhodium couple of Le Chatelier; (3) by use of optical pyrometers in cases where the flame contains incandescent solid; (4) by analysis of interconal gases and the application of thermodynamics. The subject, both theoretically and practically, is complicated, and an adequate discussion is impossible within the limits of this article. A 'theoretical temperature' of flame may be calculated from the thermal value of the reaction, and the mass and specific heat of the products. Thus, in the case of hydrogen, taking the heat of formation of a gram-molecule of steam (18 grams) to be 57,560 calories, and the specific heat of steam at constant pressure as 0.4805, we have:

$$\text{Rise of temperature} = \frac{57560}{18 \times 0.4805} = 6655^\circ.$$

As a matter of experiment, the temperature of an oxy-hydrogen flame is found to be about 2400° (Féry).

The discrepancy is easily understood, for the calculation involves several assumptions; the action is supposed to be instantaneous, so that no heat is radiated in the process, and the specific heat of steam is supposed to be unaltered at high temperatures. Both these assumptions are in conflict with experimental facts.

Calculated flame temperatures, where air is used, proceed on the assumption that the heat of reaction is distributed among all the products, including the passive nitrogen, so as to bring them to the same temperature. Thus, in the above calculation, we should, if air were used instead of oxygen, add a term for the nitrogen, &c., and so obtain a value of about 2500°.

Temperatures of flames, calculated in this way, for combustion in air, approximate more nearly to the measured temperatures, and the numbers obtained serve at least to give an estimate of the relative temperatures of different flames.

The following table is calculated by Le Chatelier, all the substances being burnt in air:—

C to CO ₂	2040°	CH ₄	1850°
C to CO	1280°	C ₂ H ₂	2420°
CO	2100°	Producer gas	1350°
H ₂	1970°		

To these may be added: combustion of C in air with 5 p.c. unused oxygen in the products, 1950°, ditto with 5 p.c. of CO in the products, 1930°; producer gas with air supply heated to 1000°, 2150°.

How far these calculated figures accord with direct measurements may be illustrated by the following results, given by Féry, who used an optical method:—

MAXIMUM FLAME TEMPERATURES (FÉRY, 1904).

	Deg. C.	Deg. F.
Bunsen burner, gas fully aerated	1871	3400
" " insufficient air	1712	3114
Acetylene flame	2548	4618
Alcohol flame	1705	3101
Denayrouze burner, alcohol and air	1862	3384
Do., half each alcohol and petroleum spirit	2053	3727
Hydrogen, free flame in air	1900	3452
Oxy-coal gas blow-pipe flame	2200	3992
Oxy-hydrogen " "	2420	4388

To these may be added a series of recorded temperatures of the flame of a Bunsen burner using coal gas:

MAXIMUM TEMPERATURE IN THE FLAME OF A BUNSEN BURNER USING COAL GAS.

Date.	Deg. C.
1860.—Bunsen and Kirchhoff	2350
1877.—Rosetti	1360
1892.—Rogers	1230
1892.—Lewes	1630
1895.—M'Crae	1725
1896.—Waggener	1770
1899.—Berkensbusch	1830
1902.—White and Traver	1780
1905.—Féry	1871

Only the later numbers are of importance. Féry estimates the temperature of the electric arc to be 3760°, and that of the sun to be 7800°. The temperature of the acetylene-oxygen flame is supposed to be between 3000° and 4000°.

Another aspect of the temperature question presents itself when the practical use of flames is involved. As an example, we may briefly discuss the use of a coal-gas air flame for heating a Welsbach mantle. The object is, of course, to get the maximum flux of light from the consumption of a fixed amount of coal gas, in other words, we seek to raise the maximum mantle

surface to the maximum temperature. A primary consideration is, that as the temperature is raised the intensity of light emitted increases in a much more rapid ratio. The total energy radiation of an ideally 'black body' increases as the fourth power of the absolute temperature, and of this radiation the proportion which is visible also increases in a rapid ratio. This is especially the case with the Welsbach mantle which has a selective radiating power for short wave lengths. Even a small reduction in temperature must therefore be accompanied by a loss of intrinsic brilliance.

Again, having regard to the shape of a mantle, to its inevitable irregularities, original or acquired, and to the unsteadiness of a flame, it is evident that a high temperature can only be attained when it is suspended in a tolerably thick stratum of flame, although the mantle has doubtless a steadying and localising effect on the flame.

Reverting to the discussion of the carbon monoxide air flame we may easily apply the conclusions to the case of a Bunsen burner, using coal gas and air. This burner, as used in its ordinary form, draws in through the air ports, at the base (by the injector action of the coal gas escaping from the nipple) from 2 to $2\frac{1}{2}$ times its volume of air, about half the amount required for complete combustion. This air effects a partial oxidation of the coal gas, and yields an inner cone of flame; the oxidation is completed when the products from the inner cone mingle with the external air, an outer cone being formed. A Bunsen or 'atmospheric' burner thus gives a double flame. If the two cones be separated by a considerable interval in the flame separator, it is easy to show that the temperature reigning in the inner cone exceeds that in the outer cone, but if the two cones are close together, the reverse is the case. The explanation is to be found in the fact that when the two cones are near, the gases coming to the outer cone have still a high temperature from the act of their formation, and their temperature is to be added to the rise occasioned by the completion of their combustion, in the outer cone. From this it might appear that the best disposition of a mantle in the flame would be that in which it occupies the surface of the outer cone. But it is to be remembered that the mantle deforms the cone by altering the currents of gas and air, and, besides, the outer surface of the mantle will lose heat very rapidly if it is at the confines of the flame. We should rather suppose, therefore, that it would be better to submerge the mantle in the flame to some extent, and if this is done and if at the same time by the use of a glass chimney we cause a more rapid flux of air round the flame to quicken the combustion in the outer cone, we get the conditions which, as a matter of fact, have been found most effective for heating a mantle with the original type of Bunsen burner.

The great gain to be secured by raising the temperature of the mantle soon led to modifications of the original Bunsen burner, whereby it was sought to introduce a larger proportion of primary air. A large number of devices have been used, of which the two most important relate to the form of the burner tube and to the construction of the burner head.

In the well-known Kern burner, the tube is formed on the Venturi principle, and has internally the form of a hyperbolic spindle *a*. This secures an intake of primary air which is practically sufficient for complete combustion. The mixing of air and gas and the stability of the flame are secured by an expanded burner head, capped by a serrated disc *b*, through the teeth of which the gas mixture issues in narrow streams. These streams coalesce and produce a conical sheet of flame of uniform character and sensible thickness. The flame, in fact, is of the blow-pipe type (Fig. 4*A*).

The Méker burner is constructed on much the same principle, but the gas mixture passes from the expanded burner head through a deep metal grid. The flame is therefore a cone of gas burning through and through. It will be

FIG. 4*A*.FIG. 4*B*.

seen that the Kern flame is designed specially for heating a mantle, whilst the Méker flame is designed to confine the combustion to the smallest attainable volume and to provide a very compact hot flame for general laboratory or furnace use (Fig. 4*B*).

Increased in-draught of air can also be secured by the use of chimneys. If the gas or air or both are put under extra pressure and so delivered with high velocity, volume flames may be obtained, which, unlike that of a Méker burner, have their base blown up into a cone, so that the flame appears to be two-coned. This really constitutes a blowpipe flame.

The inversion of a Bunsen flame modifies its form in such a way as to make it more efficient for heating a mantle. The outer film of flame becomes shorter, thicker, and more globular, and as the products of combustion necessarily drift back past the flame, there is a certain recuperation of heat.

The efficiency of various flames for giving light may be gathered from the following table of illuminating value per cubic foot of gas consumed. The numbers are, of course, only approximate, but they give an idea of the temperatures to which the mantle is raised. The fact that in all cases the same chemical action is taking place shows how misleading the term 'flame temperature' may be unless

the precise character and use of the flame are specified :—

<i>Form of burner</i>	<i>Candle-power per cubic foot consumed</i>
Ordinary batwing	2.5
Argand	3.25
Wenham (regenerative)	8.9
Upright, with mantle	20-40 (according to pressure)
Inverted "	20-70 " "

The hottest flame that is in practical use is that of the acetylene-oxygen blowpipe. In this case, we have not only the heat of oxidation of the carbon and hydrogen involved, but also the positive heat of decomposition of the molecule of acetylene. The acetylene-oxygen flame can be used for welding iron and also for perforating steel. (*V. ACETYLENE; OXYGEN.*)

The chemical changes taking place in flames.

In the foregoing part of this article, attention has been drawn to general principles which are applicable to flames as a whole, without particular regard to the detailed features of structure or the stages of chemical decomposition. Before discussing any flame in particular, we may adduce one or two further general considerations with regard to chemical changes in flame. It has been assumed, for the sake of simplicity, that in the flames of hydrogen and carbon monoxide the chemical change takes place in one simple step. When we come to other combustibles, it is obvious that such assumptions may be still less warrantable. If, for example, we are dealing with a combustible element which is capable of affording two oxides, we may have the oxidation in the flame taking place in two stages, each stage producing a distinctive feature in the flame. Or, if we have a combustible consisting of two or more oxidisable elements, the oxidation might conceivably take place selectively. Again, in a compound combustible, it is possible that the oxygen may, in the first instance, add itself to the molecule of combustible, producing a complex substance which is ultimately resolved. Lastly, it is possible that the heating effect of the burning envelope in a flame may produce a purely thermal chemical effect on some of the enclosed unburned gas.

Only in a few cases has the progressive combustion in flames been studied fully. In the case of a cyanogen-air flame, it has been shown (Smithells and Dent, *Chem. Soc. Trans.* 1894, 65, 603) that the inner crimson film of the flame marks the combustion of the gas to carbon monoxide, whilst in the blue fringe of the flame the oxidation is completed by the combustion of the carbon monoxide.

The case of hydrocarbon flames is naturally the one of most interest. The earliest investigations of the progress of combustion, made by Hilgard, Landolt, and Blochmann, in Bunsen's laboratory, dealt with the flames of the complex combustibles, wax, vegetable oils, coal gas, and consequently the results were not very easy to interpret. In more recent times, the combustion of single hydrocarbons has been carefully examined.

The flame of a hydrogen-carbon compound, or of a mixture containing some quantity of hydrocarbons, shows three distinct parts when produced in the ordinary way. Of these, the most conspicuous is the bright yellow patch from which the chief flux of light takes place.

The lower part of the flame is surrounded by a bright-blue sheath or 'calyx,' which thins off and ends where it overlaps the lower part of the yellow region. In addition to this, the whole flame is surrounded by a complete mantle of dimly burning gas. The flame is hollow, that is to say, it is filled with unburnt gas, and even the bright-yellow region is an extremely thin conical sheet. A diagrammatic section of a normal hydrocarbon flame is given in Fig. 5.

The relative development of the different parts is, of course, different in different flames. It depends on many factors, the chief of which are the richness of the gas in carbon, the character of the orifice, and the rate at which the gas issues. The flame of acetylene, suitably developed by allowing the gas to issue in such a way that it is spread out into a thin sheet, shows a very large yellowish-white luminous region, in the glare of which the other parts of the flame are indistinguishable. On the other hand, an alcohol flame exhibits scarcely any yellow luminosity.

If we take the flame of a hydrocarbon burning in an ordinary Bunsen burner with the air ports closed, and then gradually open the ports, we can see how the luminous flame passes into the 'atmospheric' type, and convince ourselves that the blue calyx and the mantle of the luminous flame represent respectively the inner and outer cones of the Bunsen flame. Turning a luminous flame low to the point where only a blue button of light remains at the burner tip, enables us to see a like transition.

The changes experienced by hydrocarbons when burning in a Bunsen burner were investigated by Smithells and Ingle by the use of the cone-separating apparatus already described (*Chem. Soc. Trans.* 1892, 61, 209), and the analyses of the interconal gases (after cooling) showed in all cases that a partial combustion had taken place, leaving very little of the original hydrocarbon unoxidised. The products of partial oxidation were carbon monoxide, carbon dioxide, hydrogen, and water vapour, accompanied, of course, by the nitrogen of the 'primary' air supply. The following are some of the analytical results :—

Gas employed.	C ₂ H ₄	CH ₄	C ₆ H ₆	Coal gas
CO ₂ . . .	3.6	6.8	13.1	4.2
H ₂ O . . .	9.5	17.6	7.7	16.0
CO . . .	15.6	4.5	5.0	8.8
Hydrocarbon	1.3	—	0.6	—
H ₂ . . .	9.4	3.9	0.6	9.3
N ₂ . . .	60.6	67.2	73.1	62.0

These analyses refer to the cooled gases, but experiments (unpublished), made by a modifica-

FIG. 5.

tion of Deville's method to entrap and preserve the gases as they exist at the high temperature, have not given any ground for doubting that the figures given in the table represent essentially the changes that occur in the inner cone. Independent experiments by Haber and Richardt (Zeitsch. anorg. Chem. 1904, 38, 5) bear out this conclusion.

We may say, therefore, that the inner cone of a Bunsen flame (and the corresponding blue calyx of a luminous flame) marks the region of a partial oxidation in which no carbon, but some hydrogen, remains unoxidised. In the outer cone (and the corresponding mantle of a luminous flame), the carbon monoxide and hydrogen coming from the inner cone (or calyx) find, and are burning with, the air necessary to complete their oxidation.

The experimental results just described stood in direct opposition to a view which, notwithstanding repeated contradictory evidence, had prevailed for three-quarters of a century, namely, that in the combustion of a hydrocarbon with a deficiency of air, the hydrogen was preferentially or selectively oxidised, and the carbon set free. It might now be said that there is a preferential or selective combustion of the carbon. The use of these expressions has, however, been objected to, and need not be insisted upon. The objection arises chiefly from a consideration of the results obtained by a long and careful series of studies made by W. A. Bone and his collaborators, on the progressive oxidation of hydrocarbons from a temperature of 250° upwards. The results of these experiments are summarised in a Report on Gaseous Combustion, drawn up by Professor Bone for the British Association (see B. A. Report, Sheffield, 1910), and in this report references to the original papers will be found. According to Bone, 'the attack of the oxygen upon the hydrocarbon may be supposed to involve a series of successive "hydroxylations," the hydroxylated molecules either breaking down or undergoing further oxidation, according to their relative stabilities and affinities for oxygen at the particular temperature.' The following is the scheme for ethane:—

(a) SLOW COMBUSTION AT 300°–400°.

(b) EXPLOSIVE COMBUSTION.

The experimental basis of these schemes lies in the actual isolation of the various members of the series of transition substances implicated.

Space allows of only one further reference to these investigations. Bone considers that one

of the most significant features 'has been the proof afforded of the relatively much greater affinity of hydrocarbons as compared with that of either hydrogen or carbon monoxide, for oxygen at the high temperature of flames.' Thus in the explosion of a mixture corresponding to $\text{C}_2\text{H}_4 + \text{H}_2 + \text{O}_2$ there is practically no formation of steam.

Luminosity of hydrocarbon flames. In the preceding paragraphs, the chemistry of the combustion of hydrocarbons in the Bunsen flame and in the blue parts of luminous flames has been explained in its general features. It remains to explain the development of the yellow luminous region of hydrocarbon flames. As is well known, the first explanation was given by Humphry Davy, in 1816, among many other observations upon flame still well worthy of attention. Davy attributed the luminosity to the deposition of solid charcoal, which he said 'might be owing to a decomposition of a part of the gas towards the interior of the flame where the air was in smallest quantity.' The ambiguity of this explanation and its supposed implication of a selective combustion of the hydrogen, have already been alluded to. Starting from this 'solid particle' explanation of the light of a hydrocarbon flame, Davy was led to consider that all flames of high luminosity contained solid particles. He knew that the phosphoric oxide was gasified at the temperature of a phosphorus flame, yet he believed that, in the flame itself, solid particles of the substance were produced, and were conserved by the elastic force of the flame producing a kind of compression.

Davy's explanation remained unassailed until 1867, when E. Frankland made an important series of researches on the luminosity of flames. He concluded:

- (1) That bright flames exist which do not contain solid particles.
- (2) That the luminosity of flames depends mainly on the density of the substances contained in them.
- (3) That feebly luminous flames may be made bright by compressing the burning gases.
- (4) That the luminosity of ordinary hydrocarbon flames, such as that of coal gas, is not due, in any important degree, to solid particles of carbon, but almost entirely to the glow of dense hydrocarbon vapours.

Frankland followed luminosity to the density of the hot gases in the flame, whether this density were due to high molecular weight or to compression. So far as hydrocarbon flames are concerned, Frankland's views were soon submitted to destructive criticism, especially by Heumann.

A crucial experiment indicating the presence of solid particles in flame, first proposed by Soret and subsequently by Burch and by Stokes, consists in focussing the image of the sun on to the flame and examining the scattered light with a Nicol prism. That test, applied to a hydrocarbon flame, gives a positive result, and the presence of solid particles in such flames is no longer disputed.

It is true that the black soot deposited on cold objects introduced into luminous hydrocarbon flames is by no means pure carbon, but this is to be expected when we remember that

any condensible hydrocarbon in the flame would be deposited along with particles of pure carbon, if such were, in fact, present.

It may now be taken as agreed that the luminosity of hydrocarbon flames is due to the separation of solid particles of carbon. The process by which the carbon becomes separated in the flame has been the subject of much experiment and discussion. Is it involved directly in the oxidation that is taking place, or is it merely a thermal effect—and in either case, what are the stages of the process? It is impossible here to give more than a brief summary of the views that have been held. In the first place, it may be said that the old, simple, and plausible explanation of a preferential oxidation of hydrogen is untenable for reasons already given. In the next it may be affirmed that, generally speaking, hydrocarbons, subjected to a high temperature, deposit solid carbon. It would appear, therefore, that the separation of carbon in a flame might be adequately explained by the fact that the unburned hydrocarbon within the burning sheath of the flame is highly heated by the burning parts. The fact that when the heat is tapped for the burning sheath by a ring of cold wire, the flame loses luminosity, is one among several indications that the deposition of carbon is a secondary and a thermal effect of the combustion. At the same time, the experiments of Bone would lead us to be cautious in denying that in some cases the chemical processes might contribute to the separation of carbon.

Taking it for granted that the decomposition of the hydrocarbon is purely thermal, we may next consider the stages that are passed through. This raises the whole question of the thermal decomposition of hydrocarbons, a subject of great experimental difficulty, on which really satisfactory results have only been obtained over a small range of substances (see Bone and Coward, Chem. Soc. Trans. 1908, 98, 1197).

The view that ethylene, on heating, undergoes the simple change $C_2H_4 = C + CH_4$, which long served to explain the luminosity of flames, is no longer tenable. The doctrine of Berthelot, according to which the molecules of hydrocarbons, on heating, undergo progressive coalescence with elimination of hydrogen until in the end a molecule is left containing a negligible proportion of hydrogen, is likewise contradicted by modern experiments. The hypothesis of V. B. Lewes (Proc. Roy. Soc. 1895, 57, 450), that the formation of acetylene and its subsequent decomposition are the essential cause of luminosity in hydrocarbon flames, is regarded by those who have concerned themselves with the subject as based on wholly insufficient evidence.

Bone and Coward have been led to the conclusion that the thermal decomposition of hydrocarbons is too complex a phenomenon to be represented by ordinary chemical equations. Dealing with methane, ethane, ethylene, and acetylene, they observe first of all that whilst at a high temperature methane, the most stable of the hydrocarbons, is resolved directly into carbon and hydrogen, this only takes place in contact with solid surfaces, whilst with the three other gases decomposition takes place throughout their bulk.

They say: 'In the cases of ethane and

ethylene, it may be supposed that the *primary* effect of high temperature is to cause an elimination of hydrogen with a simultaneous loosening or dissolution of the bond between the carbon atoms, giving rise to (in the event of dissolution) residues such as: CH_2 and $\dot{C}H$. These residues, which can only have a very fugitive separate existence, may subsequently either (a) form $H_2C:CH_2$ and $HC:CH_3$, as the result of encounters with other similar residues, or (b) break down directly into carbon and hydrogen, or (c) be directly "hydrogenised" to methane in an atmosphere already rich in hydrogen. These three possibilities may all be realised simultaneously in the same decomposing gas in proportions dependent on the temperature, pressure, and amount of hydrogen present. The whole process may be represented by the following scheme, the dotted line indicating the tendency to dissolve the bond between the carbon atoms which becomes actually effective at higher temperatures:—

'In the case of acetylene, the main primary change may be either one of polymerisation or of dissolution, according to the temperature, and, if the latter, it may be supposed that the molecule breaks down across the triple bond between the carbon atoms, giving rise to $2(:CH)$, and that these residues are subsequently either resolved into carbon and hydrogen or "hydrogenised," according to circumstances, thus:

'Incidentally, it may be observed that the rates of decomposition of these hydrocarbons are very much slower than their rates of combustion, and that therefore in the propagation of a flame through a homogeneous mixture of a hydrocarbon and oxygen, oxidation will probably take precedence of all other chemical phenomena.

The chemistry of a hydrocarbon flame has now been given as completely as present knowledge and the limits of space allow.

The art of getting the maximum of light from a hydrocarbon solely by its own combustion may be deduced and stated briefly as follows: The gas must be so burned as to liberate within the burning walls of its flame the maximum amount of solid carbon that can be heated to a high temperature and be wholly oxidised as well. Spreading out the gas stream increases the relative proportion of hot non-luminous burning walls, and diminishes the central zone of unburned gas from which the solid carbon has to be derived. It is on the right adjustment of these two elements of a flame for the particular gas in use, that the construction of a suitable burner depends, and it is obvious that the best

result can only be maintained when the composition of the gas and air, the pressure, and temperature are kept constant. Of course, the question is complicated when we introduce the factors of chimneys and heat-regenerating devices.

It may be convenient here to revert to the question of obtaining the highest temperature from the combustion of a fixed amount of a hydrocarbon. Fig. 6 is reproduced from

Fig. 6.

photographs of five gas-flames, where the rate of gas flow was constant. In the first flame, A, we have the gas burning (with some smoke) without any 'primary' air¹; in the second, we have just sufficient primary air to cause delumination; in the third, we have as much air as possible without producing instability; in the fourth, a Méker burner is used; in the fifth, we have the gas mixed, before issuing from the burner, with enough carbon dioxide to produce delumination. Speaking of each flame as a whole, we may say that the hotness is greater in proportion as the surface is less. In the carbon dioxide-fed flame, neutral molecules of that gas are wedged in between those of the combustible gas, and the mixture has to wander far before it gets mixed with enough oxygen to sustain combustion. When it acquires this oxygen, there is round each burning molecule not only the inert nitrogen of the air but the equally inert carbon dioxide. The flame is a thin, single, hollow sheet, and the temperature is quite insufficient to decompose any of the hydrocarbons within. It has the non-luminous appearance of a Bunsen flame, but it is, of course, absolutely the opposite of that in its genesis, for it represents delayed and diluted instead of quickened and concentrated combustion.

The limits of space have rendered necessary the omission of many matters relating to the chemistry and physics of flame. The exact molecular and sub-molecular mechanism by which the luminosity of wholly gaseous flames is regulated, is a subject of great interest. It is

¹ The unsteadiness of this flame makes it appear somewhat too large in a photograph.

now generally believed to be associated with electronic transactions. Some discussion of the subject is to be found in the British Association's Report, Leicester, 1907 (Smithells' address to Section B).

FLASH LIGHTS. A term usually applied to combustible mixtures which burn with a brilliant light and more or less instantaneous flash, and which are employed specially for photographic purposes. Slower-burning mixtures, which also yield a bright light on combustion, such as are used for signalling purposes, are known as *flares* (see BENGALLIGHTS; INDIAN FIRE; PYROTECHNY).

For photographic purposes, it is essential that the flash light should be (1) sufficiently brilliant, (2) of the desired rapidity, and (3) specially rich in actinic light. Of all the known available materials which, on combustion, yield a bright and highly actinic light, the metal magnesium stands pre-eminent; and the earliest and simplest methods of employing this substance consisted in projecting a definite quantity of the finely powdered metal into the flame of a spirit lamp.

Various contrivances have been devised for this purpose: one simple plan is to place the charge of magnesium powder in the bowl of a clay tobacco pipe to the mouthpiece of which is attached a rubber ball. A loose plug of tow or cotton wool, wetted with methylated spirit, is then lightly inserted into the mouth of the bowl: the spirit is ignited and, on suddenly squeezing the ball, the magnesium is thrown into the flame.

The next development consists in mixing the powdered magnesium with some highly oxygenated salt, such as potassium chlorate, in such proportion that the mixture, when placed in a small heap upon a metal tray, could be ignited by a match or taper, and would burn with much the same rapidity as a similar small heap of gunpowder. The danger inherent in such mixtures was found to be greatly reduced by substituting barium chlorate for the potassium salt; and more recently, since potassium perchlorate has become a common commercial article, this compound is more usually employed in preference to the chlorates.

Mixtures of magnesium with certain nitrates of the so-called rare earths have been made the subject of patents. One such consists of:

Magnesium powder 10 parts
Thorium nitrate 10 "

and a rather less quick mixture contains:

Magnesium powder 10 parts
Zirconium nitrate 5 "

One of the chief drawbacks to magnesium flash powders is the volume of white smoke of magnesium oxide which is produced on their combustion, and many efforts have been made to obviate this nuisance. Some of these are purely mechanical contrivances for withdrawing the smoke, but others are attempts to produce mixtures which shall emit little or no smoke.

The two following mixtures claim to yield smokeless magnesium flash powders:—

(1) Powdered magnesium, barium peroxide, and collodion. The charge of powder is blown by means of a pneumatic pump into a small iron crucible heated by a Bunsen burner.

(2) 1 part of magnesium powder mixed with 1 part of either silicic acid ('infusorial earth').

barium sulphate, anhydrous calcium sulphate, anhydrous magnesium sulphate ('kieserite'), or boric acid.

It is further claimed for this mixture that if loaded into a cylindrical case with a constricted opening, a non-instantaneous or 'time' flash may be obtained.

At the present time, since the pyrotechnic possibilities of finely powdered aluminium have become known, in most flash powders the magnesium is usually more or less replaced by aluminium, in some cases even wholly replaced; one such mixture consists of:

Aluminium powder	. 40 parts
Potassium perchlorate	. 60 "

It is usual, however, to retain some of the magnesium in order to ensure the necessary high actinic quality of the light emitted. Thus a typical mixture consists of:

Powdered magnesium	. 100 parts
Powdered aluminium	. 50 "
Ferric oxide	. 30 "
Copper carbonate	. 30 "
Magnesium sulphate (dry)	5 "

The following mixtures claim to be non-explosive and almost smokeless:—

(1) Powdered magnesium and aluminium (the quantity of aluminium usually varying from $\frac{1}{2}$ to $\frac{3}{4}$ the amount of magnesium), mixed with peroxides of calcium, magnesium, or manganese.

(2) Powdered magnesium and aluminium mixed with perboric acid or tungstic acid or their salts.

(3) Powdered magnesium and aluminium, with sulphate of cerium or thorium, or an alum. For example:

Powdered magnesium	. . . 8 parts
Powdered aluminium	. . . 2 "
Finely powdered, dry chrome alum	10 "

Many mixtures containing aluminium as an ingredient are rendered more rapid in their combustion by the addition of silica, while their rate of combustion may be retarded by the introduction of regulated quantities of carbonates of alkalis or alkaline earths or oxides of the latter. Thus the above mixture may be converted into a slow-burning 'time' mixture by the addition of 2 parts of an alkaline earth oxide or carbonate.

Flash powders are now frequently loaded into small cases or cartridges; ignition of the mixture being effected sometimes by an electric arrangement and sometimes by means of an inserted strip of magnesium ribbon. In the former case, the two electric wires are fixed into the cartridge, with either a short spark-gap or joined by a fine incandescing wire.

One of the many patented cartridges has a case which is itself inflammable. It consists of a short celluloid cylinder closed at the bottom with a cork saturated with collodion, and at the top with a disc of cork saturated with an emulsion of magnesium. Through this, there is inserted a short strip of magnesium ribbon which, on ignition, communicates its combustion to the charge.

A number of contrivances have been devised for producing a rapid succession of flash lights for purposes of cinematograph photography. These consist essentially of mechanical devices

for the intermittent feeding of metallic magnesium against the two metal terminals of an electric circuit.

G. S. N.

FLAVANILINE *v.* QUINOLINE.

FLAVANTHRENE $C_{23}H_{12}O_2N_2$. An anthracene dyestuff discovered by R. Bohn of the Badische Anilin- und Sodafabrik, by melting β -aminoanthraquinone with caustic potash. Has a large application for unordained vegetable fibres, which assume a deep-blue colour in the reduced vat, changing after a few minutes' exposure in the air to a permanent yellow. The colour is very fast, except when subjected to powerful rays of sunlight, which cause it to assume a temporary green shade.

Prepared technically from 2-aminoanthraquinone and potassium hydroxide at 350° (D. R. P. 133686); with aluminium chloride (D. R. P. 136015); with antimony pentachloride in boiling nitrobenzene (D. R. P. 138119); by oxidising with chromic acid or other acid oxidising agents (D. R. PP. 139633 and 141355); in the last-named case, it is accompanied by indanthrene, to which it is closely related (*v.* INDANTHRENE).

Flavanthrene is a weak base, sparingly soluble in high-boiling solvents, and very stable towards heat; it exists in glistening, brown-yellow needles. It is applied to the fibre after reduction with alkaline hyposulphites, forming a deep-blue vat (D. R. PP. 139634, 139835, 140573, 142963).

The constitution of flavanthrene has been determined by R. Scholl and his co-workers (Ber. 1907, 40, 1691) in the following manner:—

1-amino-2-methylantraquinone was converted by the diazo- reaction into 1-iodo-2-methylantraquinone $C_{15}H_9O_2I$, which passes by means of Ullmann's copper method (Annalen, 1904, 332, 38) at 270° into 2:2'-dimethyl-1-dianthraquinonyl (I). This substance has also been prepared from the diazonium sulphate of the methylantraquinone by means of copper powder and acetic anhydride (Knoevenagel, Ber. 28, 2448), and, when oxidised with chromic acid, yields the corresponding dicarboxylic acid $C_{30}H_{14}O_8$. The acid-amide derivative was readily obtained from this in the ordinary way, and the application of Hofmann's reaction with bromine and potash converts it into the amine (II.) and a stage further into flavanthrene (III.).

Flavanthrene must therefore have the annexed constitution III., and in obtaining it from 2-aminoanthraquinone in the process of manufacture, two molecules must unite with loss of two molecules of water and two atoms of hydrogen, according to the scheme :

The immediate precursor of flavanthrene, 2 : 2'-diamino-1 : 1'-dianthraquinonyl may be prepared by boiling 1-chloro-2-benzylidene-aminoanthraquinone with copper powder and naphthalene, extracting the 2-2'-dibenzylidene-amino-1 : 1'-dianthraquinonyl so formed with cold alcohol, and leaving the solution for some time, when the benzylidene residues are spontaneously eliminated and the desired compound crystallises. It forms microscopic red needles, and changes into flavanthrene at 250° (Scholl and Dischendorfer, Ber. 1918, 51, 452; Chem. Soc. Abstr. 1918, 308).

As the application of this dyestuff to the fibre depends upon its behaviour towards reducing agents in the vat, just as in the analogous case of indigo, careful investigations have been carried out by R. Scholl and his assistants (Ber. 1908, 41, 2304), under a variety of conditions, which show that the reduction products of flavanthrene consist of some seven definite compounds :

(a) *Dihydroflavanthrene hydrate*, obtained by reducing flavanthrene with alkaline sodium hyposulphite in an atmosphere of hydrogen. On cooling, bronze-coloured needles of the disodium salt of this hydrate crystallise out, and by acidifying with acetic acid, the free dihydroflavanthrene hydrate is isolated as bluish-green coppery crystals, which remain stable at the ordinary temperature, but readily oxidise to flavanthrene at 100° or when moist.

(b) *Dihydroflavanthrene* is obtained from the above by dehydration at 150°-170° in a stream of carbon dioxide; it consists of a green powder which is more stable than the hydrate. It may also be prepared by reducing flavanthrene with hydriodic acid and red phosphorus at 125°. Although flavanthrene itself is only a weak base, this dihydro derivative readily forms salts with mineral acids; dihydroflavanthrene hydrochloride probably contains the acid united to a N-atom. The *o*-benzoyl derivative melts at 220°.

(c) *α-Tetrahydroflavanthrene hydrate* is isolated in the form of its sodium salt when flavanthrene is reduced with zinc-dust and caustic soda. On acidifying, (a) and (f) are formed.

(d) *Flavanthrene hydrate*, prepared by reducing flavanthrene with hydriodic acid and red phosphorus at 210°, is a greenish-brown powder, losing water at 240° with formation of *flavanthrene*, which consists of large brown needles with a metallic lustre, m.p. 39°. It is readily oxidised to flavanthrene.

(e) *α-hexahydroflavanthrene*, and (g) *Flavanthrinol*, are both formed by energetic reduction of flavanthrene with zinc-dust and caustic soda.

(f)

(g)

(f) is a stable blue-black powder which loses water at 160°; dissolves in alcohol to a bluish red solution with a brilliant scarlet fluorescence. It forms fluorescent solutions in alcoholic alkalis and concentrated acids, dyeing unmordanted wool in the alkaline bath red, which changes to greenish blue with acids and violet on washing with water. Prolonged heating of the hydrate of (f) with zinc-dust in alkaline solution converts it into the hydrate of (g), whilst the anhydrous compound itself, (f), is further dehydrated at 300° in carbon dioxide, with formation of anhydrous flavanthrinol (g). By means of a current of air, an alkaline solution of (f) readily passes into flavanthrene.

Flavanthrinol (g) may be obtained from its hydrate by heating to 160°, and forms red solutions with an olive-green fluorescence in concentrated acids, and dyes unmordanted wool violet-red, becoming green with acids and blue with water. Flavanthrinol requires to be heated in air or oxidised with ferricyanide before it will yield the original flavanthrene.

Another method of obtaining flavanthrene, though only in small yields, is described below (Scholl, Ber. 1910, 43, 1734). Dianthraquinonyl, on nitration, forms a mixture of dinitro derivatives, which by reduction with sodium sulphide give flavanthrene. By warming with sodium hyposulphite, a red solution is obtained, colouring unmordanted cotton light-blue in the bath, which changes in the air to flavanthrene yellow.

When flavanthrene is digested for 8 hours with a nitrating mixture, a yellow powder separates, $\text{C}_{28}\text{H}_{10}\text{O}_{10}\text{N}_6$, which appears to be dinitrodinitrosodihydroxyflavanthrene. This is reduced by ammonia and ammonium sulphide to tetra-aminodihydroxyflavanthrene, which, on warming with alkaline hyposulphite, yields a dark-blue vat, dyeing cotton a blue-black, which turns green with hydrochloric acid, owing probably to the formation of a hydrochloride, and again assumes a blue-black colour on washing with water, owing, no doubt, to disassociation (Ber. 1910, 43, 1748).

FLAVASPIDIC ACID v. FILIX MAS.

FLAVAUrin. A yellowish-red powder consisting of either the ammonium or sodium salt of dinitrophenolsulphonic acid, and obtained by boiling mononitrophenolortho- or para-sul-

phonic acid with dilute nitric acid (Leipzig, Anilinfabr. Beyer und Kegel, D. R. P. 27271, June 8, 1883, expired October, 1886). Flavaurin dissolves readily in water, forming a yellow solution, and was introduced as a yellow dye for silk and wool.

FLAVELLAGIC ACID *v.* ELLAGIC ACID.

FLAVENOL *v.* QUINOLINE.

FLAVEOSINE *v.* ACRIDINE DYESTUFFS.

FLAVINE *v.* QUERCITRON BARK.

FLAVOGALLOL. When gallic acid in sulphuric acid solution is treated with arsenic acid and the mixture heated at 110° – 120° for 6 hours, a mixture containing flavellagic and coeruleoellagic acids is mainly produced, though when the oxidation is carried out in the presence of 80 p.c. sulphuric acid flavogallol $C_{21}H_8O_{12}$ is obtained. This consists of hair-like yellow needles, sparingly soluble in the usual solvents, soluble in sodium hydroxide solution with an orange-yellow colour. With sulphuric acid it yields the *anhydrosulphate* $C_{21}H_5O_{11} \cdot H_2SO_4$, orange-yellow prisms, whereas the *tripotassium salt* $C_{21}H_5O_{12}K_3$, prepared with alcoholic potassium acetate forms an orange-coloured crystalline powder.

Acetylflavogallol $C_{21}H_2O_{12}(C_2H_5O)_6$, small prismatic needles, melts and decomposes at 278° – 280° , and the corresponding *benzoyl compound* $C_{21}H_2O_{12}(C_7H_5O)_6$, yellow prisms, at 326° – 328° . With boiling aniline flavogallol yields the *anilide* $C_{21}H_2O_{11} \cdot NH \cdot C_6H_5$, which crystallises in yellow needles, melting above 345° . In the paste form flavogallol readily dyes mordanted fabrics, and employing woollen cloth the following shades are produced:—

Chromium.	Copper.	Tin.	Iron.
Dull olive-yellow.	Pale brown.	Pale orange-yellow.	Brownish-black.

When acetyl flavogallol is hydrolysed by the acetic ether method, *ethyl flavogallionate* $C_{23}H_{14}O_{13}$, pale yellow needles, is produced, and in a similar manner by the employment of methyl alcohol in this process *methyl flavogallionate* $C_{23}H_{12}O_{13}$ is obtained. By gentle treatment with strong potassium hydroxide solution flavogallol gives *flavogallonic acid* $C_{21}H_{10}O_{13}$, needles, which melt above 300° , and this when acetylated is reconverted into acetyl flavogallol.

The more energetic action of potassium hydroxide solution gives *flavogallone* $C_{20}H_{10}O_{11}$, minute needles, and this yields the acetyl compound $C_{34}H_{24}O_{13}$, leaflets, m.p. 257° – 259° .

When flavogallol is methylated with alkali and methyl sulphate and the product is digested with 5 p.c. potassium hydroxide, two apparently isomeric acids $C_{21}H_4O_5(OMe)_{10}$, (a) colourless prisms, m.p. 206° – 208° and (b) m.p. 238° – 240° , are obtained, and these both appear to be produced by the addition of three molecules of water to flavogallol and a subsequent methylation of ten hydroxyl groups. These are dicarboxylic acids, and when esterified give the dimethyl ethers of the formula

(a) melting at 128° – 130° , and (b) at 86° – 87° .

The acid, m.p. 206° – 208° , when digested with alcoholic potash at 175° loses one methoxy group with formation of a new acid

which crystallises in glistening leaflets, m.p. 183° – 184° . These reactions suggest the presence in flavogallol of an ellagic acid nucleus, and as a result Bleuler and Perkin (Chem. Soc. Trans. 1916, 109, 543) have tentatively suggested the formula—

for this colouring matter. In case this should prove correct flavogallonic acid (1), flavogallone (2), and the dicarboxylic acid obtained by methylation, m.p. 206° – 208° (3), will possess the following constitutions:—

A. G. P.

FLAVOLINE *v.* QUINOLINE.

FLAVONE, the mother substance of a large and very important group of natural colouring matters,

has been synthesised by the following methods:

(a) Acetyl-*o*-hydroxybenzylideneacetophenone (1) yields the dibromide (2) (Feuerstein and v. Kostanecki, Ber. 1898, 36, 1757)—

and the latter, on treatment with alcoholic potash, is converted into flavone, according to the following scheme:—

(b) Again (v. Kostanecki and Tambor, Ber. 1900, 33, 330), ethyl-*o*-ethoxybenzoate and aceto-

phenone, in the presence of sodium, give *o*-ethoxybenzoylacetophenone—

This compound, when digested with boiling hydriodic acid, gives flavone—

(c) Orthohydroxyacetophenone derivatives can be condensed with aromatic aldehydes with production of flavanones (dihydroflavones)—

On treatment with bromine bromflavonone is produced—

and this by means of alkalis splits off hydrobromic acid and is converted into the flavone—

(v. Kostanecki, Levi, and Tambor, Ber. 1899, 32, 326).

(d) Ruhemann (Ber. 1913, 36, 2188) has employed for the synthesis of flavone the esters of β -hydroxyaryl cinnamic acids. These may be prepared by the interaction of phenyl propiolic acid esters with sodium phenolates—

These esters are readily transformed into the free acids, the chlorides of which by means of

aluminium chloride give the corresponding flavones. Thus β -phenoxy cinnamic acid in this way gives flavone—

and substituted flavones can be readily prepared by the employment of cinnamic acids containing other hydroxyaryl nuclei. Phenyl thiocinnamic acid from thiophenol and phenyl propiolic acid ethyl ester

$\text{C}_6\text{H}_5\text{---C(SC}_6\text{H}_5) \text{ : } \text{CH---COOH}$ in this manner yields *thioflavone*—

a compound which crystallises in yellow needles and closely resembles flavone.

In case the β -hydroxyaryl cinnamic acids are here replaced by the corresponding derivatives of fumaric acid, benzo- γ -pyrone (*chromone*), carboxylic acids are produced which readily evolve carbonic acid gas with formation of chromone. Thus β -phenoxy-fumaric acid

$\text{COOH---C(OC}_6\text{H}_5) \text{ : } \text{CH---COOH}$ gives benzo- γ -pyrone (chromone) carboxylic acid¹—

¹ Though chromone itself was first obtained by Ruhemann and Stapleton (*loc. cit.*), chromone derivatives had been prepared slightly earlier by v. Kostanecki (Ber. 1900, 1998), who employed for this purpose methods similar to those he had found serviceable for the synthesis of flavone compounds. Thus the diketone (1), (compare method (c) above) obtained by the interaction of *o*-methoxy-benzoic acid methyl ester, and acetone on treatment with hydriodic acid, gives β -methyl-chromone (2)—

Again, according to v. Kostanecki, Paul, and Tambor, the diketone (1) prepared from resacetophenone monoethyl ether and ethyl oxalate, on treatment with alcoholic hydrochloric acid gives 3 ethoxychromone carboxylic acid (2)—

This when melted gives 3 ethoxychromone (3), and by means of hydriodic acid can be converted into 3 hydroxychromone (4)—

(e) Simonis (Ber. 1914, 47, 2229), again, has described another method for the synthesis of flavone. Whereas Pechmann and Duisberg found that phenols could be condensed by means of sulphuric acid with the esters of β -ketonic acids, to form α -pyrone (coumarin) derivatives, according to the following equation which illustrates the preparation of methyl-coumarin from phenol and acetoacetic ether,

by employing phosphorus pentoxide as the condensing agent the reaction takes another course. Thus phenol and methylaceto-acetic ether in this way gives dimethyl-chromone (Petschek and Simonis, Ber. 1913, 46, 2014)—

whereas benzoyl-acetic ether and phenol (*ibid.* 1914, 46, 2232) give flavone

For the preparation of chloroflavones, see Ruhe-mann (Ber. 1921, 54, 912), and aminoflavones, see Bogert and Marcus (J. Amer. Chem. Soc. 1919, 41, 83). Flavone crystallises from ligroin in colourless needles, m.p. 97°, and is readily soluble in the usual organic solvents. Its solution in sulphuric acid is yellow and possesses a weak blue fluorescence.

By the action of alkalis, flavone and hydroxy-flavones suffer hydrolysis according to the following scheme:—

The first product of the reaction owing to the disruption of the pyrone ring is the β -diketone (2)—

and this change may be regarded as the reverse of its synthesis according to method (b). The ketone then suffers further hydrolysis as shown by the dotted lines (a) into acetophenone and salicylic acid—

or (b) *o*-hydroxy acetophenone and benzoic acid—

The products of the hydrolysis of naturally occurring flavone colouring matters have in the past been mainly instrumental in determining their constitution.

All natural hydroxyflavones which have at present been carefully examined dye aluminium mordanted fabrics a yellow shade, the intensity of which is dependent upon the position of their hydroxyl groups.

Thus chrysin-1:3-dihydroxyflavone

and apigenin-1:3:4'-trihydroxy flavone possess but feeble dyeing property,¹ whereas luteolin-1:3:3':4'-tetrahydroxy flavone is a strong colouring matter. Though Liebermann and v. Kostanecki's rule is in this instance but partially applicable, it is evident that the dyeing property in the flavone group is only fully developed when at least two hydroxyls in the ortho-position to one another are present. There is every reason to anticipate also that a 3:4-dihydroxy-flavone would, like luteolin, possess well-marked dyeing properties. Of the influence, however, of such a grouping in the positions 2':3':2:3 and 1:2, information is at present lacking, as compounds possessing these characteristics have as yet to be discovered.

According to the quinonoid theory, it has been suggested that the flavone colouring matters, at least in the form of their lakes, may possess a paraquinonoid structure, which in the case of luteolin may be represented thus—

and such a formula has been applied by Perkin (Chem. Soc. Trans. 75, 433) to the monoalkali and oxonium salts of these compounds. It has been pointed out by Watson (Chem. Soc. Trans. 1914, 105, 759) that dyes which are quinonoid in all possible tautomeric forms exhibit a deep colour, the opposite being generally the case with those which cannot be represented in this way. Numerous instances are cited to illustrate this point, for which the paper itself should be consulted, but an examination of the formula of luteolin and alizarin will render sufficiently clear the theory of this author—

¹ The shades given by these and other feeble colouring matters of a similar type can be more satisfactorily observed by employing mordanted wool rather than mordanted calico.

Luteolin, the only flavone colouring matter possessing strong dyeing property which has been carefully examined, gives shades possessing considerable fastness to light, and these are much more permanent than those given by the present known members of the flavonol group.

NATURAL FLAVONE.

Very interesting is the occurrence of flavone in nature (Müller, Chem. Soc. Trans. 1915, 107, 872). It is well known that many varieties of the primula possess on their flower stalks, leaves, and seed capsules a characteristic dust termed by gardeners 'meal' or 'farina,' and this is most pronounced on varieties obtained from China and Japan. This powder, examined by Hugo Müller who obtained it mainly from the *P. pulverulenta* and *P. japonica*, dissolves readily in benzene and boiling ligroin, and the concentrated solution on cooling became semi-solid owing to the separation of crystalline tufts.

It possessed the formula $C_{15}H_{10}O_2$, melted at 99° – 100° , and on boiling with dilute sodium hydroxide gave slowly a yellow solution, with formation of a small quantity of acetophenone, and the latter could be obtained in greater quantity by the action of methyl alcoholic sodium hydroxide. Employing methyl alcoholic barium hydroxide, a reagent not previously suggested for the degradation of flavone compounds, Müller obtained a substance $C_{15}H_{12}O_3$. This by the action of alkalis was converted into salicylic acid and acetophenone and evidently consisted of hydroxy-benzoyl-acetophenone (*o*-hydroxy-dibenzoyl-methane)—

The compound $C_{15}H_{10}O_2$ was thus without doubt *flavone*,

and it is interesting to note that though hydroxy-benzoyl-acetophenone was assumed by Feuerstein and v. Kostanecki (Ber. 1898, 31, 1758) to be the first product of the hydrolysis of this substance, its isolation in this manner had not previously been effected.

The function which flavone exercises in the economy of the plant life of the primula is difficult to explain, though it may be of service on account of its repellent action towards water.

DIFLAVONE.

This substance was prepared by Ryan and O'Neill (Proceedings Royal Irish Academy, xxxii. B, 5, 48), who employed as a starting-point for their synthesis diacetoresorcinol—

This by interaction with benzaldehyde yields the dichalkone

the acetyl compound of which when brominated forms the tetrabromide

Alcoholic potash converts the latter compound into *diflavone*—

and this crystallises in faint yellow needles, m.p. 277° – 278° . In its general properties diflavone resembles flavone, and its faint yellow solution in sulphuric acid has a beautiful blue fluorescence. Colouring matters of this group are at present unknown. A. G. P.

FLAVONOL

It is usual to subdivide the great family of yellow colours derived from flavone into two classes, *flavone* and *flavonol*, and the latter group is distinguished by the fact that the hydrogen in the γ -pyrone ring of these compounds is substituted by hydroxyl, whereas in the former it is not.

Flavonol, so designated by v. Kostanecki, was synthesised by v. Kostanecki and Szabránski (Ber. 1904, 37, 2819) in the following manner:—

By the action of amyl nitrite and hydrochloric acid in alcoholic solution on flavanone, isonitrosoflavanone (1), m.p. 158° – 159° , is produced, and this by means of boiling dilute acids splits off hydroxylamine and is converted into flavonol—

Flavonol crystallises from alcohol in yellow needles, m.p. 169° – 170° . When warmed with aqueous sodium hydroxide it forms a yellow liquid, and on cooling the sodium salt separates in the form of yellow needles. Its solution in sulphuric acid exhibits an intense violet fluorescence. *Acetylflavonol*, colourless needles, melts at 110° – 111° .

According to Auwers and Müller (Ber. 1908, 41, 4233), benzylidenecoumaranones can be converted into flavonols. Thus benzylidene-4-methylcoumaranone dibromide when treated with potassium hydroxide gives 2-methylflavonol. The reaction may be thus expressed:—

The hydrolysis of flavonol into *o*-hydroxybenzoylcarbinol and benzoic acid may be expressed by the following equations:—

and this reaction, which is typical of the behaviour in these circumstances of the whole series of these compounds, has in general been employed to ascertain their structure. It is best effected by digesting the fully methylated flavonols with boiling alcoholic potash for some hours, for owing to the occurrence of secondary reactions it cannot be satisfactorily carried out with the unmethylated compounds.

For the synthesis of numerous flavonols, many of which occur naturally, v. Kostanecki and his co-workers have employed as a general method that found serviceable for the preparation of flavonol itself. The flavonols, with the exception of morin, which curiously enough is colourless, are yellow crystalline substances, soluble in alkaline solutions with a yellow colour, and yield with ease in the presence of acetic acid orange crystalline oxonium salts. According to Perkin, whereas as a rule hydroxyflavones are not oxidised by air in alkaline solution and can be precipitated therefrom unchanged by acids, flavonols, on the other hand, are readily decomposed in this manner with the formation of water-soluble products.

Interesting is the fact that though certain colouring matters of this group do not possess two hydroxyls in the ortho-position relatively to one another, they are nevertheless strong dyestuffs, and of these the tetrahydroxyflavonol morin may be taken as an example—

That this peculiarity arises from the presence of the pyrone hydroxyl is evident if the structure of morin is compared with the lotoflavone of Dunstan and Henry (Phil. Trans. 1901, 194, 515)

the tinctorial properties of which are exceedingly feeble. It seemed possible that this dyeing effect was to be attributed to the fact that this compound contains the hydroxyl (1) in the peri-position to the chromophore and which is present in most of the natural dyes of this group. Such a suggestion, however, became untenable on the synthesis of resomorin—

by Bonifazi, v. Kostanecki, and Tambor (Ber. 1906, 39, 86), which dyes the same shades as morin but does not contain the peri-hydroxyl in question. Evidently therefore the tinctorial properties of these hydroxy flavonols can only be accounted for by their possession of the grouping

the effect of which is considerably strengthened by the presence of hydroxyls in other positions in the molecule, and this has received support from the observation of v. Kostanecki and Szabránski that flavonol itself dyes on aluminium mordant a pale yellow shade. Though ortho-hydroxyl groups are not essential to the dyeing property of hydroxyflavonols, their presence, at least in certain positions, has considerable influence, not only in deepening the tone, but also in reddening the shade. Thus, whereas morin dyes bright yellow shades, quercetin (1)

gives a brown-orange shade on aluminium mordant, and the effect of the pyrone hydroxyl is very evident on comparing quercetin with luteolin (2) which gives in the same way only a bright yellow colour. A multiplication of hydroxyls does not effect any general alteration of shade given by these compounds, as is so well known to take place in the anthraquinone group.

The shades given by the flavonols are not so fast to light as those given by the flavone

luteolin, and this may arise in part owing to the greater susceptibility of their salts (or lakes) to oxidation. In this respect they vary again among themselves, quercetin being a somewhat faster colour than fisetin, and morin than quercetin.

On the other hand, the character of the shade given by the natural dyestuff varies in tone, as to whether the colouring matter is present as glucoside or in the free condition. Thus in dyeing with quercitron bark, quercitrin and not quercetin is the dyestuff, whereas in old fustic no glucoside is present, and the tinctorial effect is due to morin itself. The shade again given by a glucoside is naturally dependent on the position of the sugar nucleus, and thus the quercetin glucoside, quercimeritrin (see Cotton Flowers) has quite distinct properties in this respect from quercitrin itself. Again, a glucoside may be almost devoid of tinctorial property, as in the case of the kaempferol glucoside robinin and the alizarin glucoside ruberythric acid. The idea formerly held that glucosides in general were not true dyestuffs, and that during the dyeing operation by the action of the mordant they were hydrolysed with production of the colour lake of the free colouring matter, is incorrect. This evidently arose from the fact that in certain of these dyestuffs, as, for instance, madder and Persian berries, the glucoside is accompanied by its specific enzyme, which in case the temperature of the dye-bath is gradually raised from the cold upwards, effects the hydrolysis of the glucoside before the dyeing operation has really commenced.

A. G. P.

FLAVOPURPURIN v. ALIZARIN AND ALLIED COLOURING MATTERS.

FLAX. This term, as applied to the fibre of commerce, designates the product of the plant *Linum usitatissimum* (Linn.), belonging to the nat. order *Linaceæ*, a group consisting of herbs and small shrubs indigenous to all temperate climates. *Linum usitatissimum* is now only found in its cultivated condition. The plant occurs in two main 'forms': *L. usitatissimum* f. *vulgare* or *indehiscens*, with a taller stem and fruits that do not split open spontaneously; and *L. usitatissimum* f. *humile* or *crepitans*, more richly flowered and with fruits that open spontaneously. The former form is cultivated for the production of fibre, the latter for the production of seed (linseed). The herb has a solitary erect stem, attaining a height of from 20 to 40 inches. The cultivation of flax is of insignificant extent in England and Scotland, but is of much greater importance in Ireland. It forms also an important crop in some parts of Belgium, Holland, France, and Russia.

The plant having attained about two-thirds of its full height, is ready for gathering; as when allowed to grow to maturity a coarser and less valuable fibre results. The stem consists of an internal woody core, an external cortex, and an intermediate cellular tissue (the bast), from which the flax is prepared. The operations necessary in the preparation of the fibre for the purposes of the spinner are (1) pulling; (2) rippling; (3) steeping, retting, or watering; (4) grassing; (5) breaking; (6) scutching; (7) heckling. Of these, 'pulling' is a distinctive method of gathering the flax plant, which is always torn up by

the roots and not cut down like other crops. A fine day is selected for this purpose, and the stems are as far as possible arranged in sizes by the pullers; those also being assorted which may have been damaged by wind and rain. 'Rippling' is the process of removing the seed balls by drawing the heads through a species of comb set up usually in the field wherein the flax is being harvested. 'Retting' consists in immersing the stems in pools or streams of water in such a position that they shall stand almost erect, although weighted down so as to be quite submerged. The object of this is to induce fermentation, which dissolves the glutinous matter and disintegrates the fibres. Pure soft water and great judgment in the proper length of time to be allowed, which may be ten days to a fortnight, are essentials in this part of the treatment. Retting is followed by 'grassing,' whereby the separation of the flax fibre from the ligneous portions of the stalks is further facilitated. It consists in spreading the stems on the grass for a week or a fortnight, during which time they are occasionally turned. The flax during this operation becomes somewhat bleached. 'Breaking' and 'scutching' are the means employed to strip off the hard epidermis, and are effected either by hand or machinery. 'Heckling' is a still further combing, which arranges the fibres in parallel order, ready for the manufacture of yarn.

According to Kolb, retting sets up a peculiar fermentation, which results in pectose or its analogous bodies being changed into pectin and pectic acid; of which the former being soluble is left in the water, whilst the latter being insoluble remains attached to the fibre until its treatment with hot alkaline lye in bleaching, when it is changed into soluble metapectic acid.

Under the microscope, flax fibre has the appearance of a cylindrical tube, not continuous as in the case of cotton, but broken up by septa or knots at irregular distances through the length of the fibre, varying from four to six times the diameter of the tube. This diameter is from about $\frac{1}{1000}$ to $\frac{1}{800}$ of an inch. The adhesive power of the fibres, which gives the strength when spun into yarn, appears to depend on the twist given by the spindle as well as by the tenacity of the rough cellular sheath, which remains always more or less incrustated with the characteristic resinous deposit. Advantage is taken of the presence of this gummy deposit to detect the admixture in fabrics of cotton with linen; as, although the ultimate basis of both is cellulose, cotton exists in a much purer state than flax. The difference in the reaction upon them by caustic alkalis points out such admixture. When immersed in a boiling solution of caustic potash and water for about a minute, and then pressed between folds of filter paper, flax exhibits a dark-yellow colour, whilst cotton, when similarly treated, either remains white or becomes a very bright yellow. The same solution of potash employed cold colours raw flax orange-yellow, whilst cotton becomes grey, a result which Kuhlmann believed to be due to the pectic substances contained in flax.

FLEMINGIN v. WARAS; RESINS.

FLINT. (Fr. *Silex*; Ger. *Feuerstein*.) A native form of silica, being a compact massive variety of the mineral quartz with some admixed

hydrated silica (opal). It grades into chalcedony, chert, hornstone, or jasper, and may be banded and marked like agate; no sharp line of demarcation can be drawn between these several varieties of quartz. The term 'flint' is commonly limited to the nodular masses found in, or derived from, the Chalk formation. This material is of organic origin, being derived from the siliceous (opaline) remains of marine organisms (sponges with siliceous spicules, radiolaria, and diatomaceæ) deposited on the sea-floor together with the calcareous remains of other organisms which gave rise to the chalk itself. After deposition, this disseminated siliceous material became segregated into nodules; being no doubt re-deposited in the colloidal condition, and subsequently dehydrated and transformed into the crystalline condition. The fact that nodules of flint are usually arranged along the bedding planes in the chalk would suggest that these layers correspond to periods when siliceous organisms predominated, and that the solution and re-deposition of the silica took place contemporaneously in the soft ooze. On the other hand, the occurrence of flint in platy forms filling vertical joints in the chalk, suggests that solution and re-deposition may also have taken place subsequent to the consolidation of the chalk.

Flint is dull in colour and lustre, being yellowish, blackish, or more usually of a smoke-grey colour, and with a more or less waxy or greasy appearance. It breaks with a smooth conchoidal fracture, and under certain conditions with a conical fracture. Thin flakes are translucent at the edges. Thin sections in polarized light show that a large part of the material is minutely crystalline (crypto-crystalline). Sp.gr. 2.60-2.63 (somewhat less than that of crystallised quartz). The material consists of nearly pure silica (about 98 p.c.) with 1-1.4 p.c. of water, and traces of iron, aluminium, calcium, and organic matter. It is much more readily soluble in a hot solution of caustic alkali than is crystallised quartz. The white patina or crust often seen on flints consists in some cases of adhering chalk mixed with silica (CaCO_3 , 50 p.c.); or more often it consists wholly of silica, and has been produced by the weathering of the material, the opal being dehydrated or removed in solution and the crystalline particles liberated in a powdery condition.

Flints occur principally in the Upper Chalk, which is of wide distribution in the south-east of England, around the Paris basin, in Denmark, the island of Rügen, Co. Antrim, &c. With the denudation of the rock the resistant flints accumulate in gravels and other secondary deposits. The material is obtained: (1) as irregular nodules coated with chalk as a by-product from chalk quarries worked for lime, cement, whitening, &c.; (2) iron-stained pebbles from gravel pits; (3) boulders and pebbles collected on the seashore.

Flint was perhaps the very first mineral to be worked for practical uses, as witness the prehistoric palæolithic implements and the highly finished flints of the neolithic period. Flints for tinder-boxes and gun-flints are still worked by the flint-knappers at Brandon, in Suffolk (for an account of this industry, v. S. B. J. Skerchly, Mem. Geol. Survey, 1879). Apart from the

local use of flint as a building stone (v. E. T. Baggallay, Trans. R. I. Brit. Arch. 1885), and for road making and concrete, the principal use of the material is in the ceramic industry. For this purpose large quantities are collected along the French coast between Havre and St. Valéry at the mouth of the Somme. The material is burnt and thrown into cold water, when it can readily be finely ground to a snow-white powder; large quantities of flint pebbles are also ground between blocks of chert. For the manufacture of porcelain, as well as for glazing and enamelling, powdered flint is better than crystallised quartz, probably on account of the difference in texture of the material. Formerly it was also used in the manufacture of glass (hence the term flint-glass). Powdered flint bonded with a highly plastic clay is used for making refractory silica-bricks for steel furnaces. Round nodules of flint are used in tube mills for grinding feldspar, cement-clinkers, ore, &c., the silica worn from them being an uninjurious contamination. The Danish flints are best suited for this purpose. As an inert material it is used as a filler in acid towers. Powdered flint is used for making sand-paper. Flint is also cut and polished for use as agate-mortars, polishers, and burnishers. (v. W. Hill, Flint and Chert, Proc. Geol. Assoc. 1911, xxii. 61; J. W. Mellor and A. J. Campbell, Flint and Quartz, Trans. English Ceramic Soc. 1916, xv. 76).

FLORENCITE. Basic phosphate of aluminium and cerium (Ce_2O_3 , &c., 28 p.c.)—

crystallised in the rhombohedral system and isomorphous with the strontium salt hamlinite. Sp.gr. 3.586. It is found as small yellowish grains and crystals in diamond-bearing sands near Diamantina, Brazil, and in cinnabar-bearing sands and in mica-schist with topaz near Ouro Preto, Brazil.

L. J. S.

FLORES CINAE v. *SANTONICA*.

FLORIDOSE. An aldohexose found in the red sea-weed, *Floridææ*, and in *Chondrus Elatus*, *Ahnfeltia plicata*, and other sea plants. Crystallises from water; is soluble in alcohol; m.p. 152° – 153° ; $[\alpha]_D^{20} + 80.75^\circ$. Reduces Barreswil's (Fehling's) solution; is fermented by yeast; forms a hydrazone, m.p. 158° – 160° . Soluble in methyl and ethyl alcohols and in hot water; a needle-shaped osazone, m.p. 193° . Sodium amalgam reduces it to a hexahydric alcohol, *floriditol* (Takahashi, J. Tokyo Chem. Soc. 1919, 40, 157).

FLOS-FERRI v. *ARAGONITE*.

FLUID GELATIN v. *Aluminium oleate*, art. ALUMS.

FLUOCERITE. Fluoride of cerium (40 p.c.), lanthanum (30 p.c.), and yttrium (3 p.c.) earths, (Ce , La , Di) F_3 , crystallised in the hexagonal system. It is reddish-yellow with resinous lustre, and massive, rarely as crystals. Sp.gr. 5.70, 5.93. It occurs in pegmatite veins with gadolinite, orthite, &c., at Österby, Finbo, and Broddbo in Sweden (P. Geijer, Geol. För Förh. Stockholm, 1921, 43, 19).

L. J. S.

FLUORAL v. *SYNTHETIC DRUGS*.

FLUORAM. Trade name for acid ammonium fluoride.

FLUORANTHENE *Idryl*

Discovered independently by Fittig and Gebhard (Ber. 10, 2143; Annalen, 193, 142) in coal tar and by Goldschmidt in 'stupp,' a mixture of hydrocarbons obtained in distilling mercury ores at Idria (Ber. 10, 2022). Obtained from the fraction of coal tar boiling higher than anthracene, by redistilling it at 250° under a pressure of 60 mm. A mixture of pyrene and fluoranthene passes over, which may be separated by repeated crystallisations from alcohol of their picric acid compounds; the fluoranthene picrate separates as long reddish-yellow needles, melting at 182°–183°. Forms slender needles or monoclinic plates, melting at 109°–110°; boils at 250°–251° under a pressure of 60 mm. Sparingly soluble in cold, readily soluble in boiling alcohol; soluble in ether, carbon disulphide, chloroform, benzene, and glacial acetic acid. Warm concentrated sulphuric acid dissolves the hydrocarbon, producing a deep-blue colour.

Chromic acid oxidises it to a quinone $\text{C}_{16}\text{H}_8\text{O}_2$ (red needles melting at 187°–188°), which, on further oxidation, yields *diphenyleneketone-carboxylic acid*

(m.p. 191°–192°). This acid is converted by heating with lime into *diphenyleneketone* (*v. FLUORENE*), and by fusion with caustic potash

into *isodiphenic acid* $\text{C}_6\text{H}_4\cdot\text{COOH}$ (1, 2) $\text{C}_6\text{H}_3\cdot\text{COOH}$ (1, 3).

Fuming nitric acid forms with the hydrocarbon a trinitro derivative.

FLUOR-APATITE *v. APATITE.*

FLUORENE *o-Diphenylene methane*

Discovered by Berthelot in coal tar (Compt. rend. 65, 465; Ann. Chim. Phys. [4] 12, 222). Obtained (1) by passing the vapour of diphenylmethane through a red-hot tube (Gräbe, Annalen, 174, 194); (2) by reduction of diphenylene ketone either by distillation with zinc-dust (Fittig, Ber. 6, 187) or by heating with hydriodic acid and red phosphorus to 150°–160° (Gräbe, *ibid.* 7, 1625): the diphenylene ketone may be synthesised by splitting off H_2O and CO_2 from diphenic acid (Ostermayer and Fittig, *ibid.* 5, 935) or by diazotising *o*-amino-benzophenone and eliminating the diazo-group (Gräbe and Ullmann, *ibid.* 27, 3485)

(3) by condensing ethyl trichloracetate with benzene in the presence of aluminium chloride

VOL. III.—T.

and heating to 290° the 9-fluorene carboxylic

acid $\left(\begin{array}{c} \text{C}_6\text{H}_4 \\ | \\ \text{C}_6\text{H}_4-\text{C} \begin{array}{l} \text{H} \\ \text{COOH} \end{array} \end{array} \right)$ formed (Delacre, Bull.

Soc. chim. [3] 27, 875). The high-boiling fractions of tar oil after depositing naphthalene and anthracene are distilled; the fraction boiling between 295° and 310° contains the greater portion of the fluorene, which, on fusion with caustic potash at 280°, is converted into a solid potassium compound (Weissgerber, Ber. 34, 1659): the latter was originally separated mechanically from the fused hydrocarbons and the fluorene regenerated by treatment with water (D. R. P. 124150). Diphenylene oxide, present in the original mixture, is converted into potassium diphenate, and a small proportion of fluorene into *o*-phenylbenzoic acid; the alkaline mass is then treated with water and the hydrocarbons obtained pure by fractional distillation (D. R. P. 130679). The sodium compound, also used for the separation, is obtained by fusing the mixture of hydrocarbons with sodium or sodamide at 150°–200° (D. R. P. 203312). In the presence of aniline or other organic bases, the reaction proceeds more smoothly, and at a lower temperature (D. R. P. 209432). Recrystallisation from alcohol and glacial acetic acid, and precipitation of the picric acid compound (m.p. 81°), may be used in the purification.—Lustrous laminae, melting at 115° (Delacre, *l.c.*). Boils at 294°–295° (corr.). Sparingly soluble in cold, readily in hot alcohol; readily soluble in ether, benzene, and carbon disulphide. Oxidation with lead oxide yields bisdiphenylene ethane and bisdiphenylene ethylene (red needles melting at 188°); with chromic acid diphenyleneketone (yellow prisms melting at 84°, boiling at 337°); with fused caustic potash *o*-phenylbenzoic acid and with potassium permanganate *o*-phthalic acid. With nitric acid (sp.gr. 1.4) in glacial acetic solution at 80°, 2-nitrofluorene is formed (Diels, Ber. 34, 1758); fuming nitric acid produces the 2:7-paradinitro derivative, melting at 199°–201° (Fittig and Schmitz, Annalen, 193, 134), 255°–260° (Barth and Goldschmidt, Ber. 11, 846).

The corresponding amino compounds have been used in the preparation of azo dyes, but do not yet appear to have found practical application. By the action of sulphuric acid and the halogens, substitution compounds are formed. The negative character of the methylene hydrogen atoms is shown by the formation of potassium and sodium compounds (*v. supra*), and by the formation of condensation products with benzaldehyde and oxalic ester (Thiele, Ber. 33, 851; Wislicenus, *ibid.* 33, 771). The conversion of phenanthrenequinone, by fusion with potash, to 9-oxyfluorene-9-carboxylic acid (Schmidt and Bauer, Ber. 38, 3738), and the formation of phenanthrene by a pyrogenic reaction from methyl fluorene (Gräbe, *ibid.* 37, 4145), furnish instances of the mutual conversion of 5 and 6 rings. Reduction with hydriodic acid yields a decahydrofluorene, $\text{C}_{16}\text{H}_{20}$ (Schmidt, *ibid.* 40, 4566); fluorene perhydride $\text{C}_{16}\text{H}_{22}$, is described by Spiegel (*ibid.* 41, 884; 42, 916).

Isomeric diphenylenemethanes were described by Carnelley (Chem. Soc. Trans. 1880, 708), who obtained them by passing the mixed

vapours of benzene and toluene through a red-hot tube. I. S.

FLUORENE KETONE v. KETONES.

FLUORESCEIN v. **TRIPHENYL METHANE** COLOURING MATTERS.

FLUORESCENT BLUE or **RESORCIN BLUE** $C_{18}H_3Br_6N_3O_5(NH_4)$. A colouring matter obtained in 1880 by Weselsky and Benedikt by treating a solution of diazoresorufin in potassium carbonate with bromine, and precipitating with an acid. Soluble in boiling water, giving a reddish-violet solution with green fluorescence. On the addition of hydrochloric acid, the aqueous solution gives a yellowish-brown precipitate. With zinc-dust and caustic soda solution rapidly becomes colourless, but again becomes blue on exposure to air. Soluble in concentrated sulphuric acid with blue colour, which becomes violet on addition of water, and eventually gives a reddish-brown precipitate. Dyes silk and wool blue with brownish fluorescence (Brünner and Krämer, Ber. 17, 1847, 1867, 1875; Weselsky and Benedikt, Monatsh. 5, 605; Ber. 18, Ref. 76) (v. OXAZINE COLOURING MATTERS).

FLUORINDINES v. AZINES.

FLUORINE. Sym. F. At. wt. 19.0. Ampère, in 1810, first pointed out the analogy between hydrochloric acid and the gas evolved from a mixture of fluorspar and sulphuric acid; he assumed the existence of an element similar to chlorine, and further that the acid obtained from fluorspar was a hydrogen compound. Berzelius and Davy, a few years later, more fully established this view.

The name fluorine was given to the supposed element on account of its being a constituent of fluorspar. Many fruitless attempts had been made to isolate the element, but, owing to its great affinity for other elements, none could be regarded as successful until Moissan, in 1886, announced his results.

Occurrence.—Fluorine occurs in the combined state only, and generally as fluor-spar CaF_2 , crystallising in cubes and octahedrons; this compound is found in abundance in Derbyshire, where it is known as Derbyshire-spar, and 'Blue John'; it is also found in Northumberland, Durham, Yorkshire, and Cornwall, and from it most of the preparations of fluorine are made (v. FLUOR-SPAR). *Cryolite*, a double fluoride of aluminium and sodium $3NaF \cdot AlF_3$ or $Al_2F_6 \cdot 6NaF$, found in Greenland, is a mineral containing fluorine (v. CRYOLITE). Fluorine is widely but sparingly diffused, occurring in small amount in conjunction with aluminium and silicon in *topaz*; with cerium and yttrium in *fluocerite* and *ytrocerite*; it occurs also in *apatite*, *wavellite*, *wagnerite*, and other minerals. It is also found in the *idocrase* of Vesuvius, Christiansand in Norway, and in the variety from the River Wilui in Siberia (Jannasch, Jahr. Mineral. 1883, 2, 123). Traces of it exist in sea-water, and in the water of many mineral springs and rivers. Traces of fluorine have been detected by Wilson in the silicious stems of grasses and equisetaceous plants. Bones, both fossil and recent, contain fluorine (Carnot, Compt. rend. 1892, 114, 1189-1192), and it is found in the enamel of the teeth (Gabriel, Zeitsch. physiol. Chem. 18, 257-303, 1894; Wrampelmeyer, Zeitsch. anal. Chem. 32, 550-553, 1894). It is said to occur in the

blood, the brain (Horsford, Annalen, 149, 202), and in milk, also in human urine.

Tammann (Zeitsch. physiol. Chem. 1888, 12, 322-326) has shown that fluorine is of great importance in the animal economy, while Sabatier and Horstmann (Ann. Chim. Phys. 114, 510) has demonstrated that certain plants do not develop in its absence.

Isolation of fluorine.—Davy concluded, from his experiments on the compounds of fluorine, that the latter was an extremely active element. Since his time many chemists have endeavoured to obtain fluorine in the free state. It has been known since the time of Faraday that strong hydrofluoric acid is a very bad conductor of the electric current, and Moissan in his experiments found that the current from 50 Bunsen cells was not able to effect a passage through the anhydrous acid; by dissolving a little hydrogen potassium fluoride $HF \cdot KF$ in the acid, it was at once rendered a conductor. The apparatus employed consisted of an irido-platinum U-tube 9.5 cm. high and 1.5 cm. diameter (Fig. 1). At the side and near the top of each limb was a

FIG. 1.

FIG. 2.

small exit tube of platinum, F and H; each limb of the U-tube was provided with a hollow cylinder screwed into it, and the hollow part of each cylinder was closed by a stopper of fluorspar, through the axis of which passed the terminals of iridium platinum (Fig. 2); these terminals were 2 mm. square in section and side, 12 mm. long, and passed to within 3 mm. from the bottom of each limb. The whole apparatus was first entirely freed from moisture by drying at 120° , then about 6 grams of the double fluoride of hydrogen and potassium were introduced, the stoppers screwed in and covered with shellac, and then placed in a methyl chloride bath, a constant supply of which at -23° was maintained in the bath. The delivery tubes, hitherto kept in communication with desiccators of fused potash, are now connected with the vessel containing anhydrous hydrofluoric acid, and about 16 grams are gently aspirated into the apparatus. On now passing a current from 20 Bunsen cells through the solution, a continuous evolution of gas took place. To demonstrate its effects upon other bodies, they were placed in small glass tubes, and brought to the delivery tube at the positive side (Fig. 3).

On taking the apparatus to pieces after each experiment, the hydrofluoric acid remaining was found to contain a small quantity of platinum fluoride in solution, and a black mud consisting of a mixture of iridium and platinum in suspension. The negative electrode was not attacked, but the platinum rod forming the positive pole was eaten away to a point, so that

one rod only served for two experiments. The average delivery of gas was about 1.5 to 2 litres per hour.

It is probable that potassium fluoride is first decomposed, fluorine being evolved at the positive pole, and potassium, which decomposes

FIG. 3.

hydrofluoric acid, liberating its equivalent of hydrogen at the negative pole, re-forming potassium fluoride which may be again electrolysed. Hence a small quantity of the double fluoride can serve for the decomposition of a comparatively large amount of hydrofluoric acid.

To prepare the pure anhydrous acid, a known volume of commercial acid was treated with sufficient potassium carbonate to neutralise about a fourth part, and was then distilled in a leaden retort over an oil-bath at 120° . Potassium fluosilicate, formed from the hydrofluosilic acid contained as impurity, was not decomposed on distilling, and the distillate was therefore free from silica. The distillate was divided into two parts, one of which was neutralised by potassium carbonate and then added to the other half, thus forming the double fluoride $\text{HF} \cdot \text{KF}$. This was dried at 100° , and kept for several days in vacuum in the receiver of the air-pump, over sulphuric acid and sticks of potash. When perfectly dry, this compound falls to powder, and is then ready for the preparation of the anhydrous acid. The dry fluoride thus obtained was introduced into a platinum retort and gently heated; the first portions of distillate are rejected, as they contain traces of water. A platinum receiver is then adapted and placed in a freezing mixture of ice and salt: on increasing the temperature, pure hydrofluoric acid passes over and is condensed in the receiver as a limpid liquid, which boils at 19.4° , is very hygroscopic, and fumes in air (*Ann. Chim.* [6] 12, 472-537).

The double fluoride is very soluble in hydro-

fluoric acid, forming with it a crystallisable compound richer in hydrofluoric acid than the double fluoride itself, and which gives off no acid vapour at the boiling-point of the anhydrous acid (19.4°).

Moissan electrolysed the double fluoride itself, which fuses at 140° to a colourless liquid. The experiment was done, as before, in a U-tube of platinum, but the latter was strongly attacked. On dipping the platinum terminals of the battery into the fused double fluoride contained in a platinum dish, gas was freely evolved at each pole, detonation occurring on bringing the terminals together, even in the dark. The wire at the end where the fluorine was evolved was strongly corroded.

Later Moissan found it possible to use an apparatus made of copper. The metal becomes coated with a film of fluoride CuF_2 , which is insoluble and protects the copper from further corrosion. The electrodes must be made of platinum instead of copper, as the fluoride formed on the latter would diminish the current (*Compt. rend.* 1899, 128, 1543-1545).

For the preparation of anhydrous hydrogen fluoride sodium hydrogen fluoride is preferable to the potassium salt.

Fluorine can be prepared in quantity by the electrolysis of fused potassium hydrogen fluoride. A stout cylindrical copper cell, $3\frac{1}{2}$ inches diameter by 8 inches deep, heated electrically by a nichrome winding, is used. The cell itself acts as a cathode and a graphite rod as anode. The evolution of fluorine occurs at 240° - 250° with a current of 10 ampères at 12 volts (Argo, Mathers, Humiston and Anderson, *Amer. Electrochem. Soc.* 1919). For a modification of this process see Meyer and Sandow, *Ber.* 1921, 54 [B], 759.

Properties.—Fluorine is a gas of a penetrating and disagreeable smell, similar to that of hypochlorous acid. A column of the gas enclosed in a platinum tube 50 cm. long, with colourless fluor spar ends, has a decided greenish-yellow colour (Moissan, *Compt. rend.* 1890, 109, 937-940). Its dispersion is anomalous, being less at the blue end of the spectrum than it is at the red (J. H. Gladstone and G. Gladstone, *Phil. Mag.* 1891, [5] 31, 1-9).

The atomic refraction of fluorine, as determined from a number of its compounds for the line H of the solar spectrum, varies from 0.35 to 0.63, the numbers for chlorine, bromine, and iodine being 10.0, 15.2, and 25.2 respectively (Gladstone, *l.c.*). For sodium light, the values 1.082 in unsaturated and 0.775 in saturated compounds (calculated according to the Lorentz formula) have been obtained by Swarts (*Chem. Zentr.* 1897, ii. 1042-1043). The atomic refraction of fluorine in unsaturated bodies is thus almost equal to that of hydrogen, so that if a double link is really present, fluorine has the smallest atomic refraction of any known element, its magnitude corresponding to its extremely low atomic volume, shown by Traube to lie between 0 and 1 (*Annalen*, 1896, 290, 105). The refractive index of the free element is 1.000195 for sodium light, being thus almost exactly one quarter that of chlorine, and bearing the same relation to it as do the refractive indices of nitrogen, oxygen, and neon to those of phosphorus, sulphur and argon respectively. This

value was obtained directly from measurement of the electrolytic gas, due allowance being made for oxygen, ozone, and nitrogen, which are always present (Cuthbertson and Prideaux, *Phil. Trans.* 1905, 205, A, 319-331).

The density of fluorine was determined after purification of the gas by passing it through a platinum worm cooled to -50° by methyl chloride, and thence through a tube containing anhydrous sodium fluoride, which removes the last traces of hydrogen fluoride. The volume of the gas was determined by analysis after interaction with water. The first determination was made in platinum vessels, and gave the value 1.265 (air) (Moissan, *Compt. rend.* 1890, 109, 861-864), but a later value, 1.310, obtained by the Regnault method in a glass vessel (Moissan, *ibid.* 1904, 138, 728-732), corresponds almost exactly to the value 1.319, calculated from the atomic weight $F=19.05$ and molecular weight 38.10. The possibility of the existence of any measurable proportion of free fluorine atoms is thus excluded.

Fluorine was liquefied by Moissan and Dewar in 1897 (*Compt. rend.* 1897, 124, 1202-1205) by subjecting the gas to the cooling action of liquid oxygen, boiling under reduced pressure. Liquid fluorine is of a yellowish colour and very mobile. When placed in liquid hydrogen, it forms a white solid, m.p. -223° (Moissan and Dewar, *Compt. rend.* 1903, 136, 641-643). The critical temperature of fluorine is about 120° ; the critical pressure, about 40 atmospheres; and the boiling-point, -187° . The density of liquid fluorine is about 1.14. Its specific refraction is greater than that of liquid air or oxygen, its capillary constant less than that of liquid oxygen. It has no magnetic properties, and shows no specific absorption bands (Moissan and Dewar, *Chem. Soc. Proc.* 1897, 175).

Fluorine gas has an irritating effect on the eyes and upon the mucous membrane. It decomposes water with formation of hydrofluoric acid, and the oxygen which is set free is ozonised. It corrodes glass, and attacks with violence all organic compounds, cork being at once carbonised and inflamed; alcohol, ether, benzene, and turpentine take fire immediately in contact with it.

Fluorine, freed from hydrofluoric acid by subjection to the temperature of boiling air and subsequent passage over dry sodium fluoride cooled by a solution of solid carbon dioxide in acetone, does not attack glass even at 100° , provided that the surface of the glass is free from all traces of organic matter. It is impossible to dry fluorine by means of phosphorus pentoxide, as phosphoryl trifluoride is immediately formed (Moissan, *Compt. rend.* 1899, 129, 799-804).

Fluorine combines with hydrogen, even in the dark, the combination is attended with detonation, and is effected even at the temperature of liquid hydrogen (Moissan and Dewar, *ibid.* 1903, 136, 641-643). Iodine burns in fluorine with a pale-blue flame, forming iodine pentafluoride (Moissan, *ibid.* 1902, 135, 563), and, in an atmosphere of iodine vapour, fluorine burns with a similar flame. Vapour of bromine loses its colour in fluorine, and the combination is sometimes attended with detonation with formation of bromine trifluoride (Lebeau,

ibid. 1905, 141, 1015; Prideaux, *Chem. Soc. Trans.* 1906, 316). Fluorine at once releases chlorine from cold potassium chloride; chlorine is also expelled from its combination with carbon in carbon tetrachloride, but does not unite with fluorine.

Nitrogen also has no action on the gas, but excess of fluorine acts upon nitric oxide at the temperature of liquid oxygen, forming nitroxyl fluoride, m.p. -139° , b.p. -63.5° , density 2.17-2.31, a colourless gas at the ordinary temperature (Moissan and Lebeau, *Compt. rend.* 1905, 140, 1621-1626).

Sulphur, selenium, and tellurium, on being placed in fluorine, at once melt and inflame with incandescence and formation of fumes and a coating of solid fluorides. Phosphorus burns in it with formation of fluoride and oxyfluoride; arsenic in powder becomes incandescent, and forms liquid drops of the trifluoride; antimony also becomes incandescent. Silicon in crystalline form, and cold, burns with brilliancy, and sometimes with scintillations. Adamantine boron also burns in the gas.

Metals are all attacked, but with varying energy, and formation of fluorides. Sodium and potassium in the cold are rendered incandescent. Calcium, magnesium, and aluminium become incandescent when slightly warmed. Iron and manganese in a state of powder, with slight warming, burn with bright scintillations. Lead is attacked in the cold, and tin on slightly warming. Mercury is entirely converted into a yellow protofluoride. Silver, at a gentle heat, becomes coated with a satin-like deposit of fluoride soluble in water. Gold and platinum, when heated to between 300° and 400° , become converted into their respective fluorides, which are decomposed again at a red heat with evolution of free fluorine (*Ann. Chim.* 1887, [6] 12, 472-537; Moissan, *Fluorine et ses composés*). Even at -187° , liquid fluorine reacts with a large number of substances. Sulphur, selenium, arsenic, phosphorus, potassium, calcium oxide, and anthracene all react violently with it, while solid fluorine combines with liquid hydrogen at -252.5° , with violent explosion, sufficient heat being evolved to render the materials incandescent (Moissan and Dewar, *Compt. rend.* 1903, 136, 641-643). If, however, sulphur, phosphorus, carbon, silicon, boron, and iron be first cooled in liquid air, they do not react with fluorine at -185° , neither is iodine displaced from iodides at this temperature, nor glass corroded (Moissan and Dewar, *ibid.* 1897, 124, 1202-1205). If fluorine be passed into liquid oxygen, a flocculent precipitate collects, which deflagrates on rise of temperature. It is probably a hydrate of fluorine, as it is never obtained from perfectly dry oxygen.

The majority of the metallic compounds of fluorine are easily fusible, and when ignited in a current of steam many of them are converted into the corresponding oxides, whilst hydrofluoric acid is formed. The fluorides of silver and tin are easily soluble in water, while those of sodium, potassium, and iron are only sparingly soluble. They are all decomposed by sulphuric acid when heated, with evolution of hydrofluoric acid, but nitric does not so easily attack them. Heated in a current of chlorine, they are all decomposed with formation of

corresponding chlorides. Solutions of the soluble fluorides corrode glass, and they give no precipitate with silver nitrate, as the fluoride of silver is soluble. Lead, barium, magnesium, and calcium salts produce insoluble precipitates. The precipitate of calcium fluoride is so transparent as to be perceived with difficulty, but is rendered more opaque by heating.

Many metallic fluorides combine with hydrofluoric acid and form compounds obtainable in crystals soluble in water. The double fluorides of the alkali-metals with the fluorides of the electro-negative metals which form acids with oxygen may be obtained with facility, and are analogous in composition to the double fluoride of hydrogen and potassium. They are all decomposed by sulphuric acid, yielding hydrofluoric acid and a sulphate. A mixture of hydrofluoric acid and nitric acid dissolves silica which has not been previously ignited, but the mixture has no action on gold or platinum.

The atomic weight of fluorine.—With notable exceptions, all the determinations of the atomic weight of fluorine involve the conversion of fluorides of various metals into the corresponding sulphates, the fluoride most commonly employed being that of calcium, which was used in some cases in the form of a very pure fluorspar.

Berzelius (Poggendorff's *Annalen*, 1826, 8, 1), Louyet (*Ann. Chim.* 1849, [3] 25, 295), Dumas (*Annalen*, 1860, 28, 113), De Luca (*Compt. rend.* 1860, 51, 299), and Moissan (*ibid.* 1890, 111, 570-572) all made use of this method, the average weight of calcium sulphate obtained from one part of fluoride being 1.7444 ± 0.00018 gram, which gives 18.999 as the atomic weight of fluorine.

Louyet, by the conversion of lead fluoride into lead sulphate, obtained the value 19.01; Moissan, working with barium fluoride, obtained the value 19.02. Dumas, Louyet, and Moissan (*Compt. rend.* 1890, 111, 570-572) also worked with sodium fluoride, the results by this method being uniformly higher, viz. 19.08, 19.06, and 19.07 respectively. Values were also obtained by Dumas and Moissan from the conversion of potassium fluoride into potassium sulphate.

An exceptional method was employed by Christensen (*J. pr. Chem.* 1886, [2] 34, 41-46), who took advantage of the decomposition of ammonium manganifluoride $(\text{NH}_4)_2\text{MnF}_6$ to measure the atomic weight of fluorine. The manganifluoride was treated with potassium iodide, one molecule of the former, on acidification with hydrochloric acid, liberating a molecule of iodine, which was then titrated with standard sodium thiosulphate solution. In the first series of experiments, he obtained the value $F=19.00$, and in the second (*J. pr. Chem.* 1887, [2] 35, 541-559) $F=18.99$.

Meyer (*Zeitsch. anorg. Chem.* 1903, 36, 313-324) compared the results of these previous investigations, criticising both the suitability of the methods and the purity of the materials employed. To the latter cause he mainly attributed the discrepancies in the values obtained. He therefore started with pure ammonium carbonate and calcium nitrate, converted the calcium carbonate so obtained into oxide, which he slaked and converted into chloride, and passed finally to fluoride by evaporation of the chloride with specially purified

hydrofluoric acid. As the mean of 5 determinations, he obtained the value $F=19.036$, error ± 0.00149 . The general mean of all the determinations agrees well with the results of Christensen and Meyer, if all the values are recalculated with the most recent atomic weights (F. W. Clarke, *Recalculation of Atomic Weights*, 1910). The mean value for the atomic weight of fluorine is 19.041 ± 0.00135 ; the recalculated results of Christensen give an average value of 19.038, and those of Meyer 19.035.

Additional confirmation of Christensen's value is obtained from the fact that the atomic weight of manganese, $\text{Mn}=54.933$, calculated from his data, agrees well with that obtained by Baxter and Hines (*J. Amer. Chem. Soc.* 1906, 28, 1560).

Smith and van Haagen find $F=19.002$. Moles and Batuecas (*Journ. Chim. Phys.* 1919, 17, 538), by determining the weight of a normal litre of methyl fluoride, find $F=18.996$.

Comparison of fluorine with the other halogens.—Fluorine is by far the most energetic member of the halogen family, and, as is frequently the case with the first member of a series, it possesses very distinctive properties. Moissan has pointed out (*Bull. Soc. chim.* 1892, [3] 5, 880-885) that in certain of its relations, it remotely resembles oxygen rather than chlorine. Thus carbon readily takes fire and burns in it (Moissan, *Compt. rend.* 1890, 110, 276-279). Calcium fluoride is very different from calcium chloride, rather resembling calcium oxide in solubility. Silver fluoride is also anomalous, being easily soluble in water, while aluminium fluoride is much less easily hydrolysed than is the chloride.

Fluorine compounds with the non-metals are uniformly more volatile than the chlorine compounds, but the metallic fluorides usually require a higher temperature for fusion than do the other halides.

The boiling-point of a hydrocarbon is increased on the average by 5° by the substitution of fluorine for hydrogen, but if fluorine is introduced into a molecule already containing halogen atoms, the boiling-point is lowered, the same behaviour being observed in the case of aldehydes. In this respect, fluorine differs greatly from chlorine (Henry, *Rec. trav. chim.* 1897, 16, 218-225; Moissan and Dewar, *Chem. Soc. Proc.* 1897, 175).

Hydrofluoric acid or Hydrogen fluoride HF. The corrosive action of this compound on glass was known to Schwanhardt of Nuremberg as early as the year 1670. Scheele, in 1771, first recognised that fluorspar is a compound of lime and a peculiar acid, and he prepared the latter in both the aqueous and gaseous forms by distilling in a tin retort. Priestley was the first to collect the gas over mercury. It was regarded by Gay-Lussac and Thenard, in 1808, as an oxygen compound. Ampère, however, in 1810, pointed out its similarity to hydrochloric acid, a view which was subsequently supported and confirmed by Davy and Berzelius. It was first obtained in a pure state by Gore in 1868.

Its volumetric composition can be shown either by electrolysis of the acid and collecting and measuring the liberated hydrogen and oxygen, or by allowing a measured volume of fluorine to act on water, titrating the acid formed, and measuring the oxygen. In both

cases, after allowing for the contraction in the volume of oxygen, due to formation of ozone, the results show that hydrogen fluoride is formed by the union of equal volumes of hydrogen and fluorine (Moissan, *Compt. rend.* 1900, 130, 544-548; cf. *mol. wt.*, Gore, below).

The anhydrous acid is best prepared from the double fluoride of potassium and hydrogen, as previously described. Fremy obtained the anhydrous acid by decomposing lead fluoride with dry hydrogen.

Anhydrous hydrofluoric acid is a colourless, mobile liquid of density 0.9879 (Gore). It boils at 19.4° , and solidifies at -102.5° to a white crystalline transparent mass, becoming white and opaque at a lower temperature, and melts at -92.3° (Olszewski, *Monatsh.* 1886, 7, 371-374). Its vapour tension at 15.5° is equal to a pressure of 7.58 lbs. per square inch. The anhydrous acid does not attack glass even if left in contact with it for weeks; but if the least trace of moisture be present, this action is apparent at once. The acid has little action on the metalloids and the noble metals, and below 20° the other metals are not attacked. Basic oxides unite readily with it, some of them dissolving; on peroxides it has no effect.

Potassium, when thrown into the anhydrous acid, decomposes it with explosion. It combines eagerly with phosphoric and sulphuric anhydrides, with evolution of great heat, in this respect resembling water, and not its more obvious analogue, hydrochloric acid. It also combines energetically with the fluorides of potassium and sodium, just as water combines with the oxides of these metals.

The anhydrous acid decomposes carbonates with effervescence and with the formation of fluorides. Solid organic bodies immersed in it are for the most part disintegrated. Gutta-percha, caoutchouc, and numerous gums and resins dissolve to red liquids. Guncotton, silk, paper, cotton wool, calico, &c., are converted into glutinous substances, and generally dissolve. Wood spirit, alcohol, and ether, but not benzene, mix with it, and oil of turpentine, when mixed with it, forms a red liquid (Gore, *Proc. Roy. Soc.* 17, 256).

Hydrogen fluoride, at a white heat, converts aluminium oxide into the fluoride. Yttrium oxide and lanthanum oxide are converted into non-volatile fluorides. Finely divided quartz is completely volatilised without the action of heat; with titanium, zirconium, columbium, and tantalum oxides a red heat is necessary (van Haagen and Smith, *J. Amer. Chem. Soc.* 1911, 33, 1504).

The molecular weight of hydrogen fluoride has been a source of some controversy. Gore (*Phil. Trans.* 1869, 73) showed that the volume of hydrogen fluoride gas obtained by the action of hydrogen on silver fluoride was twice that of the hydrogen taken, the measurements being made at 100° , but Mallet, weighing the gas at 30.75° in a large flask coated with paraffin, obtained a value for the density corresponding to a molecular weight of 39.32, which indicates the molecular formula H_2F_2 (*Amer. Chem. J.* 1881, 3, 189).

Thorpe and Hambly (*Chem. Soc. Trans.* 1889, 163) found that the vapour density of hydrogen fluoride varies rapidly with the temperature and pressure. The following table gives the

results of their experiments at temperatures varying between 26.4° and 88.1° :—

Temperature	Pressure mm.	V.D. air=1	Mol. weight
26.4°	745	1.773	51.18
27.8°	746	1.712	49.42
29.2°	750	1.578	45.54
32.0°	743	1.377	39.74
33.1°	750	1.321	38.12
33.8°	758	1.270	36.66
36.3°	739	1.115	32.20
38.7°	751	1.021	29.46
39.2°	743	1.002	28.94
42.8°	741	0.910	26.26
47.3°	745	0.823	23.76
57.5°	750	0.737	21.28
69.4°	746	0.726	20.96
88.1°	741	0.713	20.58

These numbers show that the process of dissociation of the vapour of hydrogen fluoride is perfectly continuous, and that there is no direct evidence of the existence of a molecule corresponding to H_2F_2 . It is also found that the vapour density is lowered by diminishing the pressure of the gas at a constant temperature. The following table shows the vapour density of hydrogen fluoride under varying pressures at the constant temperature of *circa* 32° :—

Temperature	Pressure mm.	V.D. air=1	Mol. weight
32.0°	743	1.377	39.74
32.2°	686	1.239	35.78
31.8°	655	1.177	33.98
32.0°	603	1.068	30.82
32.5°	545	0.963	27.78
32.3°	498	0.920	26.54
31.9°	354	0.797	23.00
32.3°	353	0.789	22.78

Similar results were obtained by mixing the hydrogen fluoride with air so as to lower the partial pressure of the gas.

The anhydrous acid, on addition of water, is changed in sp.gr. from 0.988 to as much as 1.25, further dilution causing a regular decrease in sp.gr. (For a table showing the relation between the sp.gr. and strength of hydrofluoric acid, *v. Winteler*, *Zeitsch. angew. Chem.* 1902, 15, 33-34; *J. Soc. Chem. Ind.* 1902, 277.) The acid of sp.gr. 1.15 may be distilled unchanged; it boils at 120° , and contains about 36 to 38 p.c. of the anhydrous acid, but does not thus form a definite hydrate; when allowed to evaporate over caustic lime in the air, the aqueous acid attains a constant composition containing 32.6 p.c. of the anhydrous acid (Roscoe, *Chem. Soc. Trans.* 1861, 13, 162).

According to Deussen (*Zeitsch. anorg. Chem.* 1906, 49, 297-300), a constant boiling mixture of boiling-point 111° at 750 mm. pressure has a sp.gr. of 1.138 at 18° and contains 43.2 p.c. hydrofluoric acid by weight.

Hydrogen fluoride gas is formed from its elements with great evolution of heat :

(Berthelot and Moissan, *Compt. rend.* 1889, 109, 209). (For heat of dissolution, *cf.* Guntz, *Bull. Soc. chim.* 1884, 40, 54-57.) The dilution of acid containing more than two molecules of water does not produce a sensible evolution of heat, as does similar dilution of the other halogen acids (Guntz, *l.c.*).

Hydrofluoric acid is also unique in that it combines with its own salts with absorption of heat $\text{NaF} + \text{HFAq.} = -228$ (Thomsen). The freezing-point of water is depressed by hydrofluoric acid, and quantitative determinations point to the existence of molecules of H_2F_2 in solution (Abegg, Fox, and Herz, *Zeitsch. anorg. Chem.* 1903, 35, 129-147; Paternò and Peratoner, *Chem. Zentr.* 1891, 306).

This view is supported by the fact that the heat of dissociation of hydrofluoric acid is 3550 cal., which is three times the corresponding value for hydrochloric acid, and is most easily explained by assuming the preliminary dissociation $\text{H}_2\text{F}_2 \rightleftharpoons 2\text{HF}$ (Abegg, *Ber.* 1900, 33, 393-394), and further evidence is obtained from the fact that by the application of Ostwald's basicity rule, the value for the basicity = 2.08. This observation is confirmed by measurements of specific conductivity after the addition of successive quantities of potassium, sodium, and ammonium hydroxides (Pellini and Pegoraro, *Zeitsch. Elektrochem.* 1907, 13, 621). Acid, containing 55 p.c. hydrogen fluoride, cooled to -45° , is converted into small truncated prisms, having the composition $\text{HF} \cdot \text{H}_2\text{O}$ and melting at -35° (Metzner, *Compt. rend.* 1894, 119, 682-684). Other evidence as to the existence of hydrates is derived from the relation of the specific conductivities of different solutions of hydrofluoric acid to the corresponding concentrations. It is found that breaks in the curve obtained by plotting these values occur at concentrations of 91 p.c., and between 51 and 55 p.c. corresponding to the hydrates $9\text{HF} \cdot \text{H}_2\text{O}$, and $\text{HF} \cdot \text{H}_2\text{O}$ (*cf.* Metzner, *l.c.*; Hill and Sirkar, *Proc. Roy. Soc.* 1900, A, 83, 130-148).

The temperature coefficient of conductivity for solutions containing less than 7.7 p.c. HF = 0.0125 and is constant. Hydrofluoric acid can be electrolysed with platinum as a positive electrode, the products being hydrogen, oxygen, and ozone, but with acid of 30 p.c. strength, the platinum is attacked.

The dilute acid dissolves all the metals except platinum and some of the metals associated with it—gold, silver, lead, and mercury—with evolution of hydrogen. On this account, it is kept in platinum vessels when concentrated, and in leaden or guttapercha vessels in the dilute form.

Aqueous hydrofluoric acid may be kept in glass bottles coated with a film of guttapercha as follows. Guttapercha is dissolved in carbon disulphide and the solution put in a bottle, every part of the interior of which must be brought in contact with the solution; the excess, if any, is then poured out, and the bottle laid aside until the solvent has volatilised. Caoutchouc stoppers are required (*Chem. News*, 49, 201).

On mixing one part of finely powdered and pure fluorspar with about twice its weight of strong sulphuric acid, no evolution of gas takes place at ordinary temperatures, but a

transparent gelatinous mass is formed, and, on gently heating, dense and highly irritating fumes arise, somewhat similar to those produced in the manufacture of hydrochloric acid: $\text{CaF}_2 + \text{SO}_4\text{H}_2 = \text{SO}_4\text{Ca} + 2\text{HF}$. For ordinary purposes, the decomposition is effected in a leaden retort, divided into two halves for convenience in cleaning, which, when in use, are accurately fitted together by an overlapping grooved joint. The receiver may be a leaden V-tube, blind at one end, and fitted by grinding at the other to the neck of the retort; the retort is heated on a sand-bath, and the acid is condensed in the receiver, which is surrounded by a freezing mixture.

According to Ruff and Braun (*Ber.* 1914, 47, 646), it is best to use 90 p.c. sulphuric acid. When 97-100 p.c. is used, a yield of 60 p.c. of hydrofluoric acid is obtained; this acid is of 95-96 p.c. strength. When sulphuric acid containing a high percentage (50-60 p.c.) of sulphur trioxide is used, the product consists of *fluorosulphonic acid*:

first obtained by Thorpe and Kirwan by the action of liquid hydrogen fluoride on liquid sulphur trioxide (*Chem. Soc. Trans.* 1892, 61, 921). It is a thin colourless liquid fuming in the air and boiling at 162.6° (*v.* FLUROSULPHONIC ACID).

To prepare the aqueous solution on a large scale, a leaden retort, on the upper part of which a leaden head can be cemented, is used; the neck of the retort fits into the side of a leaden receiver or chamber, in which is placed a basin of water. The acid vapours are absorbed by the water, and air, with any excess of acid vapours, is conducted through an escape pipe into the atmosphere.

The impure commercial acid may be purified by passing an excess of hydrogen sulphide through the liquid, neutralising the sulphuric and silicofluoric acids present with potassium carbonate, then decanting and adding silver carbonate to remove excess of hydrogen sulphide, filtering, distilling the filtrate from a leaden retort with a platinum receiver, and finally rectifying. As in the case of fluorine itself, copper can readily be employed as the material of the containing vessels (Goldschmidt, *Monatsh.* 1907, 28, 297-298).

Use of hydrofluoric acid.—The chief use of this compound is in etching glass. In making the graduations on a thermometer the tube is first coated with engravers' etching varnish; the divisions are then accurately traced with a fine-pointed instrument through the varnish. The tube is then plunged for a short time into a long tube containing dilute hydrofluoric acid, when, after cleaning the thermometer tube, it will be found to be permanently engraved. If the engraving is done by the vapour of hydrofluoric acid, the tracings are white and opaque, whereas if the liquid acid be employed, the lines are transparent.

There are three processes in use for the preparation of opaque etchings on glass: viz. (a) the application of solutions of acid fluoride of the alkalis; (b) a mixture of fluorspar with sulphuric acid; and (c) hydrofluoric acid gas. The first of these always contains uncombined hydrofluoric

as well as an indifferent salt as shown in the following recipes:—

	I.		II.		III.	
	grams.					
Water	1000	100	1000	1000	1000	1000
Acid potassium fluoride	250	—	—	—	—	—
Sodium fluoride	—	—	40	250	—	—
Ammonium fluoride	—	—	—	—	1000	—
Alkali fluoride	—	8	—	—	—	—
Hydrochloric acid	250	—	—	160–175	—	—
Sulphuric acid	—	1	—	—	250	—
Glacial acetic acid	—	—	50	—	—	—
Potassium sulphate	140	—	—	200	—	—
Ammonium sulphate	—	—	—	—	100	—

The first of these recipes is recommended by Tessié du Mothay and Maréchal; the two under heading II. by Siegwart, and those under heading III. by J. B. Miller. In practice, however, an acetic solution of sodium fluoride is much used, and is prepared by dissolving 25 parts of sodium carbonate crystals in 5 parts of fuming hydrofluoric acid, and adding to 1 litre of this solution after clarifying, 1 litre of glacial acetic acid. For light shades of etching, a single application of the acid is sufficient, but for deeper shades repeated applications are necessary, as is the case in etching landscapes, &c., on glass. An etched glass surface viewed by the microscope has the appearance of an aggregation of crystals, hexagonal in shape, and agrees with those of silicon-sodium fluoride, and in addition there are some longer in shape, which much resemble those of silicon-calcium fluoride. Small crystals are formed from concentrated solutions, and the smaller the crystals the more delicate is the etching. The strength of an etching solution must be varied according to the compound used, and regard must also be paid to the kind of glass to be operated upon. The application of gaseous hydrofluoric acid does not produce a uniform opacity, and is, therefore, not suitable for the production of opaque plates (J. Soc. Chem. Ind. 5, 669).

It has been suggested that hydrofluoric acid should be employed in the purification of beet sugar, the alkalis present in the juice being effectually removed by the acid, whilst the organic matter remains unaffected (*cf.* Verbiess, J. Soc. Chem. Ind. 1900, 160).

Antiseptic properties of fluorine compounds.—W. Thompson found that the compounds of fluorine, such as hydrofluoric acid, the acid and neutral fluorides of sodium, potassium, and ammonium (as well as the fluosilicates of these bases), are effectual as antiseptics. Free hydrofluoric acid retards the activity of yeast, 5.5 mgm. per 100 c.c. of saccharine solution arresting fermentation. Potassium fluoride, up to the same strength, however, augments it (Effront, Bull. Soc. chim. 1891, [3] 5, 476–480). The free acid promotes the activity of diastase by retarding lactic and butyric fermentations (Effront, *ibid.* 1891, 4, 337–339; 627–632; 1892, 6, 786–793), and its application in breweries has been suggested (Just, J. Soc. Chem. Ind. 1902, 131). Acid ammonium fluoride is especially used for disinfecting rubber hose-pipes in breweries, as it is a powerful antiseptic and does

not attack the rubber (Schonfeld, J. Soc. Chem. Ind. 1901, 830; Brand, *ibid.* 1904, 265; Bidel, *ibid.* 1904, 620).

Fluorides have also been used as preservatives for sweet wines and beer, sodium fluoride having been put on the market for this purpose under the name 'Remarcol'.

Tests for hydrofluoric acid.—For the detection of this compound, its corrosive action on glass is utilised. The compound suspected to contain a fluoride is reduced to powder and moistened with strong sulphuric acid in a platinum or leaden capsule. A watch-glass is thinly coated with wax, and, after tracing some design with a sharp-pointed instrument, is inverted over the capsule. The capsule is then gently warmed and the watch-glass placed over it, a little water being put in to prevent the melting of the wax. On removing the watch-glass after a few minutes' exposure, and cleaning off the wax with a little oil of turpentine, the parts exposed will have become etched if fluorine was present in the mixture. When the etching is very faint, a good plan is to breathe upon it, which makes the markings more apparent.

In the absence of boron, this test can be made more delicate by placing the suspected substance, mixed with quartz powder and a little magnesite, in a test-tube fitted with a cork, carrying a glass rod having a knob at the lower end. This knob is painted black and a drop of water is placed on it. On adding conc. sulphuric acid to the mixture in the tube and warming cautiously, a white film will be seen if as little as 0.1 mgm. of fluorine is present (Daniel, Zeitsch. anorg. Chem. 1904, 38, 257).

For the detection of fluorine in butter, the aqueous portion from 50 grams of melted butter is treated with calcium chloride solution and a small excess of sodium carbonate. The resulting precipitate, consisting probably of borate, carbonate, phosphate, sulphate, and fluoride, is extracted with acetic acid, ignited and heated on a sand-bath with sulphuric acid, under a waxed watch-glass cooled by water on its upper surface for 2 hours. 1 mgm. of calcium fluoride will, under these circumstances, give a distinct etching on glass (Hehner, Analyst, 1902, 27, 173–179).

For methods of estimating fluorine *v.* ANALYSIS.

A gravimetric and volumetric estimation of fluorine, depending upon Pisani's method of precipitation as thorium fluoride, has been devised by Gooch and Kobayashi (Analyst, 1918, 360).

Silicon fluoride may be estimated by measurement, in a dry gas burette, of the volume of gaseous silicon fluoride produced by the interaction of quartz, fluoride, and sulphuric acid (Oeltel, Zeitsch. anal. Chem. 1886, 25, 505; Hempel and Scheffler, Zeitsch. anorg. Chem. 1899, 20, 1–11).

Hydrofluoric acid may be estimated by the amount of etching produced (Ost, Ber. 1893, 26, 151; Wislicenus, Zeitsch. angew. Chem. 1901, 706; Leiniger, Chem. Zeit. 1902, 26, 967; Woodman and Talbot, J. Amer. Chem. Soc. 1906, 28, 1437–1443).

Fluorine in soluble fluorides can be estimated volumetrically by taking advantage of the fact that ferric fluoride, unlike ferric chloride,

does not liberate iodine from iodides. The liquid is acidified with hydrochloric acid, mixed with a known excess of ferric chloride solution, then with excess of zinc iodide, allowed to remain in a closed vessel at 35°–40° for half an hour, and the liberated iodine titrated with sodium thiosulphate solution (Knobloch, Chem. Zentr. 1894, ii. 533–534).

For the estimation of fluorine in wine, a standard method has been worked out, as fluorine preservatives are so frequently used. 100 c.c. of wine are made feebly alkaline with sodium hydroxide, silver nitrate is added, so long as it produces a precipitate, and the solution made up to 250 c.c. and filtered. 200 c.c. of the filtrate are treated with excess of sodium chloride, made up to 250 c.c. and left for 24 hours. 175 c.c. of clear liquid are treated with 3–4 c.c. 2N-sodium carbonate solution and precipitated with a large excess of calcium chloride solution and boiled for 5 minutes. The precipitate is collected and ignited and digested with 24 c.c. of 3/2N-acetic acid until its weight is constant within 5 milligrams. For each 100 c.c. of washings, 0.0016 gram is added to correct for solubility (F. P. Treadwell and Koch, Zeitsch. anal. Chem. 1904, 43, 469–506). For beer, a slight modification of Penfield's method (Chem. News, 1897, 39, 79–180) has been recommended.

Silicofluoric acid or Hydrofluosilic acid H_2SiF_6 . This compound is prepared by heating a mixture of sulphuric acid and fluorspar, sand, or powdered glass in a flask and passing the evolved silicon fluoride into water $3\text{SiF}_4 + 2\text{H}_2\text{O} = \text{SiO}_2 + 2(\text{H}_2\text{F}_2 \cdot \text{SiF}_4)$. The tube from which the fluoride escapes must dip into mercury at the bottom of the vessel of water, otherwise it would soon be stopped up by the deposition of silica. The bubbles of gas as they rise through the water are decomposed, and a gelatinous mass accumulates. The solution of acid is strained through linen to separate the silica, and is then filtered and concentrated at a low temperature. The acid is obtained more easily when required in quantity by dissolving silica in dilute hydrofluoric acid. The saturated solution fumes strongly, and has a very sour taste. It does not attack glass, but if allowed to evaporate on it the glass is attacked, especially on heating; silicon fluoride is volatilised, and the free hydrofluoric acid attacks the silica of the glass. The salts are called silicofluorides or fluosilicates, are generally soluble in water, and may be obtained well crystallised. The potassium salt is one of the least soluble salts of potassium, and the copper salt one of the most soluble of copper salts. Silicofluoric acid is sometimes employed as a test for potassium.

Hydrofluosilic acid reacts with potassium ferrocyanide, especially in boiling solution, forming a greenish liquid, which, on contact with air, deposits a precipitate of Prussian blue. The same reaction takes place with the ferricyanide, but in the absence of air (Materschek, Chem. Zeit. 1901, 25, 158; 327). Calcareous stone surfaces can be hardened by means of a fluosilicate of some metal which forms an insoluble oxide, such as magnesium, aluminium, or lead. Carbon dioxide is given off, and calcium fluoride, silica, and alumina, or the carbonate of

lead or magnesium fluoride, are formed, and the surface rendered hard and insoluble (Kessler, Compt. rend. 1883, 96, 1317–1319).

For modes of estimating hydro-fluosilicic acid *v.* ANALYSIS.

Antiseptic properties.—The fluosilicates possess more powerful antiseptic properties than the fluorides. They are not poisonous, possess no smell, and are sparingly soluble in water. As they have only a very slight alkaline taste, they may be employed for preserving food without communicating any taste to it.

They have been used in surgical operations. A solution containing 0.61 p.c. of ammonium fluosilicate is not irritating to wounds, whilst it possesses greater antiseptic power for animal tissues than 1 part of mercuric chloride in 1000 of water, which latter is a stronger solution than that which can be generally employed for surgical purposes without producing poisonous effects (Chem. News, 56, 132) (*v.* DISINFECTANTS).

A solution of free hydrofluosilicic acid containing 26 p.c. of the acid, has been placed on the market under the name 'Keramyl' (Prior, J. Soc. Chem. Ind. 1909, 904).

FLUOROCYCLENE C_8H_{28} . A hydrocarbon obtained by heating acenaphthene with lead oxide at 330°–340°. Crystallises in small orange-yellow triclinic rhombohedra, m.p. 396°–397° (Dziewonski and Saknarowski, Ber. 1918, 51, 457).

FLUOROFORM. A gas at ordinary temperatures, said to be obtained by heating a mixture of iodoform and silver fluoride (Valentiner and Schwarz).

FLUOROSULPHONIC ACID $\text{F} \cdot \text{SO}_3 \cdot \text{OH}$. First prepared by Thorpe and Kirman (Chem. Soc. Trans. 1892, 61, 921) by the action of hydrogen fluoride on sulphur trioxide. Is a colourless mobile liquid which fumes in the air and boils with slight decomposition at 162.6°. Has a faint pungent smell, and has but little action on the skin and feels greasy to the touch. It slowly attacks glass, more rapidly in presence of moist air. Is decomposed with almost explosive violence by water, but the decomposition, as shown by Traube, is not complete, as equilibrium exists between sulphuric and hydrofluoric acids on the one hand and fluorosulphonic acid and water on the other in not too dilute aqueous solution (Traube and Reubke, Ber. 1921, 54 [B], 1618). For salts of fluorosulphonic acid, see Traube, Ber. 1913, 46, 2525; Traube, Hoerenz, and Wunderlich, Ber. 1919, 52 [B], 1272. All the fluorosulphonates are freely soluble in water with the exception of the *nitron* salt, which forms pale green needles, m.p. 225°. In presence of mineral acids they are readily hydrolysed, but are more stable in alkaline solution. With aqueous ammonia they yield aminosulphates.

FLUOR-SPAR. *Fluor*, or *Fluorite*. (Ger. *Flussspat*; Fr. *Fluorine*.) A common mineral composed of calcium fluoride (CaF_2), crystallising in the cubic system. It is frequently found as well-developed crystals, usually cubes, but occasionally as octahedra; interpenetrating twinned cubes are common. An important character is the possession of perfect cleavages parallel to the faces of the octahedron. Sp.gr. 3.18; hardness 4 (the mineral can be scratched

with a knife). The crystals have a bright vitreous lustre, and are frequently transparent; they may be colourless or various shades of purple, green, yellow, pink, &c., the mineral displaying a very extensive range of colour. Dull cleavage masses and massive material, sometimes quite compact or earthy, are of abundant occurrence.

The cause of the colour of fluor-spar has long been a subject of discussion, and although not yet definitely determined, it may, in some cases at least, be ascribed to the presence of traces of organic matter. Some crystals undergo a change in colour when exposed to sunlight; for example, certain greens are changed to purple. Changes in colour are also effected when the crystals are exposed to the cathode rays, or to the rays emitted by radium salts. Many crystals are decolorised when heated to a temperature ranging from 220° to 300°. The heating of the mineral is usually accompanied by a bright phosphorescence (thermo-luminescence), violent decrepitation, and the liberation of water and gases (carbon dioxide, carbon monoxide, hydrogen, nitrogen, argon, and oxygen). The water which distils off is sometimes brown, and has a strong 'emphyreumatic' odour; and it is on this account, together with the fact that the mineral is decolorised at a low temperature, that the colour has been ascribed to organic matter. It must, however, be remarked that the water and gases, and possibly also any organic matter present, are contained in the fluor-spar in vast numbers of cavities, usually of microscopic dimensions, but sometimes large enough to show a moving bubble when a crystal is turned about in the hand. A remarkable phenomenon, sometimes associated with the colour of fluor-spar, is that of fluorescence; this is best displayed by certain purple or green crystals from Weardale, Co. Durham. A crystal, which by transmitted light is pinkish or greenish, exhibits when viewed in reflected light a rich plum-blue colour with a velvety softness which has the appearance of being diffused immediately beneath the surface of the crystal. This effect is destroyed when the crystals are heated to 220° or 300°.

Fluor-spar occurs under a variety of conditions: in cavities in granite rocks, in veins of tin-ore, occasionally as a cementing material in sandstone, and most abundantly as an associate of lead-ore in veins traversing limestone. Some of the veins in limestone, consisting almost entirely of pure massive fluor-spar, have a thickness of 20 feet. The whole of the production in England, amounting at the present time to about 40,000 tons per annum, is from north Derbyshire, and Weardale in Co. Durham, where it is obtained chiefly as a by-product in lead-mining. Formerly, when there was little or no demand for fluor-spar, this mineral was thrown out on the waste heaps; and now that the material is of value (10s. to 20s. per ton), these extensive waste heaps are being worked over. A considerable amount, some 50,000 tons per annum, is mined in the United States, principally in southern Illinois and western Kentucky. Curiously, however, a large portion of the English fluor-spar is exported to America. Smaller quantities are obtained in Bavaria, Saxony, France, and Spain.

The name fluor, from the Latin *fluo*, to flow, was used in the form *fluores lapides* by G. Agricola in 1529, and has reference to the use of this mineral as a flux in metallurgical operations. Within recent years, its application in this direction has been very considerably extended, and now large amounts are used in the manufacture of iron and steel, chiefly in the basic open-hearth process, and of ferrosilicon and ferromanganese. If not contaminated with too much silica (not over 3 or 4 p.c.), it acts better than limestone for fluxing; but it corrodes the furnace-linings, and the resulting slag contains less soluble phosphates available for fertilisers. To some extent, fluor-spar is also used in iron and brass foundry-work, as it produces a greater fluidity in the metal; in the smelting of lead-, copper-, silver-, and gold-ores; in the electrolytic refining of antimony and lead; and in extracting aluminium from bauxite. Other applications are in the glass and enamelling industries, and in the manufacture of opaline glass. In the form of sand, the mineral is used as a binding material in emery-wheels and carbon-electrodes, and for mixing with mortar and cement.

Owing to its low refractive index ($\mu_D = 1.43385$) and weak dispersion, clear and colourless fluor-spar is used with glass for the construction of the apochromatic lenses of microscope objectives, but material which is perfectly isotropic and sufficiently transparent and free from colour is difficult to obtain. German firms are said to have secured a supply from an unknown locality in Switzerland; and there is a fine specimen of clear colourless fluor-spar from Brienz, Switzerland, in the mineral collection of the British Museum. A limited amount of suitable material can be obtained by decolorising by heat the clear purple fluorescent cubes from Weardale, Co. Durham; and small colourless cubes are abundant in the neighbourhood of Matlock, Derbyshire. Suitable material in sufficient quantity is said to be found in Illinois; and a very promising deposit has been prospected in the Transvaal, between Zeerust and Mafeking. Material suitable for optical use has also been obtained at Madoc in Ontario.

A special variety of fluor-spar, known as 'blue-john,' for which the Tray Cliff cavern near Castleton in Derbyshire has long been famous, has been much used for fashioning vases and other small ornamental objects. Although occasionally used as a gem-stone on account of the delicate colouring, the mineral is much too soft for this purpose. Beads of fluor-spar have been found amongst prehistoric remains in North and South America.

Being the only common mineral containing fluorine in large amount (F 48.9 p.c.), fluor-spar is used for the preparation of hydrofluoric acid and other fluorine compounds. It is slightly soluble in hydrochloric acid and in solutions of alkali carbonates, and is readily decomposed by sulphuric acid even in the cold (on this depends its use for etching glass, a process in use long before the discovery of the element fluorine). Being almost the only substance not attacked by free fluorine, it was used by H. Moissan in the construction of his apparatus for the isolation of this element.

L. J. S.

FLUX. A term applied in metallurgy to the material which is added to a charge of ore for the purposes of combining with earthy or metallic impurities and removing them as slag, or to any substance which is fluid at a high temperature and protects the regulus from oxidation.

All ores contain gangue, either of an acidic (silicious) or of a basic character, which, if the ore were subjected to the action of a reducing agent alone, would retain a large proportion of the reduced metal and also foul the furnace. In order to remove the gangue and the accumulated impurities from the reduced metal, it is necessary to add materials which will combine with them to form a fusible slag.

A distinction may be made between the fluxes which are used for assaying and those which are used for smelting on a large scale, though even among the latter there are many special fluxes, *e.g.* antimony glass (*v.* **ANTIMONY**), for details concerning which the articles on the extraction of the several metals should be consulted.

The more important fluxes used in assaying are:

Sodium carbonate (or potassium carbonate, or a mixture of the two), which gives very fluid slags with acidic ores, and acts also as desulphurising agent.

Borax fluxes with basic materials, forming readily fusible borates of the metals. Borax has a marked influence in increasing the fluidity of most slags.

Fluorspar, used especially with phosphates, is a 'neutral' flux.

Litharge and Red lead are useful fluxes for oxides of iron or copper, &c.

Potassium cyanide, which acts chiefly as a reducing agent, being converted into cyanate. (For further details, see art. **ASSAYING**.)

The fluxes used on the large scale are few in number, as it is essential to the economic success of a process that the cost of slag-producing materials should be as low as possible. An economy is frequently effected by mixing together in proper proportions an ore in which the gangue is silicious in character with another containing basic impurities. In general, the character of the fluxes to be used must be decided by the nature of the ore, the object usually being so to arrange matters that the furnace charge shall contain basic and silicious constituents in the proportions required to form a fusible double silicate containing two bases. The proportion of silica present should be

sufficient to combine with all the basic oxides except that which it is desired to reduce.

Fluxes are of three classes:

(1) **Acidic.** *Silica*, as quartz, sand, &c. *Natural silicates.* *Silicious slags.*

(2) **Basic.** *Lime* or *limestone* is the most important, being used in enormous quantities in iron smelting.

Dolomite or *magnesia* is useful also, but is more expensive.

Clay, *clay-slate*, &c., are largely used when the introduction of alumina is desirable.

(3) **Neutral.** *Fluor-spar.* This should be free from copper pyrites, blend, and galena, and, if possible, from quartz. Derbyshire spar is the best. It fluxes sulphates of calcium, lead, barium, calcium phosphate, silica, silicates, &c., with formation of a very fusible slag.

Roberts Austen (*Metallurgy*, 294) gives the following rules for the selection of fluxes to form a fusible silicate slag:—

If the gangue is silicious, two bases must be added, *e.g.* clay slate or argillaceous limestone.

If the gangue is argillaceous, the addition of one base, *e.g.* limestone, will suffice.

When the gangue is basic and contains two metallic oxides, the addition of quartz only is necessary, but when it contains only one base, clay, silicious slag, &c., must be added.

FORCITE *v.* **EXPLOSIVES.**

FORDIT. An explosive consisting of nitro-glycerin (24·5), collodion cotton (1·0), nitro-toluene (34·0), flour (2·0), dextrin (2·0), glycerol (5·5), ammonium nitrate (32·0), and potassium chloride (30·0 parts).

FORGENIN. Trade name for tetramethyl ammonium formate.

FORMAL *v.* **SYNTHETIC DRUGS.**

FORMALDEHYDE (*formic aldehyde*, *formol*, *methanal*) CH_2O . Discovered in 1867 by A. W. Hofmann as a product of the flameless combustion of methyl alcohol. A red-hot coil of platinum wire suspended over methyl alcohol contained in a beaker, is kept red-hot so long as it is in contact with the mixture of air and methyl alcohol vapour, acting as a catalyst for the formation of the formaldehyde

Hofmann succeeded in isolating a small quantity of formaldehyde by passing the mixture of methyl alcohol vapour and air through a platinum tube heated to dull redness. Armand Gautier passed the methyl alcohol vapours through a horizontal tube heated in a sulphur bath.

Methods for preparing formaldehyde in larger quantities were devised by Tollens, Loew, and Kablukow. Air was bubbled through methyl alcohol at 40° to 50°, and the mixture of air and alcohol vapours passed over a spool of copper wire gauze 5 cm. long and moderately heated. The product was collected as an aqueous solution in a flask on a water-bath, and the gases and uncondensed vapours passed on to a receiver cooled by ice or water. Tollens found that the yield depended largely on the temperature of the methyl alcohol, and therefore on the degree of saturation of the air with alcohol:

Temp. of bath	Yield of CH_2O
22°–32°	17·95
38°–44°	28·90
45°–50°	31·15

Trillat proposed the first method for the production of formaldehyde on a manufacturing scale (Fr. Pat. 199919, 1889). His apparatus is shown in Fig. 1. Crude or rectified methyl alcohol is heated in the copper vessel A of about 100 litres capacity by passing steam through the bottom compartment *a*. The

FIG. 1.

alcohol vapours are carried away by the copper pipe B fitted with a conical perforated mouthpiece C, and issue from the perforations in form of a fine spray. The mouthpiece penetrates a short distance into tube D of 10 cm. diameter and 1 m. length. Air can be aspirated through *x* at the conical end of D as indicated by the arrows. Platinised asbestos is placed in the widened part at E and heated by direct fire. Other contact substances which were suggested by Trillat are copper oxide, retort carbon, porcelain, coke,

firebrick, and the like. The method of working is as follows:—

The tube is heated at E to a dull or bright red heat, according to the nature of the contact substance; the receiver, communicating with a vacuum pump, is then connected to *y*. The methyl alcohol is in the mean time brought to boiling-point; and the vapours produced, forming a spray, are mixed with air drawn in at *x*. The mixture reacts on meeting the contact substance, whereby the alcohol is oxidised to formaldehyde. The vapours contain water, undecomposed methyl alcohol, and traces of formic and acetic acids. The products are condensed or dissolved in water, and the solution is redistilled to drive off the impurities. Trillat gave no statement of yields, but these cannot have been very good, and his apparatus is therefore to-day only of historic interest. It formed, however, the basis for the present processes. Instead of boiling the alcohol and subsequently mixing its vapours with air, later processes drive or draw air through the methyl alcohol, kept at a temperature suitable for saturation, and pass the mixture over the contact substances.

M. Klar and C. Schulze proposed the introduction of the scrubber principle for this operation (Ger. Pat. 106495). They consider the large excess of alcohol over air obtained by the older method to be disadvantageous, and otherwise

FIG. 2.

undesirable. At the same time, there is too little control over the ratio of the mixture. They therefore employ a scrubber, made of metal or stoneware, into which they pass a fine spray of wood spirit through a rose. Air, which has previously been heated high enough to obtain a mixture temperature of 45°–50°, is blown in at the bottom of the scrubber which may also be provided with a steam-jacket. By adjusting the flow of alcohol and air, the ratio of the mixture can be varied to any desired

extent. In order further to moderate the oxidation, the air is diluted with a certain proportion of nitrogen obtained from the process itself, with the result that a smaller degree of saturation of the air is required. They claim advantages both in regard to the safety and the yield of their process. This process relates only to the preparation of the reacting mixture, but has no reference to the contact process proper.

Fig. 2 shows the formaldehyde plant of a

French factory (Côte d'Or), as described by A. Morel (J. Pharm. Chim. 1905, 21, 177). The principal unit is the oxidiser, a metal cylinder c, fitted with copper tubes b in which the reaction takes place. Wood spirit is supplied from the tank R to the mixer M, constructed on the carburettor principle, and is here vapourised by, and in suitable proportions mixed with, air pressed in from reservoir A. The mixture reacts during its passage over copper contacts placed in the oxidiser tubes b kept at an elevated temperature. Sight holes permit of the observation of colour and luminosity, and consequently the temperature of the contact zone. The products are carried off through a single pipe, and are condensed in coil d surrounded by a current of water. The condensate, being crude formaldehyde solution, runs into a receiver. The uncondensed vapour is extracted from the gases in three washers, L. The crude product is freed from methyl alcohol in a rectifying still.

The modern plants for the manufacture of formaldehyde are built on the same lines, although greatly improved in some of the details, with the result of a greatly increased yield. In Fig. 3 a modern plant is shown. Compressor 1 aspirates air from the atmosphere and presses it into the air vessel 2, in which a constant pressure is kept. Methyl alcohol runs from tank 3 into the carburation vessel 4. A heating arrangement is placed in this apparatus which raises the temperature of the incoming air. This current of air meets a thin stream of methyl alcohol, which also takes up heat, and a mixture of constant composition is thereby formed. This enters the oxidiser 5, charged with the contact substance, which usually consists of copper gauze, but in some cases silver or silver-coated copper gauze is used in preference. The products of reaction issuing from the oxidiser, which consist of vapours of formaldehyde, water, and the excess of methyl alcohol, as well

FIG. 3.

as nitrogen and hydrogen, pass into a separator, 6, in which, by a washing process, commercial formaldehyde (40 p.c. solution)—so-called 'formalin'—is obtained, which is drawn off into the receiver 8, whilst methyl alcohol vapours are almost completely condensed in 7, whence they run into reservoir 12, and are sent by pump 13 back into the feeding tank 3. The gases still contain some methyl alcohol, and are made to pass the washer 9 which extracts the last traces. This dilute alcohol is concentrated in the continuously working rectifying still 10. The concentrated alcohol vapours are again condensed in 11, and pumped back to 3.

J. E. Orloff has designed an apparatus which in many of its details is not unlike the above described. In Fig. 4 the 'carburettor,' A, consists of a vessel of 750 mm. diameter and 800 mm. height charged with methyl alcohol, to about one-half its capacity, from an overhead tank, B, and fitted with copper steam coils, a. Air is aspirated through the methyl alcohol by means of a perforated pipe. The air-alcohol mixture then passes a 'dephlegmator,' c, fitted with a steam coil, c, any excess alcohol being allowed to drain back into the carburettor. The mixture thus heated to the desired temperature enters the oxidiser. This consists of a tubular vessel set at an angle of about 10° and containing 169 copper tubes of 19 mm. internal diameter, 2 mm. thickness, and 800 mm. length,

arranged in seven concentric circles between two plates of 820 mm. diameter, which are separated from the two cover plates by bronze rings of 720 mm. int. diam. A steam coil is placed in the ring on the inlet side to heat the mixture, which enters through a pipe 50 mm. wide. A number of sight holes are provided in the front plate, and a conical exit pipe is connected with the back ring. Glass tubes, 16 mm. wide, 1.25 mm. thick, and 300 mm. long, are placed in the copper tubes containing spools 120 mm. long, made of copper gauze. The gases after leaving the oxidiser are passed through a scrubbing column, B, 2000 mm. high from which the formaldehyde solution is run off through a water-cooled pipe, F. The gases are then led through a cooling coil, G, and a small scrubber, H, for the removal of methyl alcohol vapour. The condensate from the coil and the alcohol solution from the scrubber are collected in sump K, and pumped back into the feed tank. The gases leave the plant through a gas meter, M, and the exhauster. The air may be aspirated into the carburettor direct from the surrounding atmosphere or through the oxidiser drum, whereby it is preheated, and the catalyst incidentally cooled. In order to start the work of the oxidiser without the application of external heat, Orloff employs 'ignition pills,' made of platinised asbestos or pumice, close to the catalyst. These initiate the action at

ordinary temperature when the alcohol vapours pass over them. When dispensing with external heating he found that alcohol vapour of 90 p.c. strength gives satisfactory results: this makes it possible to distil the alcohol completely without a rectifying column, whilst when working with a vapour of 100 p.c. strength the alcohol

has to be rectified after a quarter has been distilled off. The dephlegmator is kept at 53° – 54° , whilst 42° – 43° is sufficient when 100 p.c. alcohol vapour is used. The methyl alcohol should not contain more than 1 p.c. acetone. The ratio of the volume of exit gases to the volume of air admitted should be 1.15 : 1

FIG. 4.

on an average. An apparatus of the size given oxidises 175 kgs. methyl alcohol in 10 hours, and the yield should be 150–155 p.c. by weight of the alcohol employed, the formaldehyde having a strength of 38–39 p.c.

In G. C. Calvert's plant (Eng. Pat. 814, 1915), shown in Fig. 5, the carburettor consists

of a rotary fan, A, of the annular blade type, enclosed in a steam-jacket. The methyl alcohol is run on the rotor through a sight feed. Air, which may be preheated by a steam coil, is taken in at *a*, and intimately mixed with alcohol in the fan. The mixture passes through an externally heated oxidiser, B, which is pierced

FIG. 5.

with vertical flattened cooling tubes, through which water or steam may be circulated in order to keep down the temperature. The reaction gases then pass through a horizontal cooling chamber, C, fitted with a nest of cooling tubes, through which a current of air passes. The saturator, D, follows as an extension of the cooling chamber, and consists of a horizontal tube of the same diameter fitted with a shaft carrying vanes revolving at a high speed.

Formaldehyde solution is fed into the saturator from feed-tank E, and discharges into the tank F, from which it is circulated by pump G, and periodically drawn off when it has reached the desired strength. The waste gases leave the apparatus at Z.

The bulk of the world's production of formaldehyde is made from methyl alcohol. There have, however, been various proposals for the employment of other raw products,

for instance, methane or ethylene. The conversion of formates into formaldehyde by thermal decomposition has also been suggested, but no great success has been obtained with the industrial application of any of these methods (see Hofmann and Schibsted, Ber. 1918, 51, 1398).

W. A. Bone has shown that formaldehyde is formed as an intermediate product in the combustion of hydrocarbons, which he regards as a process of hydroxylation and scission of water molecules. The industrial application of partial combustion up to the stage of formaldehyde formation offers, therefore, a promising problem. Glock (Ger. Pat. 109014) suggests the oxidation of methane, or mixtures containing methane, by oxygen in the presence of copper, pumice or asbestos as a catalyst. Methane is mixed with an equal volume of air and passed through a tube filled with granulated copper heated to 600°. The products are cooled, washed with water, mixed with an equal volume of air, and again passed through a second tube with contact substance, and this process is repeated until all methane is oxidised. The first tube is kept hot by the reaction, the others require external heating. J. Gruszkiewicz proposes, in Austr. Pat. 46693, to burn methane, or natural gas rich in methane, with air insufficient for complete combustion, and to utilise the catalytic property of the soot, thereby produced, for effecting the oxidation to formaldehyde. The gases produced by the checked combustion are passed rapidly through a chamber fitted with baffle plates, for the removal of the soot, and are finally scrubbed with water, for the extraction of the formaldehyde produced. According to the inventor's claim, the carbon produced forms a valuable by-product. G. Fernekes, in U.S. Pats. 1038546 and 1038547, also proposes the production of formaldehyde from natural gas by partial combustion with air in baffled flames and cooling products.

The Verein f. chem. Ind. (Ger. Pat. 286731) employs a gas mixture consisting of about 3 parts methane and 100 parts moist air, and conducts this mixture in a closed system over a contact substance such as copper or silver, or both, at a temperature of 150°–200°, when a portion of the methane is converted into formaldehyde.

Since acetaldehyde is produced from acetylene with mercury as catalyst, it is possible that wet methods carried out on similar lines may give better results in the formation of formaldehyde than direct atmospheric combustion. Hydrogen peroxide, or, according to Lange and Elworthy's Fr. Pat. 352687, electrolytically produced persulphuric acid, have been suggested as oxidising agents in the production of formaldehyde from alcohol.

Theory of the catalytic process. After the early work of Hofmann, Tollens, Loew, Kablukow, the subject was closely investigated by Trillat, who published these researches in his book 'Oxydation des Alcools par l'action de contact.'

He studied the influence of varying temperatures, proportion of air and of water, and of different contact substances, on the oxidation process. His conclusions were partly incorrect,

particularly with regard to the proportion of water vapour to methyl alcohol, which he, in contradistinction to other investigators, did not consider injurious.

J. E. Orloff, in a series of papers in the Journal of the Russian Chemical Society (see also his 'Formaldehyd,' Leipzig, 1909), assumed the main reaction to be:

with a secondary oxidation to formic acid and carbon dioxide, and carbon monoxide and water. No traces of formic acid could, however, be found, but always hydrogen, and he therefore suggested a partial decomposition:

The main reaction is not in accordance with the facts established by Ipatieff and by Sabatier and Senderens, who had proved the catalytic decomposition of alcohols into aldehydes and hydrogen generally, with copper as catalyst. M. Le Blanc and E. Plaschke (Zeitsch. Elektrochem. 1911, 17, 45) have established that the formation of formaldehyde is due not to oxidation, but to catalytic dehydrogenation of methyl alcohol. The activity of freshly reduced copper or silver decreases rapidly unless air is introduced with consequent temporary oxidation of the metal. This is again reduced at the expense of alcohol and possibly aldehyde. An undesirable secondary reaction is the decomposition of formaldehyde into hydrogen and carbon monoxide. The yield is dependent upon the temperature of the contact body, the ratio of alcohol to air or oxygen, and the surface of the contact body. The highest yield was 58 p.c., and the lowest loss of destroyed alcohol 12 p.c.

M. D. Thomas (J. Am. Chem. Soc. 1920, 42, 867) confirms Le Blanc and Plaschke's work, but obtained rather higher yields. The absolute yields with silver, copper, and gold were 95.0 p.c., 90.5 p.c., and 88.5 respectively, corresponding to process yields of 55.6 p.c., 50.5 p.c., and 40 p.c. A reaction mixture containing 0.4 to 0.5 gram of oxygen per gram of alcohol gave the best results with silver, whilst copper required 0.55 to 0.65 gram of oxygen.

Catalysts.—In the early attempts to produce formaldehyde, platinum wire, platinum sponge, or platinised asbestos were mostly employed as catalytic bodies, and these are still used in the familiar type of formaldehyde lamp for disinfecting rooms (e.g. Schlichter, Eng. Pat. 401, 1887).

In most of the industrial plants copper, in the form of fine wire gauze, has been employed until recently. A number of other catalysts, such as copper filings, copper-coated asbestos, fire-brick, coke or charcoal, vanadium oxide, silver, and metals of the platinum group have been proposed from time to time. S. Fokin (J. Russ. Phys. Chem. Soc. 1913, 45, 286) studied the effect of different catalysts on mixtures of methyl alcohol vapour and air, and found their activity to be in the following order: Co 2.8, Ni 1.08, Al 1.5, Mn 2.01, Pt 5.2, Cu 43–47, Ag 64–66, Au 71, and Cu+Ag 84 p.c. of the theory. In other comparative experiments Fokin found the order of efficiency to

be $\text{Au} < \text{Cu} < \text{Ag}$, and he assumes as probable the formation of labile oxides.

On the other hand, Le Blanc and Plaschke (*l.c.*) found in their researches that the catalytic effect of silver was not appreciably superior to that of copper. In a number of patents, however, a greatly improved efficiency is claimed for silver as catalyst (Blank, Ger. Pat. 228697; Kusnezow, U.S. Pat. 1067665; Bouhard, Fr. Pat. 412501; H. von Hochstetter and Holzverkohlungs, Ind. A. G. Eng. Pat. 464, 1914; U.S. Pats. 1100076 and 1110289), who employ as catalyst metal couples particularly of metals of the platinum group and silver claim for these highly increased yields. These couples must not be in the form of alloys, but in mechanical combination. In effect, this arrangement has been used in all cases where several metals have entered into the construction of a formaldehyde lamp or oxidiser using a platinum catalyst.

Yields.—The yield of formaldehyde from a given quantity of methyl alcohol may vary within very wide limits and never reaches the theoretical value of the equation

The yield depends on the purity of the methyl alcohol and air, the ratio of the mixture, the catalyst employed, its surface, temperature, and length, the velocity of the gases over it and, therefore, the time-contact, the rapidity of cooling of the gases, and, finally, the completeness of extraction of formaldehyde and methyl alcohol vapour from the exit gases. The actual loss is caused by decomposition of alcohol into CO_2 , CO , and H_2O . A certain amount of methyl alcohol must pass through the system undecomposed. A portion of this is left in the final product, whilst the balance can be recovered almost completely in an efficient plant. A yield of 150–160 parts 40 p.c. formaldehyde solution from 100 parts methyl alcohol may be regarded as normal, although yields up to 175 p.c. have been obtained from specially purified alcohol and under particularly favourable conditions of supervision and working. The apparent increase in weight is due to the addition of water as the solvent.

The '40 p.c. formaldehyde' of commerce contains 40 grams per 100 c.c. and has, therefore, a true strength of only 36 p.c. It is in fact usually weaker. The article required by the British Pharmacopoeia contains not less than 36, and not more than 38 grams CH_2O per 100 c.c. and has a specific gravity of 1.080.

On keeping, formaldehyde is converted by polymerisation into diformaldehyde and trioxymethylene, causing cloudiness and deposits in solution. To prevent this a certain percentage of methyl alcohol is left in the product, which may, for instance, have the following composition: 36 p.c. formaldehyde, 12 p.c. methyl alcohol, 52 p.c. water.

Formaldehyde is a gas of characteristic smell which, on cooling, condenses to a liquid of b.p. -21° and of sp.gr. 0.8153 at -20° or 0.9172 at -80° . Liquid formaldehyde changes at -20° readily into a solid modification; the melting-point of monomolecular CH_2O is -92° . Water absorbs up to 52 p.c. formaldehyde; the freshly prepared concentrated solution, which

has a pungent smell and strong irritant action on the mucous membranes, contains diformaldehyde or methyleneglycol $\text{CH}_2(\text{OH})_2$, which changes into formaldehyde on standing. Dilute solutions contain the monomolecular form CH_2O , and do not undergo any change when kept in closed vessels. But on concentrating the solution in a desiccator or by evaporation, polymerisation takes place, flocculent masses of $(\text{CH}_2\text{O})_n \cdot \text{H}_2\text{O}$ ($n=6$ to 8) being precipitated, which form the commercial paraformaldehyde.

The specific gravity of commercial formaldehyde solutions freed from methyl alcohol were determined by W. A. Davis (*J. Soc. Chem. Ind.* 1897, 16, 502).

Spec. grav. at 60°F.	P.c. CH_2O by weight	Grams CH_2O per 100 c.c.
1.005	2	2.0
1.010	4	4.0
1.015	6	6.1
1.020	8	8.2

1.121	39	43.7
1.125	40	45.0

The aqueous solution precipitates from an ammoniacal silver solution a specular deposit of silver, and, on treatment with hydrogen sulphide, yields crystals of trithiomethylene $(\text{CH}_2\text{S})_3$ (Hofmann, *Annalen*, 145, 360). On heating formaldehyde with a dilute solution of sodium hydroxide, formic acid and methyl alcohol are produced. With concentrated sodium hydroxide solution and a little Cu_2O , formic acid is produced at ordinary temperature, accompanied by violent evolution of hydrogen (Loew). Formaldehyde readily combines with ammonia to form the monacid base hexamethylenetetramine, according to the equation:

As this reaction takes place even in dilute solution, it forms a convenient method for the titrimetric determination of formaldehyde (Butlerow, *Annalen*, 115, 322; Legler, *Ber.* 16, 1333; Loew, *J. pr. Chem.* 1886, 33, 326). It crystallises from alcohol in rhombohedra, is very soluble in water and alcohol, and insoluble in ether.

Formaldehyde condenses with aniline with loss of water to *anhydroformaldehydeaniline*

On heating formaldehyde with a solution of ammonium sulphate, *trimethylamine sulphate* is formed, whereby one-third is oxidised to CO_2 (Plöchl, *Ber.* 21, 2117). $\text{CH}_2\text{O} \cdot \text{NaHSO}_3 \cdot \text{H}_2\text{O}$ is formed by adding NaHSO_3 and alcohol to formaldehyde solution; this is readily soluble in water and methyl alcohol, less soluble in

ethyl alcohol. By the action of hydrogen chloride on formaldehyde, Tischtschenko obtained *dichloromethyl ether* and water. Lösekann obtained, by the same treatment, *oxychloromethyl ether*, which further yielded *monochloromethyl alcohol* (Ber. 25, 92). By careful treatment with bases such as calcium hydroxide or lead oxide, formaldehyde may be polymerised into a mixture of saccharine substances. By continued boiling of such a solution with tin, *isoformose* is obtained; treatment with lime water yields α -acrose $C_6H_{12}O_6$.

If formaldehyde solution is concentrated in the presence of dehydrating agents, it polymerises to *trioxymethylene* $(CH_2O)_3$, a crystalline mass fusing at 171° – 172° , but subliming below 100° ; insoluble in water, alcohol, or ether at ordinary temperature, but soluble in water when heated to 130° , when it appears to be converted into formaldehyde or paraformaldehyde (Tollens and Mayer, Ber. 21, 3504). When trioxymethylene is volatilised, it dissociates completely into formaldehyde (v.d. 15'3, Hofmann). When boiled with lime water, it yields formic acid and an amorphous saccharine substance, *methylenitan* (Butlerow, Annalen, 120, 295).

When dry trioxymethylene is heated in a sealed tube with traces of sulphuric acid at 115° , it is converted into the isomeric α -trioxymethylene $(CH_2O)_3$, which crystallises in needles, melts at 60° – 61° , and sublimes at ordinary temperature, and is soluble in water, alcohol, and ether (Pratesi, Gazz. chim. ital, 14, 139).

Auerbach and Barschall (Arb. Kais. Gesundh. Amt. 27, part 1) claim to have established the identity of six individual polymerides: paraformaldehyde $(CH_2O)_n + H_2O$, four polyoxymethylenes $(CH_2O)_n$ and α -trioxymethylene $(C_3H_6O_3)$ of ring structure, characterised by their form (amorphous, colloidal, indefinite crystals, definite crystals, and well-developed crystals), melting-point, solubility, &c.

Formaldehyde is capable of reacting with practically any class of organic, and a large number of inorganic, substances, and forms numerous condensation products. It reacts with hydrocarbons, carbohydrates, aldehydes, and ketones, carboxylic, oxy- and keto- acids and their esters, phenols, oxaldehydes, gallic and tannic acid, amines, ammonia, hydrocyanic acid, hydrazines, hydroxylamine, urea, uric acid, guanidine, the proteins, nitro compounds, quinoline, pyridine, and sulphur compounds.

Its formation plays an important part in the assimilation of carbon dioxide by chlorophyll-containing plants (Baeyer, Bach, Loeb, Délépine). For the synthesis of formaldehyde and carbohydrates from carbon dioxide and water by photocatalysis, see Baly, Heilbron, and Barker, Chem. Soc. Trans. 1921, 119, 1025).

Atraclylis gummifera contains an active glucosidal principle, *atractilin*, which with 2 or 3 drops of concentrated sulphuric acid gives a yellow coloration, changing to violet and bright blue if treated with a trace of formaldehyde. By means of this reaction the presence of formaldehyde in the juices of green leaves, when exposed normally to light, may be detected; formaldehyde is absent from the juices of the leaves of the same plants after being kept 24 hours in the dark (Angelico and Catalano,

Gazz. chim. ital. 1913, 43, 38; Analyst, 1913, 152).

The industrial employment of formaldehyde is manifold, in keeping with its enormous reactivity. The coal-tar colour industry uses it very largely for condensation products; a great number of pharmaceutical preparations have formaldehyde as their active principle. In most of these, use is made of its antiseptic powers by condensation with a variety of drugs.

The antiseptic properties of formaldehyde are essentially due to its chemically combining with the cell skin of the micro-organisms, thereby hardening it and inhibiting their growth. It is employed in a number of ways and in different combinations. It is used in the treatment of wounds and for sterilising surgical instruments and the hands of operators, occasionally compounded with soap, as in *lysoform*. For disinfecting rooms a 1 or 2 p.c. solution of formaldehyde may be used as spray, and is non-injurious to coloured fabrics. A concentrated solution or solid paraformaldehyde may be vaporised in a lamp, and its diffusive and penetrating qualities make it applicable where other disinfectants cannot be employed. The best known forms of apparatus for this purpose were devised by Trillat, Tollens, Krell, Barthel, and Schering. In certain cases, as for instance in the treatment of frozen meat on board ship, an air current is passed through a vessel containing formaldehyde solution heated by steam coils. It has also been proposed to treat a mixture of paraformaldehyde and peroxides of the alkaline earths with water, when a violent liberation of formaldehyde vapour takes place (Autan). Permanganate, or other oxidising agents, are similarly used with paraformaldehyde.

Its preservative qualities are made use of in embalming and for the preservation of corpses for dissection. It is largely used for the preserving of foodstuffs, and possibly the effect of 'curing' is in a measure due to the formaldehyde produced from burning wood and other carbonaceous materials.

Formaldehyde is employed in the brewing, distilling, and sugar industries, and besides its preservative action, a certain stimulative effect on the diastatic properties of the malt, and on the activity of yeast, has been observed. Formaldehyde is largely used for tanning purposes, especially for sole leather. By its action on proteid bodies, it makes the leather hard and firm without having the bad effect of acids. Formaldehyde solution is also used for coagulating rubber latex; and the result of curing para rubber over wood fires has been ascribed, at least in part, to the presence of formaldehyde vapour. In the paper-making and textile industries, it is used for fixing glues and sizes, and also for water-proofing fabrics, by rendering gelatin or casein insoluble. Upon the same reaction is based its employment in hardening the gelatin films of photographic plates, and for hardening microscopic preparations and anatomical museum specimens.

Formaldehyde is also used as a reducing agent in the recovery of silver and gold, and in the preparation of metallic mirrors. A material for the manufacture of bone-like articles is made

by the action of formaldehyde on caseinogenate (galalith). The water-proofing of straw hats is effected by impregnating them with a solution of gelatine which is then hardened with formaldehyde. On the condensing reaction of formaldehyde with phenol or cresols is based the manufacture of a substitute for horn, tortoiseshell, &c. The best known of these condensation products is 'bakelite,' which is used in solution as a lacquer or varnish, or, in its solid form after being subjected to high pressure, for electrical insulation purposes (*v.* BAKELITE).

The action of dry gaseous hydrogen chloride in the cold on commercial formaldehyde solution (about 40 p.c.) in a reflux apparatus yields, first, the compound $\text{OH}\cdot\text{CH}_2\text{Cl}$. If the action is prolonged, a heavy liquid $\text{O}(\text{CH}_2\text{Cl})_2$ separates. This liquid, treated with a mixture of concentrated nitric and sulphuric acids at 5° , forms a colourless oil of sp.gr. 1.522, of the composition $\text{C}_2\text{H}_4\text{O}_6\text{N}_2$, or $\text{NO}_2\cdot\text{CH}_2\cdot\text{O}\cdot\text{CH}_2\cdot\text{O}\cdot\text{NO}_2$, which on hydrolysis yields formic acid and nitromethane. It is extremely sensitive to shock and decomposes with detonation. It dissolves considerable amounts of cellulose nitrate and an explosive jelly containing 7 p.c. of cellulose nitrate (12.11 p.c. N) gives a greater increase in volume on explosion than one containing 7 p.c. of glyceryl nitrate (Moreschi, *Atti. R. Accad. Lincei*, 1919, [v.] 28, i. 277).

For the qualitative detection of formaldehyde, a number of reactions have been proposed, most of which are based on colour reactions. On warming with ammoniacal silver solution, the silver mirror is produced. Schiff's reagent is frequently used; 0.4 gram magenta is dissolved in 25 c.c. of water; 10 c.c. of sodium bisulphite solution (sp.gr. 1.375), and then 10 c.c. of strong sulphuric acid are added; formaldehyde causes a red coloration which, on addition of hydrochloric acid, changes to bluish violet. Other reagents suggested are alkaline resorcinol, phloroglucin, codeine, morphine, phenyl hydrazine, and ferric chloride.

For the quantitative determination, the following are used: Legler's method based on the reaction of ammonia on formaldehyde, gives low results. For impure concentrated solution, the method of Blank and Finkenbeiner (*Ber.* 31, 2979) may be employed. It consists in oxidising formaldehyde to formic acid by means of hydrogen peroxide in alkaline solution. An iodometric method was suggested by Romijn (*Zeitsch. anal. Chem.* 36, 19), and many colorimetric reactions have been worked out for the exact estimation of small quantities of formaldehyde. 1 part of formalin in 100,000 parts of milk can be detected by distillation and application of colour reactions to the distillate. Rideal and Hehner have studied the rate of disappearance of formalin when added to milk by formation of condensation products. Schryver uses phenyl hydrazine and potassium ferri-cyanide for the estimation of formaldehyde in a dilution of 1:1,000,000. R. L.

FORMALIN. A 40 p.c. solution of formaldehyde.

FORMAMIDE $\text{HCO}\cdot\text{NH}_2$. First obtained by Hofmann (*J. pr. Chem.* 91, 61) by heating ethyl formate with ammonia in a sealed tube at 100° .

It is a product of the oxidation of amino-acids, lactic acid, albumin, &c., by ammoniacal

potassium permanganate (Hasley, *Zeitsch. physiol. Chem.* 25, 325).

It is formed by the action of the silent discharge on a mixture of carbonic oxide and ammonia (Losanitsch and Jovitschitsch, *Ber.* 30, 138); by distilling sodium formate with ammonium chloride in a vacuum (Verley, *Bull. Soc. chim.* 9, [3] 691); or by heating crystallised ammonium formate in a sealed tube at 230° for 5 hours (Hofmann, *Ber.* 15, 980), but is best prepared by heating pure dry ammonium formate for 2 hours at 100° – 180° in an atmosphere of ammonia, then fractionating in the same atmosphere at $\frac{1}{2}$ mm. pressure (Freer and Sherman, *Amer. Chem. J.* 20, 223).

Formamide is a liquid, b.p. 85° – 95° ($\frac{1}{2}$ mm. pressure); at ordinary pressure it decomposes, when heated above 100° , into carbon monoxide, ammonia, hydrogen cyanide, and water. It crystallises in needles, m.p. $2\cdot25^\circ$ (Brann); sp.gr. 1.76 at 4° (Freer and Sherman, *l.c.*). Phosphorus pentoxide converts it into water and hydrocyanic acid: $\text{HCO}\cdot\text{NH}_2 = \text{HCN} + \text{H}_2\text{O}$. Strong caustic potash decomposes it, even in the cold, into potassium formate and ammonia. It is also decomposed by a mixture of potassium chromate and sulphuric acid, forming carbon dioxide and ammonium hydrogen sulphate; by hydrogen peroxide with production of ammonia and carbon dioxide (de Coninck, *Compt. rend.* 128, 503); and by sodium hypochlorite on heating (de Coninck, *ibid.* 121, 893). Formamide combines with chloral forming chloral-amid or *chloralum formamidatum*, used as a disinfectant and as a preservative, and for its hypnotic properties (*v.* CHLORAL). Sodium, silver (Freer and Sherman, *Amer. Chem. J.* 562 and *l.c.*; Titherley, *Chem. Soc. Trans.* 1897, 466) and mercury salts have been obtained (Fischer and Grützner, *Arch. Pharm.* 232, 329). Condensation products of value as antiseptics and solvents for uric acid are obtained by condensing formamide with formaldehyde, paraldehyde, or trioxymethylene (*J. Soc. Chem. Ind.* 25, 283).

FORMAMIDINE, Methenylamidine

This compound, the lowest member of the amidine series, may be regarded as formamide $\text{HCO}\cdot\text{NH}_2$ in which the oxygen atom has been replaced by imidogen. Obtained by acting on the double compound of hydrocyanic acid and hydrochloric acid with absolute alcohol:

and alcoholic ammonia (Pinner, *Ber.* 16, 375, 1647). Formamidine hydrochloride crystallises from alcohol in hygroscopic granules, melting at 81° , and decomposing at 100° into hydrocyanic acid and ammonium chloride:

When liberated from its salts by caustic potash, formamidine is at once decomposed into ammonia and potassium formate. Its salts crystallise with difficulty. $(\text{CH}_4\text{N}_2\cdot\text{HCl})_2\cdot\text{PtCl}_4$ forms very soluble, orange-red, quadratic pyramids.

Formamidine picrate

obtained by the addition of formamidine hydrochloride to picric acid, crystallises in long lustrous yellow needles, m.p. 248° (Diechmann, Ber. 25, 705).

Substitution derivatives of formamidine have been studied by Dains (*ibid.* 35, 2496).

FORMAMINT. Trade name for a preparation of lactose and formaldehyde.

FORMAN. Trade name for chlormethylmenthyl ether $\text{C}_{10}\text{H}_{19} \cdot \text{O} \cdot \text{CH}_2\text{Cl}$, formed by the action of formaldehyde upon menthol in the presence of hydrochloric acid. A colourless, fuming oil, b.p. $160^\circ\text{--}162^\circ$, 16 mm. pressure, decomposed by water into its original constituents. Employed in medicine in catarrhus affections of the air passages (*v. SYNTHETIC DRUGS*).

FORMANILIDE $\text{HCO} \cdot \text{NH} \cdot \text{C}_6\text{H}_5$, or

(Claisen, Annalen, 287, 360; Wheeler and Medcalf, Amer. Chem. J. 19, 217). First obtained by Gerhardt (Annalen, 60, 310) by heating aniline oxalate. Best prepared by heating together molecular proportions of aniline and strong formic acid on the water-bath under reduced pressure to remove the water, then distilling under ordinary pressure until the thermometer indicates 250° , and finally pouring out the undistilled portion, when it solidifies on standing (Wallach and Wüsten, Ber. 16, 145).—Long four-sided prisms melting at 46° , moderately soluble in water, readily so in alcohol. Dilute acids decompose it into aniline and formic acid. Formanilide is rapidly attacked by chromic acid, various colouring matters being formed (de Coninck, Compt. rend. 128, 503).

Sodium, silver (Comstock, Ber. 23, 2274; Comstock and Kleeberg, Amer. Chem. J. 12, 493), and mercury compounds have been obtained (Wheeler and McFarland, *ibid.* 18, 540).

Other derivatives are described by Comstock and Kleeberg (*l.c.*), Claisen (*l.c.*), and Comstock and Wheeler (Amer. Chem. J. 13, 514).

FORMATOL. Trade name for a preparation of formaldehyde. Used as an antiseptic.

FORMESTON. Trade name for basic aluminium formate. Used in wound dressing.

FORMIC ACID (Ger. Ameisensäure)

$\text{H} \cdot \text{COOH}$. Discovered by Rey, in 1670, by distilling red ants with water. Formed in the acid secretions of certain caterpillars; in the common nettle (*cf.* Dobbin, Proc. Roy. Soc. Edin. 1919, 39, 137); in the fruit of the soap-nut tree (*Sapindus saponaria* (Linn.)); in tamarinds, &c. Occurs in sweat, urine, and muscular plasma. Formed by the dry distillation of starch, sugar, gum, tartaric and oxalic acids, &c. It may be prepared from acetylene by dissolving in fuming sulphuric acid and diluting with water. On boiling with baryta and filtering, the soluble barium formate remains in the filtrate. Best obtained in the laboratory by heating a mixture of glycerol (or other polyatomic alcohol of high boiling-point) with crystallised oxalic acid. The anhydrous glycerol is heated with the oxalic acid to $75^\circ\text{--}90^\circ$ until the evolution of carbon dioxide ceases, when a fresh quantity of oxalic acid is added, and the process repeated.

The interpretation of this reaction usually

accepted is that the oxalic acid $\text{C}_2\text{H}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ decomposes into water, carbon dioxide, and formic acid, which reacts upon the glycerol, forming *monoformin*. On the addition of a further quantity of crystallised oxalic acid, the water of crystallisation decomposes the monoformin, producing glycerol and formic acid, which distils over

Monoformin is thus being continually formed and destroyed, with the eventual production of formic acid of from 87 to 88 p.c. (Lorin, Bull. Soc. chim. [ii.] 5, 7; 20, 241; 24, 22 and 436).

According to Chattaway (Trans. Chem. Soc. 1914, 151), glyceryl oxalate and glyceryl acid oxalate are the first products of the reaction. The latter is unstable at a slightly higher temperature, and decomposes, giving carbon dioxide and monoformin. The further addition of acid displaces formic acid from the monoformin.

The formates (*see* below) are the starting-point for the manufacture of formic acid. Whereas, at one time, oxalic acid was the source from which formic acid was obtained, now formates can be used as a source of oxalic acid (D. R. P. 111078, 144150, 161512). Formic acid is obtained by heating formates *in vacuo* with acids or acid salts (Hempel, Eng. Pat. 3428; J. Soc. Chem. Ind. 1909, 259); by treating formates with hydrofluoric acid (Strauss, D. R. P. 209418; J. Soc. Chem. Ind. 1909, 674); and by heating in a still 1 part of sodium formate with 2 parts of sodium hydrogen sulphate or other acid salt; in the last method, acid of from 97 to 98 p.c. is obtained (Ch. Fab. Grünaw, Landshoff, und Meyer, Akt. Ges., Eng. Pat. 14438; D. R. P. 192881; Fr. Pat. 367316; U.S. Pat. 857046; *v.* also Hamel, Eng. Pat. 7534; Fr. Pat. 341764; U.S. Pat. 806660; J. Soc. Chem. Ind. 1904, 9113, and Soc. Anon. des Etab. Eycken and Leroy; Fr. Pat. 393526; J. Soc. Chem. Ind. 1909, 160).

Anhydrous formic acid may be obtained by gently heating lead formate with sulphuretted hydrogen, by heating the dehydrated sodium salt with anhydrous oxalic acid, by distilling the ordinary acid over anhydrous copper sulphate under a pressure of 120 mm., or by the careful addition of phosphoric oxide and subsequent distillation under 15–18 mm. pressure (Jones, J. Soc. Chem. Ind. 1919, 38, 362 T.). It is a colourless, slightly fuming liquid, with a penetrating smell, and is intensely corrosive. Boils at 99.9° , sp.gr. 1.226 at 15° , 1.2200 at 20° ; b.p. 101° (corr.) (Thorpe and Rodger); solidifies at a low temperature, forming large brilliant plates; m.p. 8.35° . Traces of water lower the m.p. and raise the b.p. The specific gravity of aqueous solutions is given in the following table (Richardson and Allaire, Amer. Chem. J. 19, 150):—

P.c.	Sp.gr. $20^\circ/4^\circ$	P.c.	Sp.gr. $20^\circ/4^\circ$
10	1.0247	60	1.1425
20	1.0489	70	1.1656
30	1.0730	80	1.1861
40	1.0964	90	1.2045
50	1.1208	—	—

Formic acid is readily decomposed catalytically according to one or more of the following equations: (1) $\text{HCOOH}=\text{CO}_2+\text{H}_2$;

By leading the vapour over the following heated substances it is decomposed in accordance with equation (1) at varying rates and temperatures: palladium, platinum, copper, nickel, cadmium and oxides of zinc and tin. Palladium sponge and platinum sponge bring about total decomposition at 245° and 215° respectively. Titanic oxide and the blue oxide of tungsten decompose the acid according to equation (2): Silica, zirconia, alumina, and uranous oxide in addition to carbon monoxide and water produce formaldehyde. With thoria all three reactions are possible, depending upon the temperature. A heated Jena glass tube at 340° decomposes the acid into carbon dioxide and hydrogen. Powdered pumice, magnesia, and wood charcoal resolve it into carbon monoxide and water (Sabatier and Mailhe, *Compt. rend.* 1911, 152, 1212).

Heated with concentrated sulphuric acid, formates evolve carbon monoxide; with ferric chloride neutral solutions give a red colour. Silver nitrate is reduced to metallic silver, which is precipitated, partly as a black powder, and partly as a lustrous deposit on the tube. Mercuric chloride is reduced to mercurous chloride, and if excess of formic acid is present, to metallic mercury.

Formic acid may be estimated by the method of Jones (*Amer. Chem. J.* 17, 539). The solution is made alkaline with sodium carbonate, warmed, and an excess of standard permanganate added. The solution is acidified, and a measured volume of oxalic acid is run in, until the precipitate of manganese hydroxide has dissolved and the permanganate disappeared. The excess of oxalic acid is estimated by titration with standard permanganate. A volume of oxalic acid equal to that taken is also titrated with permanganate solution, and the difference between the result and the total permanganate used gives the quantity of permanganate required to oxidise the formic acid (*v. also* Rupp, *Zeitsch. anal. Chem.* 1906, 687; Grossmann and Aufrecht, *Ber.* 1906, 2455). Other methods depend on the reduction of mercuric chloride to mercurous chloride (Scala, *J. anal. and appl. Chem.* 5, 233; Lieben, *Monatsh.* 1893, 746; Leys, *Mon. Sci.* 12, 632; Franzen and Greve, *J. pr. Chem.* 1909, 80, 368; Riesser, *Zeitsch. physiol. Chem.* 1915, 96, 355); the titration of the acid with standard alkali, or the decomposition of the acid in the carbonic acid apparatus with sulphuric acid and potassium dichromate (Rupp, *Arch. Pharm.* 243, 69). For estimation in the presence of acetic acid, *v. Freyer*, *Chem. Zeit.* 1895, 1184; Heuser, *ibid.* 1915, 57; Laufmann, *ibid.* 1915, 575. In presence of other substances, *v. Fincke*, *Biochem. Zeitsch.* 1913, 50, 253; *Analyst*, 1913, 378.

Formic acid is a strong reducing agent and a powerful antiseptic. It is used as a food preservative (Woodman and Burrell, *Tech. Quart.* 1908, 21, 1), and in brewing is added to the yeast mash as an antiseptic (Lange, *J. Soc. Chem. Ind.* 1905, 1025; Henneberg, *ibid.* 1906, 192). It is used in dyeing as an assistant

or reducing agent with potassium dichromate mordant and also for dyeing woollen goods or unions with acid dyestuffs (Kapf, *ibid.* 1905, 129; Meltner, *ibid.* 435; and Ruby, *ibid.* 1907, 467).

The formates.—Industrial methods for the preparation of the formates are based on three reactions: (1) The interaction of carbon monoxide and metallic oxides. In this method, carbon monoxide under pressure is passed over metallic oxides, basic minerals, or alkali hydroxides, the conditions varying slightly in the different processes (Usines des Moulins, *Fr. Pat.* 382001; *J. Soc. Chem. Ind.* 1908, 183; Ellis, *U.S. Pat.* 875055, *ibid.*; Raschen, *J. Soc. Chem. Ind.* 1908, 420; *Eng. Pat.* 13953; Farb. Meister, Lucius, and Bruning, *Fr. Pat.* 389065; *J. Soc. Chem. Ind.* 1908, 769; Haase, *Eng. Pat.* 4771; *J. Soc. Chem. Ind.* 1908, 898; Elect. Werke, D. R. P. 179515; *Chem. Soc. Abstr.* 1907, [i.] 378; Koepf and Co. D. R. P. 209417; *Fr. Pat.* 342168; *Chem. Zentr.* 1909, [i.] 1785). (2) The hydrolysis of the cyanides of the alkaline earth metals. The cyanides of the alkaline earth metals are treated with water vapour under pressure at temperatures below 300° , whereby ammonia and a formate are produced (*Bad. Anil. und Soda Fab.*, *Eng. Pat.* 22038; *Fr. Pat.* 372714; *J. Soc. Chem. Ind.* 1907, 527; *Eng. Pats.* 784, 1912; 11485, 11486, 1915). The interaction of a solution of potassium ferrocyanide with caustic potash according to the following equation has also been patented by Haakh (D. R. P. 281044):

(3) The reduction of carbonic acid or the carbonates by hydrogen. Rogatzen (*Eng. Pat.* 12604; *J. Soc. Chem. Ind.* 1893, 864) obtained a mixture of ammonium formate and bicarbonate by passing moist nitrogen, hydrogen, and carbon dioxide over slightly heated pumice or other absorbent bodies. Water gas and 'Ebelmen gas' were used to supply the hydrogen and nitrogen respectively. More recently the reduction of carbonic acid and the bicarbonates by hydrogen under pressure has been studied by Bredig and Carter (*Ber.* 1914, 541). They showed that calcium carbonate heated with hydrogen under 50 atmospheres pressure and carbon dioxide (20 atmospheres) at 70° in the presence of spongy palladium in $4\frac{1}{2}$ hours gave a 100 p.c. yield of calcium formate. A 75 p.c. yield of potassium formate was obtained by passing hydrogen at 60 atmospheres pressure through a 5 p.c. solution of potassium bicarbonate containing palladium black (*Eng. Pats.* 801 and 9762, 1915).

Decomposition of the formates.—The formates of the alkali metals on heating in absence of air to 400° decompose, giving mainly hydrogen and oxalic acid, at lower temperatures carbonates are chiefly formed. The formates of the alkaline earths give only carbonates. The presence of two molecular proportions of calcium hydroxide lowers the temperature of decomposition of calcium formate from 375° to 260° , the proportion of hydrogen rising from 35 to 93 p.c. (Levi and Piva, *Ann. Chim. Applicata*, 1916, 271). Under certain conditions formaldehyde is one of the products of the reaction (Hofmann and Schumpelt, *Ber.* 1916, 303).

Potassium formate HCO_2K and *Sodium formate* HCO_2Na are readily soluble deliquescent salts which, according to Bineau, form acid salts on solution in hot concentrated formic acid. *Calcium formate* $(\text{HCO}_2)_2\text{Ca}$ and *Barium formate* $(\text{HCO}_2)_2\text{Ba}$ crystallise in rhombic prisms, readily soluble in water, insoluble in alcohol. *Lead formate* $(\text{HCO}_2)_2\text{Pb}$ is less soluble in water than other formates, 1 part dissolving in 63 parts of water at 16° , and is insoluble in alcohol; the solution forms a series of basic formates on being warmed with lead oxide, which have an alkaline reaction and crystallise in needles. *Copper formate* $(\text{HCO}_2)_2\text{Cu} \cdot 4\text{H}_2\text{O}$ crystallises in light blue monoclinic prisms: forms basic salts, $\text{Cu}(\text{HCO}_2)_2 \cdot 2\text{Cu}(\text{OH})_2$ and $\text{Cu}(\text{HCO}_2)_2 \cdot 3\text{Cu}(\text{OH})_2$ (Trans. Chem. Soc. 1915, 1281). Silver and mercurous formates decompose even in the dark, and the latter deflagrates when heated and decomposes on percussion. Chromous formate $\text{Cr}(\text{HCO}_2)_2 \cdot 2\text{H}_2\text{O}$, red cubes (Ber. 1916, 1679). *Methyl formate* boils at 30.4° (712 mm.), sp.gr. 0.9928; it is best made by acting on dry sodium formate with a mixture of methyl alcohol and aqueous hydrochloric acid, or by digesting methyl alcohol with concentrated formic acid. *Ethyl formate* boils at 50.4° , and has sp.gr. 0.9445 at 0° . It is made by heating a mixture of 6 parts of alcohol (90 p.c.), 7 parts of sodium formate, and 10 parts of concentrated sulphuric acid.

FORMICIN, FORMIDIN v. SYNTHETIC DRUGS.

FORMINS are esters produced by the condensation of glycerol or other polyhydric alcohol with formic acid.

Monoformin $\text{HCO} \cdot \text{OC}_3\text{H}_5(\text{OH})_2$ is produced in the preparation of formic acid by heating glycerol with oxalic acid at 190° (Tollens and Henninger, Bull. Soc. chim. [ii.] 11, 395), and is extracted from the mixed product by means of ether. It is also prepared by the interaction of monochlorhydrin and sodium formate at 160° (van Romburgh, Rec. trav. chim. 1, 186). On distillation under atmospheric pressure it decomposes into carbon dioxide, water and allyl alcohol, but may be distilled unchanged *in vacuo*.

Dinitroformin is a yellow oil, sp.gr. 1.5 at 15° . It is formed together with nitroglycerin by heating anhydrous oxalic acid with glycerol at 150° and treating the product with nitrosulphuric acid (Vender, D. R. P. 209943; Chem. Soc. Abstr. 1909, i. 692).

Diformin $(\text{HCO} \cdot \text{O})_2\text{C}_3\text{H}_5 \cdot \text{OH}$ is the chief constituent of the residue obtained in the preparation of formic acid by heating anhydrous oxalic acid and glycerol at 140° (van Romburgh, J. 1881, 508). It is extracted with ether and purified by distillation under reduced pressure. B.p. 163° – 166° under 20–30 mm.; sp.gr. 1.304 at 15° . Insoluble in carbon disulphide and decomposed by water with the formation of glycerol and formic acid. On heating under atmospheric pressure it is decomposed into carbon dioxide, water and allyl formate. With 5 parts of glycerol at 220° , carbon monoxide, carbon dioxide and allyl alcohol are the products, whilst with oxalic acid, carbon dioxide and formic acid are produced.

Triformin $(\text{HCO} \cdot \text{O})_3\text{C}_3\text{H}_5$ is prepared by heating glycerol with excess of 100 p.c. formic acid. By cooling the viscous product by liquid

ammonia, a crystalline mass is obtained. Pure triformin is colourless; has m.p. 18° ; b.p. $266^\circ/762$ mm.: $n_D^{18} = 1.4412$. It is saponified slowly by cold, readily by hot water (van Romburgh, Zeitsch. physikal. Chem. 1910, 70, 459).

By heating erythrol with formic acid and distilling off the acid at 200° , a mixture of formins is obtained, from which a tetraformin has been isolated. This forms silky needles, m.p. 150° (Henninger, Compt. rend. 98, 149).

FORMITROL (formolyptrol). Trade names for a preparation of formaldehyde.

FORMOL. Trade name for a preparation of formaldehyde.

FORMOLITES. A term applied to the various classes of phenol-formaldehyde, resins, e.g. lakelites, resinite, issolin, albertole, etc.

FORMOPYRINE. A compound of antipyrine and formaldehyde $\text{C}_{11}\text{H}_{13}\text{ON}_2 \cdot \text{CH}_2\text{O}$; m.p. 142° ; insoluble in cold water, soluble in chloroform and alcohol. Forms salts with acids (Marcourt, Bull. Soc. chim. 1896, 520). Stolz (Ber. 1896, 29, 1826) and Pellizzari (Gazz. chim. ital. 1896, 26, ii. 407) state that Marcourt's 'formopyrine' is identical with methylene diantipyrine $\text{CH}_2(\text{C}_{11}\text{H}_{12}\text{ON}_2)_2$, described by Pellizzari (Chem. Soc. Abstr. 1890, 645).

FORMOSE v. CARBOHYDRATES.

FORMURAL. Trade name for an addition product of hexamethylenetetramine and sodium citrate.

FORMUROL. An additive compound of hexamethylenetetramine and sodium citrate. Used as a urinary antiseptic.

FORNITRAL. Trade name for a compound of two mols. of formic acid with one mol. of endo-anilo diphenyldihydrotriazol $(\text{HCOOH})_2 (\text{C}_6\text{H}_5)_2 (\text{N}_4\text{C}_2\text{H})$. Used for the detection and estimation of nitric acid instead of nitron (Ann. Chim. Anal. 1921, 3, 207; Analyst, 1921, 385).

FORSTERITE v. OLIVINE.

FORTOIN. Methylene-dicotoïn

Formed by the action of formaldehyde on cotoïn. Used in the treatment of diarrhoea.

FOSSIL RESINS v. RESINS.

FOWLER'S SOLUTION. A solution of potassium arsenite.

FRACTIONAL DISTILLATION v. DISTILLATION.

FRAGARIANIN v. TANNINS.

FRANCKEITE. A complex sulphide ore of tin, $\text{Pb}_5\text{FeSn}_3\text{Sb}_2\text{S}_{14}$, containing, according to this formula, Sn 16.71 p.c. It consists of platy, tetragonal crystals, with a perfect cleavage parallel to the surface of the folia, which are often aggregated in more or less pronounced radiating groups, sometimes forming spherules and reniform masses. It is iron-black with a bright metallic lustre; marks paper and is malleable, like graphite. The mineral occurs in some quantity near Chocaya and in the Trinacria mine at Poopó in Bolivia, and is known locally as *Uliceria*. The above formula written in the form $3\text{PbSnS}_2 + \text{Pb}_2\text{FeSb}_2\text{S}_8$ brings out a relation between franckeite and the allied Bolivian minerals teallite (PbSnS_2) and cylindrite ($3\text{PbSnS}_2 + \text{SnFeSb}_2\text{S}_8$). Analyses I and II by G. T. Prior, 1904 (II on less

distinctly crystalline material with some massive), III by C. Winkler, 1893 (also germanium about 0.1 p.c., and gangue 0.71 p.c.) :—

	I.	II.	III.
Pb . . .	46.23	48.02	50.57
Fe . . .	2.69	2.74	2.48
Zn . . .	0.57	—	1.22
Ag . . .	0.97	0.99	n.d.
Sn . . .	17.05	13.89	12.34
Sb . . .	11.56	13.06	10.51
S . . .	21.12	20.82	21.04
	100.19	99.52	98.87
Sp.gr.	5.88	5.92	5.55

L. J. S.

FRANGULIN *v.* GLUCOSIDES; also CASCARA SAGRADA.

FRANKINCENSE *v.* OLIBANUM; art. GUM RESINS.

FRANKLINITE. A member of the spinel group of minerals with the general formula $R''OR_2''O_3$, where $R''=Fe, Zn, Mn$, and $R'''=Fe, Mn$. The actual composition is very variable; ferric oxide always predominates (56–67 p.c.), zinc oxide ranges from 6 to 23 p.c., and manganese oxides (MnO, Mn_2O_3) average 15–20 p.c. The mineral occurs as well-developed crystals of octahedral habit, as rounded grains, and as granular masses. It is black with a sub-metallic lustre, much resembling magnetite in appearance, but is readily distinguishable from this in being only slightly magnetic. Sp.gr. 5.0–5.2; hardness, 6.

Although known only from Franklin in New Jersey (hence the name), it is found there in considerable abundance in association with ores of zinc in crystalline limestone. After the extraction of the zinc, the residue is used in the manufacture of spiegeleisen.

L. J. S.

FRAXETIN *v.* HORSE CHESTNUT.

FRAXIN *v.* GLUCOSIDES; also HORSE CHESTNUT.

FRAXITANNIC ACID *v.* TANNINS.

FREDO. Trade name for calcium hydro-sulphite.

FREESTONE. An indefinite term used by quarrymen for a rock which admits of being freely worked in any direction for use as a building stone. Such a rock shows a uniformity or evenness of grain and no distinct bedding. Many stratified rocks may be readily sawn when freshly quarried, and while holding the 'quarry-water,' but acquire considerable hardness on exposure to the atmosphere. Most freestones are either limestones or sandstones. In the Inferior Oolite there are certain beds known to geologists as the Lower and Upper Freestones, which are largely quarried as building stones, near Cheltenham. The Bath stone from the Great Oolite, and the Portland stone from the Upper Oolites, are also well-known Oolitic freestones. The term freestone is also applied to many of the red Permian and Triassic sandstones of the north-west of England, *e.g.* the St. Bees sandstone. Many of the Coal-measure sandstones admit of being readily cut and tooled, and, being without any marked tendency to split in definite directions, are valuable freestones; such, for instance, are the sandstones of Craigleith, near Edinburgh, and of Darley Dale in Derbyshire.

L. J. S.

FREIBERGITE *v.* FAHLORE.

FRENCH CHALK. A variety of steatite, or soap-stone, used for marking cloth and for removing grease from silk. It is a hydrated magnesium silicate, with a smooth unctuous feel. In a powdered state it is sprinkled inside new gloves and in the heels of boots to produce a smooth surface and enable them to be readily slipped on (*v.* STEATITE).

FRENCH GREEN, EMERALD GREEN *v.* PIGMENTS.

FRENCH POLISH. A solution of shellac in alcohol; occasionally containing gum elemi and copal.

FREUND'S ACID (1-Naphthylamine-3:6-disulphonic acid) *v.* NAPHTHALENE.

FRITTS and GLAZES. The 'glaze' of pottery is a vitreous coating, which serves to make the articles impervious to liquids, and may also be used for decorative purposes. According to the context, however, the word is also employed to denote (1) the mixed and powdered dry materials to be used for the coating, or (2) an emulsion of these materials suspended in water ('wet glaze').

Usually the glaze is applied by dipping the dry or 'biscuit' ware into this emulsion. The water soaks into the porous 'body,' leaving a deposit of the solid materials on the surface. When the ware is subsequently heated to a sufficiently high temperature, this layer melts, forming a glassy coating fused more or less completely with the underlying body of the article. Sometimes, however, the glaze is poured over the ware, or sprayed upon it, or dusted on as a dry powder, instead of being applied by 'dipping.' In the special case of salt glaze (used for stoneware), the salt is volatilised on to the ware in the kiln during firing.

The normal quantity of dry glaze on table and toilet ware ranges from about 4 to over 9 p.c. of the weight of the ware, the average being between 6 and 7 p.c.

A good glaze should be clear, bright, and uniform; hard enough to resist wear; and in the case of domestic and sanitary articles, should withstand the action of all the ordinary acids.

Defects.—Two principal defects to which the glaze on ware is prone are (1) 'crazing,' and (2) 'scaling' or 'moulting.' In the first, a network of fine cracks spreads over the glaze; in the second, the glaze chips off at the edges. They are usually accounted for as follows :—

Broadly speaking, the coefficient of expansion of a glaze should be that of the underlying 'body.' If, on cooling, the glaze contracts much more than the body, it is under tension, and either at once or during subsequent usage it yields to the stress, and cracks. The 'crazing' may not develop for several months. In some ware—*e.g.* tiles—crazing is not of itself a serious fault; in fact, makers hold that the refraction effects which result render the ware more artistic. The purchaser, however, may be prejudiced against it; and in the case of table ware there is the additional objection that the cracks may harbour dirt and micro-organisms.

On the other hand, if the glaze contracts much less than the body, it is under pressure when cold, and portions chip off, even sometimes breaking the body itself. This 'scaling' or

'moulting' is a less frequent evil than crazing. Moreover, it usually shows itself immediately after firing, and a remedy can thus be looked for before turning out further similar goods.

Other reasons for crazing are given in some cases. Thus 'short-fired' glaze, where fusion with the body is imperfect, is prone to craze.

Either the body or the glaze, or both, may be modified to remedy crazing. In the glaze, the proportion of alkalis is diminished, or that of the lime, silica, or boric oxide increased.

Composition.—Glazes after fusion are either alkali silicates (salt glaze), or silicates and borosilicates of aluminium, alkalis, and the alkaline earths, with or without lead. In coloured glazes, various colouring oxides, *e.g.* those of cobalt, copper, iron, manganese, are also present. Before fusion, the glaze may be merely common salt or feldspar; but the usual materials of glazes are certain natural silicates, namely feldspar, china clay or kaolin, and Cornish stone, mixed with flint or sand, chalk, borax or boric acid, soda, white lead, red lead, and litharge. Cullet (broken glass) is also sometimes an ingredient, and for coarse earthenware glaze, galena.

Fritting. Borax, boric acid, and soda, however, being soluble in water, would pass into the porous body of the biscuit ware during dipping if they were merely mixed with the other ingredients of the wet glaze. Hence they must be made insoluble in water. This is done by fusing them with a portion of the other ingredients containing lime, alumina, and silica, and the complex borosilicate thus obtained is a 'borax fritt.'

By 'fritt,' therefore, is to be understood certain ingredients of a glaze, which have been mixed and subjected to a preliminary fusion before being ground up with the remaining materials. Occasionally, the whole of the ingredients may thus be formed into a 'fritt.'

When lead is a constituent of the glaze, frittting is also advantageous, for two reasons: (1) it can thus, with due care, be rendered almost insoluble in dilute acids, and therefore much less dangerous to the health of the workers than when in the 'raw' form of oxide or carbonate; (2) the high density of 'raw' lead tends to make it settle down in the dipping tub more rapidly than the lighter ingredients do, thus making the glaze less uniform; this tendency is largely counteracted by having the lead in the form of a fritt. This, of course, also applies to other heavy materials, such as barium carbonate. Other cases where frittting is beneficial are when an ingredient is present in very small proportion, since it is then distributed more evenly; or when certain of the constituents are fusible with difficulty at the temperature employed for 'firing' the ware. A higher temperature may be used for the frittting, and much of the chemical work done which, with the 'raw' glaze on the ware, would have to be performed at a less effective temperature.

On the other hand, a certain proportion of material in the 'raw' state, especially clay, is advantageous for keeping the glaze suspended in water for dipping; hence it is not usual for all the ingredients of a glaze to be frittited.

Formulae of glazes. In ceramic calculations it is customary to express the chemical formula

of a glaze in terms of molecular 'equivalents' the sum of the RO constituents being made unity. Thus the glaze described on p. 248 will reduce to $1\text{RO}, 0\cdot27\text{Al}_2\text{O}_3, 3\cdot5(\text{SiO}_2, \text{B}_2\text{O}_3)$. Typical English glazes similarly work out as follows:—

	RO	Al_2O_3	$\text{SiO}_2, \text{B}_2\text{O}_3$
China	1	0.31	3.57
Earthenware	1	0.26	2.80
Granite	1	0.32	3.43

The theoretical acids corresponding to the above four formulæ, expressed as ratios of $\text{H}_2\text{O}:\text{SiO}_2$, are respectively 1:2.1, 1:1.9, 2:3.1, and 4:7. That is, the four glazes lie between the bisilicate type ($\text{H}_2\text{O}, 2\text{SiO}_2$) and the polysilicate ($2\text{H}_2\text{O}, 3\text{SiO}_2$). Seger gives for white ware glazes the limits $1\text{RO}, 0\cdot1\text{Al}_2\text{O}_3, 2\cdot5\text{SiO}_2$ and $1\text{RO}, 0\cdot4\text{Al}_2\text{O}_3, 4\cdot5\text{SiO}_2$. The first is somewhat less acid than a bisilicate, the second rather more. A soft, heavily leaded English majolica glaze, however, $1\text{RO}, 0\cdot16\text{Al}_2\text{O}_3, 1\cdot68(\text{SiO}_2, \text{B}_2\text{O}_3)$, corresponds to $7\text{H}_2\text{O}, 8\text{SiO}_2$, and is but slightly more acid than a monosilicate.

Lead glazes. The number of recipes for these is legion, but on calculating them out to the constituent oxides, they reduce to a few main types. They may be broadly classified as follows:—

(1) *China, earthenware, granite, ironstone, and semi-porcelain.* Contain 12–20 p.c. of PbO, occasionally more, usually about 17 p.c.

(2) *Rockingham, jet, and majolica.* 25–50 p.c. of PbO. Rockingham glazes contain Mn_2O_3 , and jet CoO. Many majolica glazes have from 25 to 35 p.c. of PbO; the 'soft' varieties 40–50 p.c.

(3) *Tile glazes.* Usually 40–50 p.c. of PbO; the harder varieties less; in the softer kinds as much as 60 p.c.

(4) *General coloured glazes.* Described later; the proportion of PbO in these varies widely.

Examples showing the general percentage composition are:

	Granite	China	Rockingham	Jet	Soft majolica	Soft tile
SiO_2	54.8	50.8	35.6	34.8	32.3	32.6
PbO	12.9	17.6	42.1	55.0	48.1	59.1
Al_2O_3	10.1	9.1	8.7	5.2	5.9	5.3
CaO	4.8	5.4	2.9	1.2	3.8	0.8
Na_2O	7.5	3.8	2.4	0.6	3.5	—
K_2O	3.8	4.8	—	—	2.5	2.2
B_2O_3	6.1	8.5	0.7	—	3.9	—
Mn_2O_4	—	—	6.1	—	—	—
CoO	—	—	—	2.1	—	—

Other things being equal, the larger the proportion of lead the 'softer' is the glaze, and the lower the temperature of firing. There is little doubt that for this reason more lead than is really necessary is often used.

Lead fritts. Lead oxides and carbonates are readily dissolved by the acid of the gastric juice, giving rise to plumbism. By suitable frittting, however, complex silicates containing lead, alkalis, alumina, and lime can be obtained of such character that, even when finely powdered, dilute acids attack them very slightly.

To be of this insoluble character, the complex silicate must not be more basic than would correspond to the metapoly silicic acid $\text{H}_4\text{Si}_2\text{O}_6$ (Chem. Soc. Trans. 79, 803–804). Preferably they should be less basic. Moreover, only a limited

proportion of boric oxide appears to be admissible if the silicate contains a large percentage of lead, and the materials must, of course, be thoroughly fused. Previous fine grinding and good mixing are important in securing such fusion. Under these conditions, lead fritts may be made containing any proportion of lead up to 50 p.c. of PbO or over, but yielding only a very small quantity of lead to the action of dilute acids. The other bases may also vary considerably in their proportions, replacing one another and the lead oxide within wide limits, without notably affecting the amount of 'soluble' lead:

	PbO	Al ₂ O ₃	CaO	(Na,K) ₂ O	PbO dissolved
1.	16.2	10.3	8.5	9.2	1.7 per cent.
2.	44.1	5.5	0.9	3.4	2.1 „

Simple lead bisilicate PbSi₂O₆, containing theoretically 65 p.c. of PbO, and in practice about 60–63 p.c., is also used, but is somewhat more attackable by acids than the complex silicates. Nevertheless, there are some advantages attending the use of the simple bisilicate. The proportion of PbO in it being very high, less of the fritt is required to furnish a given amount of PbO in the glaze; this leaves so much the more room for clay and other materials to be used raw, if desired, to facilitate suspension of the materials in the water of the dipping tub. It implies, too, a minimum of alteration in changing from a raw lead glaze to one with fritted lead. For example, if the 17.6 p.c. of PbO in the china glaze, mentioned in the table above, were supplied by lead bisilicate, nothing but 9.5 p.c. of SiO₂ would have to be taken from all the rest of the materials. Without pressing this point unduly—for it should not be forgotten that the complex lead polysilicates may contain as much as 50 p.c. of PbO, and still be of 'insoluble' character—its importance will easily be recognised. The bisilicate is chiefly of value for the more heavily leaded glazes, Rockingham, jet, and majolica. The quantity of 'soluble lead' (*v. post*) extractible from commercial samples of the bisilicate is from 4 to 8 p.c.; hence majolica glazes containing 30–40 p.c. of total PbO would yield only 2–5 p.c. of 'soluble lead' if compounded by means of the bisilicate.

Simple lead polysilicate, Pb₃Si₃O₈, yields more soluble lead than the bisilicate; and from the monosilicate, PbSiO₃, the whole of the lead is easily dissolved. Even the complex silicates, if of the monosilicate type, H₂SiO₃, readily yield up a large proportion of their lead to the action of dilute hydrochloric acid. Lead fritts of this (monosilicate) character were almost the only form of 'fritted lead' used in the English potteries up to a few years ago, and it is not surprising that they gave rise to cases of lead poisoning.

Complex lead polysilicates and bisilicates containing alumina yield less soluble lead than the corresponding simple lead silicates. There is evidence to show that the alumina renders the silicate more stable—perhaps by acting as an acidic oxide (Chem. Soc. Trans. 97, 2286).

Where fritts contain only small quantities of 'soluble' lead—say up to 3 p.c. or so—one treatment of the ground fritt with dilute hydrochloric acid removes nearly all this soluble lead,

which there is reason to believe is usually present as an admixture of silicate more basic than the bulk. On subsequently testing the residue, mere traces of lead are extracted.

The various forms of lead fritt are heavy glass-like substances of yellow colour. They should be of uniform texture, showing no fragments of unfused materials. They have no sharp melting-points; when heated they soften gradually until fused. Vitreous silicates, however, conduct electricity (Doelter), and the relative fusibilities of fritts may be compared by determining the temperatures at which the coarsely powdered fritts soften and blend into a continuous mass, such as will allow the passage of the electrical current. As thus determined, the 'softening-points' of some simple lead silicates are as follows: PbO, SiO₂, 480°; PbO, 2SiO₂, 570°; PbO, 3SiO₂, 620°. The inclusion of boric acid or borax in the silicate lowers these softening-points; lime or alumina raises them (Beck, Löwe, and Stegmüller; *v. reference at end of article*).

Effect of fine grinding upon solubility of the lead. For a full discussion of this, see Manchester Memoirs, vol. 45 (1901), No. 15, or Parliamentary Paper Cd. 679 on Lead Compounds in Pottery, 33. The conclusion is that fineness of subdivision is not absolutely without influence upon the quantity of lead dissolved; but that within the limits of fineness occurring in actual practice the effect is too small to be of serious moment.

Method of determining the 'soluble' lead. The British official method is as follows: 1 gram of the dried glaze or fritt, ground ready for use, is shaken continuously for an hour with 1000 times its weight of 0.25 p.c. solution of hydrochloric acid. After being allowed to settle for an hour, an aliquot part is filtered off, silica separated by evaporation in the usual way, the lead precipitated as sulphide, and finally weighed as sulphate.

In the United Kingdom potters who use no glaze yielding more than 5 p.c. of 'soluble lead' (PbO), as thus tested, are exempted from certain restrictions. Further exemptions are allowed where the glaze used gives not more than 2 p.c. of such soluble lead. If the total amount of lead is not more than 1 p.c. (calculated as PbO), the glaze is classed as 'leadless,' and this carries with it additional privileges.

Percentage composition of some complex lead silicates, with the amounts of PbO dissolved from them by 0.25 p.c. HCl:—

No.	Type	PbO	CaO	(Na,K) ₂ O	Al ₂ O ₃	B ₂ O ₃	SiO ₂	PbO dissolved
1.	Bisilicate	21.8	8.5	3.8	7.4	3.8	54.4	traces
2.	„	44.1	0.9	3.4	5.5	—	44.7	2.1
3.	Polysilicate	16.2	8.5	9.2	10.3	5.8	49.7	1.7
4.	„	41.1	2.1	5.9	7.2	—	43.6	3.0
5.	Monosilicate	37.9	10.8	3.7	8.2	—	37.6	28.0
6.	„	70.3	0.5	1.6	1.1	2.6	23.9	70.3

Fritts similar to Nos. 2 and 4 are the more generally useful for compounding glazes. Those like Nos. 1 and 3, containing less PbO and more SiO₂, have more restricted application; and Nos. 5 and 6, in so far as soluble lead is in question, are quite inadmissible.

The proportion of lead oxide dissolved from

a few fritts containing 57-63 p.c. of PbO, and approximating to lead bisilicate in composition, is appended :

PbO present, p.c.	57.3	58.5	59.3	63.4
PbO dissolved „	2.6	4.2	5.1	7.2

If these fritts are used to supply the lead in glaze containing 15 p.c. of lead oxide, the amount of soluble lead in such glaze will range from 0.7 to 1.7 p.c.

The German official method is to heat for half an hour with a 4 p.c. solution of acetic acid. Petrik has suggested a much more stringent method (Sprech Saal, 1914, 47, 1). It consists in digesting 5 grams of the finely-ground substance for an hour with 150-200 c.c. of 0.33 p.c. hydrochloric acid at 37°-40°. Sodium acetate is then added to promote settling and to dissolve lead chloride. The residue after filtration is also washed with sodium acetate solution. Lead is then estimated as sulphate. In a comparison of these methods, a glaze which had a solubility of 0.17 p.c. PbO by the English official method, yielded 0.25 by the German official method, and 0.56 by Petrik's method.

Lead dissolved from finished ware. Lead may be extracted by acids from the glaze on the fired article, as, for example, by vinegar or fruit acids from culinary vessels. There is evidence to show that, speaking broadly, the more 'soluble' lead there is in the glaze before firing, the more it is liable to be extracted from the glaze on the finished article. The actual quantity, however, is less from the fired glaze than from the original, on account both of the smaller surface presented and of the chemical changes resulting from the fusion.

Compounding of glazes. In compounding glazes from the raw materials regard must be had to several considerations besides the formula and the analytical composition. The proportion of clay, for instance, influences the shrinking of the glaze before firing; too much causes a tendency to flake off. Again, it may be that sufficient alkali cannot be introduced as feldspar or stone without adding too much alumina; some alkali must then be included as a fritt, which may also contain the borax and the lead, if these are constituents of the glaze. An example from actual practice will illustrate the compounding of a glaze by the use of fritts.

The proximate composition of a certain glaze used for earthenware and china is given¹ as: SiO₂ 50.9, PbO 17.0, Al₂O₃ 7.7, CaO 7.6, (Na,K)₂O 6.0, and B₂O₃ 10.8 p.c. To obtain all the advantages of fritting, two fritts must be made, one to contain the lead, and the other the boric oxide; for if a single fritt contained both, the high proportion of boric oxide would render the lead too easily soluble in acids, and thus one important advantage of fritting would be lost. A lead fritt is therefore made by fusing: litharge 39, flint 21, orthoclase and oligoclase feldspars, each 10 parts; and a borax fritt by fusing: borax 150, flint 75, china clay 50, and whiting 50 parts. The calculated composition of these two fritts, allowing for the CO₂ and H₂O expelled on heating, is as follows:—

	SiO ₂	PbO	Al ₂ O ₃	CaO	Na ₂ O	K ₂ O	B ₂ O ₃
Lead fritt	42.3	48.8	5.1	0.6	1.1	2.1	—
Borax fritt	43.1	—	8.5	13.1	11.1		24.2

(In practice, however, a little lead is lost by volatilisation and by fusion with the walls of the 'sagger' during fritting. Actual analysis of the lead fritt showed 44.1 p.c. of PbO, the proportions of the other constituents being correspondingly increased.)

To form the glaze, these two fritts are then combined with raw materials, flint, china clay, and whiting, in the proportions: lead fritt 205, borax fritt 260, flint 81, china clay 34, and whiting 20 parts. The lead fritt, it may be noted, would have the same composition if it were made from the following ingredients: Cornish stone 25, litharge 48½, flint 25½, soda, calcined, 2 parts. This dispenses with the feldspars.

Coloured glazes. So far as the glaze is concerned, coloured ware is obtained (1) by applying the colouring materials to the raw or biscuit body, which is afterwards glazed with a transparent glaze ('under-glaze' process); (2) by placing the colouring materials on the already glazed article, and refiring it ('on-glaze' process); or (3) by embodying the colour in the glaze itself ('coloured-glaze' method).

For the last-named process, a fritt may be made to contain the colouring oxide in chemical combination, and ground up with the other materials to form the glaze. Alternatively, a lead fritt or glaze may be taken as colourless fusible basis, and colouring oxides ground up or fritted with it.

The first of these two methods, for example, is that adopted by Messrs. Villeroy and Boch, Dresden. Their colourless² glaze for earthenware has the chemical formula:

Its molecular and percentage composition are:

	K ₂ O	Na ₂ O	CaO	PbO	Al ₂ O ₃	B ₂ O ₃	SiO ₂
Mols.	0.25	0.75	1.50	2.00	1.50	1.50	12.00
P.c.	1.49	2.94	5.31	28.17	9.68	6.63	45.78

For convenience of dipping, 15 p.c. of the materials are left unfritted, the remainder being made into a fritt, as follows:—

	Fel-spar	Chalk	Lith-arge	Sand	Borax	Pot-sherds	Kaolin
Fritted	3.5	5.4	24.7	18.5	15.4	17.5	—
Raw	3.0	2.9	—	—	0.5	—	8.6

For coloured glazes, the CaO in the fritt is replaced by CoO, CuO, NiO, &c., or the Al₂O₃ by Fe₂O₃, Mn₂O₃, Cr₂O₃, U₂O₃, &c. These coloured fritts are then diluted with the colourless glaze to the desired tints.

The second method is exemplified as follows (Salvetat): The materials of a colourless flux, namely, calcium borate, flint, and red lead, are mixed in the proportions of 1:2:4; this mixture with 1-4 p.c. of CoO gives blues; with 3-14 p.c. CuO, greens; with 2-6 p.c. Fe₂O₃, yellows; and so on. All the ingredients are fritted to facilitate perfect mixture. An English colourless fritt for similar purposes is made by fritting: flint 10, china stone 9, red lead 30, and borax 4 parts: this is ground and mixed with various colouring oxides.

¹ Alnstrom, Lead Compounds in Pottery (Parliamentary Paper, C9207, p. 24).

² Lead Compounds in Pottery, Cd. 679, p. 21.

Enamels are opaque glazes, the opacity being due to tin oxide in suspension. In this country, however, the term 'enamels' (enamel colours) is also applied to the colours used for 'on-glaze' decoration.

White enamel may be obtained (Brongniart) by fritting calcine (=mixed oxides of lead and tin), sand, soda, and salt. Various proportions are used, a general formula being SiO_2 45, PbO 36, SnO_2 10, and NaCl 9 p.c. Coloured enamels result from the addition to this of 3-10 p.c. of colouring oxides. Thus 9 p.c. of lead antimonate, 5 of CoO , 5 of CuO , and 4 of MnO_2 , give yellow, blue, green, and violet respectively.

Colours. *Under-glaze* colours are generally oxides or chromates, with flint, whitening, Cornish stone, or fluxes containing borax or lead. *On-glaze* colours are fusible glasses, composed usually of a lead borosilicate flux with colouring oxides. A common flux ('No. 8') used in this country consists of flint, borax, and red lead in the proportion of 1:2:3, but various proportions are employed.

Leadless glazes. The salt glaze used for *stoneware* has already been mentioned. For *hard porcelain*, the glazes employed are (1) 'alkaline' or feldspathic glazes, consisting of silicates of alumina, alkalis, and alkaline earths, in which the alkalis preponderate over the lime and magnesia; and (2) 'calcareous' glazes, similar to (1), but in which the lime exceeds the alkalis. The materials used are pegmatite, with an addition of silica to modify the fusibility, or a mixture of felspar, quartz, and kaolin, with or without chalk.

For *soft porcelain*, *china*, and *earthenware*, glazes containing boric oxide are usually employed. One recipe for such glaze is: felspar 48.7, borax 27.0, whitening 13.5, and flint 10.8 p.c. This is fritted, and mixed with one-third of its weight of china clay to form the glaze.

ANALYTICAL COMPOSITION OF VARIOUS LEAD-LESS GLAZES.

	Peg- matite ¹ (Sèvres)	Cal- careous ¹	English ²	
			Minton's	Owen's
SiO_2	70.6	64.8	57.5	50.4
Al_2O_3 & Fe_2O_3	17.6	15.7	14.7	12.2
CaO	1.3	10.1	8.5	12.1
MgO	0.2	1.5	0.2	0.5
Na_2O	5.0	0.8	3.8	8.3
K_2O	4.2	5.6	4.1	2.5
B_2O_3	—	—	10.7	10.7
CO_2	—	—	—	2.5

'Leadless' glazes not infrequently contain traces of lead, arising probably from their having been ground in mills previously used for lead glaze. Occasionally larger quantities are found, due to the use of flint glass as an ingredient.

Ware coated with leadless glaze may, on analysis, show traces of lead in the glaze, not only from the foregoing causes, but also from having been fired in a lead-washed sagger, or in proximity to lead-glazed goods. Lead in one form or another may be volatilised from the latter, and some of the lead vapours are absorbed by the leadless glaze. It is not difficult, however, to distinguish between such ware and that glazed

with ordinary lead glaze. In the glaze removed from a definite area of the ware by means of hydrofluoric acid, the lead is determined; the proportion on leadless-glazed ware is usually less, and often much less, than 0.1 gram PbO per square decimetre; whereas that on lead-glazed table ware ranges from about 3 times to 8 times this quantity, and on heavily-lead-glazed ware, such as tiles, it may be upwards of 40 times as much.

As regards the suitability of leadless glazes for pottery, it may be said that in all classes of ware a great many articles can be manufactured with leadless glaze, in a very high state of perfection. The cost of production in the commonest qualities is less than with lead glaze, and in some others is not appreciably greater. But in certain of the best and medium classes there is an undue proportion of 'seconds', that is, ware not of the highest finish, and this raises the cost or lowers the quality. It is not clear, however, that this is due to anything inherent in the use of leadless glaze. For certain colours and methods of decoration leadless glazes at present cannot replace those made with lead. On the other hand, there is no doubt that a great deal of white and cream-coloured ware for domestic, sanitary, and electrical purposes, now coated with lead glaze, could be glazed without the use of lead.

For a summary of present knowledge and experiments respecting soluble lead in frits and glazes, see Beck, Löwe, and Stegmüller, *Zür Kenntniss der Bleihaltigen Glasuren und deren Bleiabgabe an saure Flüssigkeiten* (Arbeiten aus dem Kaiserlichen Gesundheitsamte, Band 33, Heft 2, 1910). C. S.

FRUCTOSE v. CARBOHYDRATES.

FUCHSIA. The chlorides of α - and β -dialkyl-safranines are met with in commerce under this name (v. AZINES).

FUCHSIN, RUBIN, ROSEIN, MAGENTA (v. TRIPHENYL METHANE COLOURING MATTERS).

FUCOSE. CARBOHYDRATES.

FUCITOL. An alcohol, $\text{C}_6\text{H}_{14}\text{O}_5$, m.p. 153° - 154° , obtained by reducing fucose (q.v.) by sodium amalgam. Is the optical antipode of rhodeitol. In presence of borax in aqueous solution its rotatory power was $[\alpha]_D^{20} = +4.7$, and when mixed with an equivalent quantity of rhodeitol in hot alcoholic solution, it yields racemic fucitol (*d*-, *L*-rhodeitol), m.p. 168° - 170° (Votocek and Potmesil, Ber. 1913, 46, 3653).

FUCOSOL. This product which Stenhouse obtained by the distillation of certain *algæ* with dilute sulphuric acid (Proc. Roy. Soc. 20, 80), and which he considered as isomeric with furfural, has been shown by Bieler and Tollens (Ber. 1889, 3062) and by Maquenne (Compt. rend. 109, 571) to be a mixture of furfural and methyl-furfural derived from pentaglycoses contained in the *algæ* (v. also Muther and Tollens, Ber. 1904, 298).

FUEL. This term includes all combustible substances obtainable in bulk which may be burned by means of atmospheric air in such a manner as to render the heat evolved capable of being economically applied to domestic or industrial purposes. Fuels may be divided into (a) *solid fuels*, including (i.) natural fuels, consisting of woody tissues in an unaltered (wood)

¹ Bourry, Treatise on Ceramic Industries.

² Analysed in the Government Laboratory, London.

or an altered form (peat, lignite, coal); (ii.) carbonised fuels (charcoal, coke); (iii.) compressed fuels (briquettes); (b) *liquid fuels* (petroleum, benzenes, alcohol); (c) *gaseous fuels* including (i.) natural gas; (ii.) gases produced by the carbonising of solid fuels (coal gas, &c.); (iii.) gases produced by the partial combustion of solid fuels (blast furnace gas, producer gas, water gas). All fuels, having been originally derived from some form of living matter, or the products of its alteration, are composed of the elements C, H, O, N, and S, together with (in the case of solid fuel) a variable amount of mineral matter, which constitutes the incombustible ash.

The economic importance of a fuel depends upon (1) its distribution; (2) its cost of production, transport, and storage in bulk; (3) the total amount of heat obtainable on burning unit weight of it; and (4) the rapidity, efficiency, and smokelessness of its combustion with atmospheric air. Of all natural fuels coal is by far the most important, for despite the probability that there is more combustible matter in the peat deposits than in all the known coalfields of the world, and the marked inferiority of coal to petroleum in respect of calorific value, no other fuel combines so many economic advantages as coal.

The calorific value, or the total amount of heat obtainable by the combustion of a given fuel, is expressed by the number of parts by weight of water which may be heated through 1° on the thermometric scale by the combustion of one part by weight (or, in the case of gaseous fuels, by volume at N.T.P.) of the fuel under conditions such that the whole of the heat of combustion is transferred without loss to the water, and that the products leave the system at atmospheric temperature and pressure. The metric unit of heat adopted for technical purposes (the K.C.U.) is the quantity of heat required to raise 1 kilog. of water through 1°C . in the neighbourhood of 15°C ., whilst the British unit (the B.Th.U.) is the amount of heat required to raise 1 lb. of water through 1°F . in the neighbourhood of 60°F . Thus, 1 K.C.U. = 3.9683 B.Th.U., and 1 B.Th.U. = 0.252 K.C.U.; moreover, in the case of solid or liquid fuels, a calorific value of x K.C.U.s. per kilog., is equivalent to $1.8x$ B.Th.U.s. per lb. (or, conversely, x B.Th.U.s. per lb. = 0.5555 x K.C.U.s. per kilog.), whilst, in the case of a gas, x K.C.U.s. per cubic metre is equivalent to $0.11236 x$ B.Th.U.s. per cubic foot (or, conversely, x B.Th.U.s. per cubic foot = $8.90 x$ K.C.U.s. per cubic metre). For purposes of calculation, the calorific value of a gas may often be expressed more conveniently in K.C.U.s. per gram-molecule (*i.e.* 22.38 litres at 0°C . and 760 mm.) than in any other form; in such a case, x K.C.U.s. per gram-molecule = $44.68 x$ K.C.U.s. per cubic metre at 0° and 760 mm., or $5.02 x$ B.Th.U.s. per cubic foot at 0° and 760 mm.

In cases where hydrogen enters into the composition of a fuel, it is usual to differentiate between its *gross* and *net* calorific values, the former implying that the products of combustion have all been cooled down to atmospheric temperature (15°C .), the latter, that the heat liberated by the condensation of the steam produced on combustion and by the subsequent cooling of the water to 15° has not been included. The difference between *gross* and *net* values will

always be 11.196 K.C.U.s. per gram-molecule of steam produced on combustion (= 622 K.C.U.s. per kilog., or 1119.6 B.Th.U.s. per lb.).

The determination of the calorific value of a solid or liquid fuel may be best carried out by burning a known weight of it in compressed oxygen in some form of bomb calorimeter, that known as the Berthelot-Mahler apparatus being well adapted for this purpose. In the hands of an experienced worker, the method is a very accurate one, provided that all the proper 'corrections' (*e.g.* for 'cooling' and for the formation of nitric acid) are determined and applied; it must be remembered, however, that the method gives the heat of combustion under 'constant volume' and not under 'constant pressure' conditions, and in the calculation of the latter from the experimental results a proper 'correction' must be applied. In the case of coals, the combustion of which is attended by very little change in chemical volume (*e.g.* 1 lb. of a coal containing C=80.0, H=5.5, S=1.0, N=1.5, O=5.0, and ash =7.0 p.c. requires 135.2 cubic feet of air, and yields 130.8 cubic feet of gaseous product at 0° and 760 mm.), the difference between the heats of combustion under 'constant volume' and 'constant pressure' is negligible in practice, but not so in the case of a hydrocarbon such as heptane

The calorific value of a gas is usually determined by burning a measured volume of it at atmospheric pressure in a chamber surrounded by a system of coils or the like, through which a flow of water at a constant 'head' is maintained. By suitable regulation of the pressure and flow of the gas and water supplies respectively, the gas may be completely burnt and the heat developed transferred substantially without loss to the water, the products leaving the apparatus at a temperature only slightly above that of the atmosphere. Several forms of this apparatus are in use, the most satisfactory being those designed by Junkers and C. V. Boys respectively. With suitable modification (*e.g.* the provision of a differential thermojunction arrangement for registering the rise in temperature of the water on a moving chart), the method can be made a 'recording' one.

The heat of combustion of amorphous carbon is 8080 K.C.U.s. per kilog. when completely burnt to the dioxide, and 2417 when burnt to the monoxide; the values for the principal single gases (taken from Julius Thomsen's researches) are as follows:—

	K.C.U.s. per gram molecule		B.Th.U.s. per cub. ft. at 0° and 760 mm.	
	Gross	Net	Gross	Net
Hydrogen	68.4	57.2	343.3	287.2
Methane	212.0	189.5	1064.0	951.3
Ethane	370.5	336.9	1860.0	1691.0
Ethylene	333.3	310.9	1673.0	1561.0
Propylene	492.7	459.1	2474.0	2305.0
Acetylene	310.0	298.8	1556.0	1500.0
Carbon monoxide		68.0		341.4
Cyanogen		259.6		1303

The *gross* values for single liquid fuels, in K.C.U.s. per kilog. are *n*-hexane = 11,620, benzene = 10,250, toluene = 10,390, methyl alcohol = 5694,

ethyl alcohol=7400. According to Julius Thomsen, an increase of $>\text{CH}_2$ in ascending a homologous series of hydrocarbons or alcohols corresponds to a constant increase of 158.5 K.C.U.s. in the gross value of the molecular heat of combustion.

It is not possible to calculate the calorific values of compound fuels such as coal or petroleum from their elementary analyses, since the heat of combustion of a compound is never equal to the sum of those of its elements taken proportionately. In the case of bituminous coals empirical formulæ, such as :

$$Q = \frac{1}{100} [8080C + 34,460(H - \frac{1}{8}O) + 2250S]$$

K.C.U.s. per kilog., where C, H, O, and S=percentage of carbon, hydrogen, oxygen, and sulphur, have been proposed for this purpose; but they cannot be considered as more than approximately correct. There is often a fairly close agreement between the results calculated by means of this formula and those actually found by the bomb calorimeter in cases where the oxygen content of the coal does not exceed about 7.5 p.c. In coals with a high oxygen content, however, there is usually a marked disagreement. On the other hand, since the properties of a gaseous mixture are additive in respect of its constituents, the heats of combustion of gaseous fuels of which the composition has been accurately determined by analysis (and this applies more particularly to such cases as water gas or producer gas, the combustible constituents of which are hydrogen, carbon monoxide, and methane only) may be calculated from those of their constituents. In the case of coal gas, where the composition of the heavy hydrocarbons absorbable by bromine is always uncertain, this rule is not strictly applicable, although numbers calculated on the assumption that the heavy hydrocarbons have an average calorific value equal to that of propylene C_3H_6 , are generally not widely different from those determined by the calorimeter.

The so-called 'calorific intensity' of a fuel is an unscientific term, inasmuch as the highest temperature which a particular fuel is capable of producing depends entirely upon circumstances which are, to some extent, indefinable, and difficult of control. The notion that the calorific intensity of a fuel may be deduced by dividing its calorific power by the mean specific heat of its products, is misleading, inasmuch as (1) the specific heats of gases, and especially of steam and carbon dioxide, increase with temperature, and at high temperatures are as yet not accurately known; (2) part of the potential energy of a fuel is directly radiated away during combustion, and does not appear as sensible heat in the products; and (3) combustion is ordinarily not sufficiently instantaneous to warrant the assumption above referred to. The measurement of furnace temperatures and the like is, however, of great practical importance, and many instruments have been designed for this purpose (see PYROMETRY). These depend upon (1) the variations with temperature in the pressure (at constant volume) or volume (at constant pressure) of a gas which does not appreciably deviate from Boyle's law (air thermometer); (2) the production of thermo-

electric currents (thermojunction methods); (3) the increase in the electrical resistance of a platinum wire with temperature (resistance methods); and (4) the variation with temperature of the radiation emitted by an incandescent solid as defined by Stefan's law (*radiation pyrometry*). Methods (1) to (3) inclusive, whilst capable of great accuracy, are practically useful up to temperatures of 1000° - 1200° only; they can be made 'recording,' however, and are invaluable for recording the temperatures of hot gases passing into furnaces from 'regenerative' systems (hot-blast stoves, melting-furnace regenerators) or of hot products passing into chimneys. Method (4), whilst of relative significance only, is invaluable for temperatures higher than 1000° ; as a modification of method (4) may be mentioned various forms of *optical pyrometers*, in which the light emitted by an incandescent surface is compared with that from a standard source (e.g. an amyl acetate flame).

A. SOLID FUELS.

1. Natural Fuels.

All natural fuels of this class have originated in cellulose $n(\text{C}_6\text{H}_{10}\text{O}_5)$, which, in fact, constitutes about 95 p.c. of dry woody tissue. The gradual transformation of vegetable *débris* into coal has proceeded during nearly all geological epochs. All the important coal-fields adjacent to the N. Atlantic and Arctic areas (which include nearly all those of N.-W. Europe and the E. part of N. America) originated in the Carboniferous Period of the Primary Era. The 'Indian Ocean' group of coal-fields (which include those of China, India, Australia, and S. Africa) originated in the somewhat later Permo-Carboniferous Period. Mesozoic coals are found in the interiors of N. America and Asia (intra-continental group); whilst Tertiary coals are chiefly found in the Pacific borderland (W. of N. America, Japan, and New Zealand), as well as in regions bordering on the Gulf of Mexico and the Mediterranean. The vegetable forms which flourished in the Carboniferous Period were of simpler structure, but of much greater size, than those which are predominant to-day (gigantic ferns, club mosses, horsetails, and forms intermediate between ferns and cycads), and it is demonstrable that in certain cases (e.g. the Moisa seam near Loughborough in Leicestershire) entire beds of coal have been formed from the spores of such plants.

At one time it was generally believed that coal formation had taken place upon the actual site of growth, the requisite conditions being dense forests in swampy areas, together with oscillations of level, the coal-measures produced during a period of subsidence being overlaid by beds of water-deposited clay or sandstone, which, on re-elevation, formed the soil for renewed forest growth. Hence coal is found in strata of undoubted estuarine or lacustrine origin (Carboniferous, Jurassic, Cretaceous); the common occurrence of 'under-clays' in the coal-measures is cited in support of this hypothesis, which probably is true for some British coal-fields. It has been contended by some geologists that in many cases the transformation of vegetable *débris* into coal has taken place not upon the site of growth, but after

transportation by river currents and deposition in deltas; it has also been suggested that certain coal-seams are of marine origin.

There has also been much speculation and diversity of opinion as to the nature of the transformation process, and the factors operative therein; it is usually supposed that its earlier stages were characterised by slow oxidation under water or other covering sufficient to protect the decayed wood from direct atmospheric action, and that supervening upon this were changes gradually brought about by increasing pressure and temperature as the deposits were overlaid and 'blanketed' by accumulating newer *strata*. The final transition from a bituminous coal to anthracite—if such, indeed, has taken place—may be attributed (i.) to intense earth pressure accompanied by seismic disturbance; or (ii.) to the later intrusion of igneous matter from below. It should, however, be stated that in some instances at least there are grounds for believing that anthracite has been formed from vegetable matter of a kind distinct from that concerned in the formation of bituminous coal, without necessarily passing through the intermediate 'bituminous' stage (*vide* section of this article on British Coal Fields (1) *South Wales*, p. 262). M. Renault, from an extensive study of peat formation, has advanced the hypothesis that the chief agents in the early stages of the transformation process have been certain aerobic fungi, and anaerobic bacterial ferments, the relative activities of which would depend upon the varying water-level in the bog and the formation of ulmic acid. He represents the transition from cellulose into bituminous coal by the equation:

(C_9H_6O would contain $C=83.1$, $H=4.6$, $O=12.3$ p.c., which approximates to the composition of many bituminous coals.) But whatever may have been the nature of the process, it is generally agreed that the existing coal-measures represent some 20–25 p.c. only of the weight of the original cellulose, and less than half of its heating value; in a few cases, where the original vegetable *débris* has undergone local 'petrification,' it has been established that the shrinkage in bulk during transformation into coal has been of the order 9:1 approximately. The composition and calorific values of the dry ashless cellulose and intermediate products up to coal itself is shown in the following table:—

	C	H	O and N	K.C.Us. per kilog.
Cellulose	44.5	6.2	49.3	4167
Wood	50.0	6.0	44.0	4000–4300
Peat	50–64	4.5–6.8	28.6–44.0	5000–6000
Lignites	60–75	5.0	20.0–35.0	6000–7000
Bituminous coals	75–90	4.5–5.5	5.5–15.0	8000–9600
Anthracite	90–95	2.4	3.0	9200–9800

Wood when dry consists of about 95 p.c. of cellulose and 4 p.c. sap, associated with a small amount of mineral ash (chiefly $CaCO_3$ and K_2CO_3). Recently felled timber contains a large proportion of water which 'air-drying' reduces to about 20 p.c. An 'air-dried' wood is classed as 'hard' or 'soft' according as its sp.gr. exceeds or falls below 0.55; 'hard'

woods are less inflammable than 'soft' varieties. As a fuel wood is very combustible, and burns with a great amount of flame; it is well adapted for domestic fires and the firing of tubular boilers, its low content of infusible ash making it a clean fuel without a vestige of 'clinking' properties. Owing to its large content of hygroscopic water, it is quite unsuitable for the attainment of high temperatures, unless it first be carbonised (charcoal), or be gasified in a producer. On distillation in closed retorts or chambers it yields, under favourable conditions, 20–25 p.c. of charcoal, 9–13 p.c. of tar, 40–45 p.c. of crude 'pyroigneous acid' (corresponding to 2–4 p.c. anhyd. acetic acid), and 22–32 p.c. of inflammable gases. The chief timber-producing countries are those which before the war comprised the Russian Empire with 920 million acres of forests (575 in Europe and 350 in Asia), Canada with 800 million acres (of which probably less than half represents timber of commercial value), the United States, Norway, and Sweden with 70 million acres, and Germany with 35 million acres. Russia was, however, the only European country which before the war produced more timber than it required. It is as yet too soon to estimate the effects of the war upon timber supplies. The rapid demolition of the world's reserves is becoming a serious economic problem, and it is improbable that wood will ever again take important rank as a fuel.

In countries where wood, peat, or coal is scarce, vegetable refuse (cotton stalks, brushwood, straw, &c.) is used as fuel for tubular boilers; as a rule it has between 70 and 80 p.c. of the heating value of dry wood.

Peat is a widely distributed and abundant fuel of great future potentiality, it being estimated that the amount of combustible matter in the world's peat deposits exceeds that in all the known coal-fields. It is principally found in high latitudes; one-seventh of the area of Ireland is covered with peat, whilst in Great Britain there are about 6 million acres covered to an average depth of about 12 feet. Extensive deposits occur in Russia, where peat is an important metallurgical fuel, in Scandinavia, N. Germany, Bavaria, Austria, Italy, and N. France, to mention European countries only. Also considerable attention has recently been paid to peat deposits in Canada (*vide* Reports by A. v. Anrep and B. F. Haanel of the Canadian Department of Mines, 1912–1914). Peat deposits vary considerably in age, the oldest having a dark-brown or black colour, with but merest traces of its original organic structure, whilst the recent varieties are light-brown in colour, of spongy texture, with distinct vegetable structure; unlike wood, it contains a fairly large and variable proportion of mineral ash (5–15 p.c. as a rule) of (usually) infusible character. The composition of the ash varies considerably; sulphate and carbonates of lime and magnesia, ferric oxide, and silica being usually the most prominent constituents. The difficulty in the way of utilising the potential energy of peat for economic ends lies in the fact that even a well-drained peat-bog contains 80–90 p.c. of water, for the evaporation of which more energy would be required than is represented by the whole fuel value of the bog.

Consequently, 'air-drying' has hitherto been universally resorted to, but as this can only be carried out during the summer months, and must obviously depend upon climatic conditions, it cannot be considered seriously as a means of preparing large quantities of peat for the market. Moreover, 'air-dried' peat still contains from 15 to 25 p.c. of water, its calorific value (which varies between 2235 and 4307, with an average of about 3000 K.C.U.s. per kilog.) is usually considerably less than half that of a bituminous coal, whilst bulk for bulk its heating power probably does not exceed one-eighth that of coal. Dry 'ashless' peat contains C=50-64, H=4.7-6.8, O=28-44, and N=0.5-2.5 p.c., its cal. value=5200 K.C.U.s. per kilog., and its sulphur content is low.

As recently as 1905 the Royal Commission on Coal Supplies reported that '*in order to make the manufacture of peat fuel a success in this country, it is necessary that some process should be discovered by which the moisture can be got rid of without "air-drying," and at a cost which would not be prohibitive; at present there is no such process.*' In 1909, however, the late Dr. M. Ekenberg prepared a process of '*wet carbonisation*' as a practical solution of the problem (Jour. Iron and Steel Institute, 1909, i. 313). This process was based upon the supposition that 'peat substance' consists of vegetable debris, the cells of which contain and are surrounded by a slimy '*hydrocellulose*,' formed by prolonged contact of the original cellulose with water. It was further supposed that although this constituent is present to the extent of 0.2-1.2 p.c. only, it is in the form of an enormously swollen jelly of the consistency of soft-soap, containing as much as 25 times its own weight of water, which latter cannot be expelled by mechanical pressure unless the supposed 'hydrocellulose' has been previously hydrolysed. It is claimed that this can, however, be rapidly accomplished by water at 150°-200°, forming the soluble dextrose, and peat pulp so hydrolysed readily parts with its water under hydraulic pressure. The Ekenberg process (as originally proposed) consists in forcing a peat pulp containing 12½ p.c. of peat substance and 87½ p.c. of water at 220-300 lbs. per sq. in. pressure through a series of tubes heated externally to about 200°, the operation being combined with a system of heat recuperation, whereby the outgoing hot 'carbonised' peat imparts heat to the incoming cold pulp. The 'carbonised' pulp is dehydrated by mechanical pressure, and the dehydrated fuel is subsequently briquetted. The process has not, however, advanced beyond an experimental stage, whilst doubts have been expressed as to the validity of the 'hydrocellulose' supposition on which it is based. Meanwhile, attempts have been made, with some measure of success, to expel the greater part of the water contained in raw peat by a process of mechanical pressure combined with a degree of heat materially below that proposed by Ekenberg. It seems possible that a pressed cake containing only 50 p.c. of water can be so produced, corresponding to the expulsion of nearly 90 p.c. of the water originally present in the raw peat, and that a solution of the peat fuel problem may ultimately be found in this direction.

The Fuel Research Board issued, in 1920, a report upon the "Peat Resources of Ireland" (Special Reports No. 2), and more recently a further report on "The Carbonisation of Peat in Vertical Gas Retorts" (Technical Paper No. 4), to which the reader is referred.

Peat containing as much as up to 60 p.c. moisture has been successfully gasified on a large scale in gas producers under ammonia recovery conditions (*vide PRODUCER GAS*); the following results have been obtained on Mond plants:—

Origin of peat	German	Italian	English
Per cent. moisture	40-60	45	57.5
nitrogen	1.0	1.58	2.3
Yield of gas in cub. ft. at 0° and 760 mm. per ton dry peat	85,000	60,000	90,000
Gross cal. value of gas B.Th.U.s. per cub. ft. at 0° and 760 mm.	150	166	134

The richness of the gas depends upon the moisture in the peat; where the moisture is not excessive, the gas may contain as much as 35-40 p.c. of combustible constituents, *e.g.* 9.8CO, 23.2H₂, 4.8CH₄, with 20.3CO₂. It seems probable that a ton of dry peat is capable of yielding up to 90,000 cub. ft. of gas of an average gross calorific value of 140 B.Th.U.s. per cub. ft. Part of this would be required to fire the boilers and to work the ammonia recovery plant, the remainder being available for heating, or power purposes outside the plant. In addition to ammonium sulphate, it should be possible to recover other by-products (tar, acetate of soda or lime, acetone, wood spirit).

With regard to power production from peat (*via* gas producers and internal combustion engines) tests made at the Fuel Testing Station at Ottawa by the Canadian Department of Mines in 1910-1911 showed that the consumption of fuel per horse-power hour (including stand-by losses) is for fuel load, 1.7 lb., and for three-quarter load, 2.1 lbs. of dry peat.

Lignite and Brown Coals. Under this general term are included coals (intermediate between peat and bituminous coal) of Cretaceous or Tertiary age. They are widely distributed, (1) in what may be termed the 'Pacific Borderlands' (N.W. America, Japan, Australia, New Zealand, and the E. Indies); (2) in regions adjacent to, or in continuation with, the Gulf of Mexico; and (3) in regions north of the Mediterranean, including the Central European Plain. Cretaceous coals of the lignite class occur over a large area between lats. 49° and 43° N. and long. 100°-107° W. (the states of N. Dakota, Montana, and Wyoming) in N. America. Lignites occur also in Canada (Manitoba, Alberta, and Saskatchewan); whilst there are enormous deposits of brown coal in Australia (Victoria) of great potential value. Indeed the total thickness of the Gippsland deposits at Morwell (Victoria) amounts to about 780 ft. of coal within 1000 ft. of the surface; and it is anticipated that before long not only will the City of Melbourne derive the whole of its electric power from them, but also that the Victorian State Railways will be worked electrically from them. Classified according to external

characters and geological age, lignites are usually divided into (1) woody or fibrous brown coal, with a distinct ligneous structure; (2) earthy lignite devoid of organic structure and easily powdered; (3) common brown coal, with a slaty cleavage and dark-brown colour, *e.g.* Bovey coal; and (4) bituminous lignite, pitch black in colour, and having a conchoidal fracture. Up to the outbreak of the war lignites were, relatively speaking, of little economic importance except in Germany and Austria-Hungary, where (in 1913) 87.1 and 27.4 million tons respectively were raised for home consumption. The war has, however, greatly enhanced the importance of lignites, both as fuels and as the raw materials for the manufacture of motor spirit, fuel oils, waxes, &c., by low temperature distillation processes, the carbonaceous residue from which may be briquetted after admixture with a pitch 'binder.' Freshly-mined lignites may contain up to 50 p.c. of water, which, on air-drying, is usually reduced to between 10 and 20 p.c.: many varieties, when completely dried, crumble to powder, which, however, may be again consolidated into a serviceable block fuel by pressure. The ash content usually varies between 5 and 15 p.c., but may run considerably higher. The composition of the dry 'ashless' fuel varies between the following limits: C=60-75, H=5, O=19-34, N=0.5-1.5 p.c., and it has a calorific value of 6000-7000 K.C.U.s. per kilog. Lignite burns with a very long smoky flame, and is generally non-caking (*i.e.* it does not yield a coherent coke); it is largely used in Germany and Austria for firing boilers, and for the heating of evaporating pans, the better qualities being sometimes used for metallurgical purposes. Like peat, it may be gasified in producers. W. A. Bone has described a heat treatment of dry lignites and brown coals at temperatures below 400° C. whereby a considerable condensation in their cellulosic or humic constituents may be effected, with simultaneous elimination of H₂O and CO₂, but without any expulsion of either H or hydrocarbons, which may be employed to enhance their fuel values (Proc. Royal Soc. 1921, A. 99. p. 236).

Bituminous coal. This term is applied to a whole series of 'flaming' coals of Primary or Mesozoic origin, and it includes all the economically important coals except anthracites. More than 90 p.c. of the world's total output of 1250 million tons of coal in 1913 (including anthracites, but excluding lignites) was due to six countries (United States 562.6, Great Britain 287.4, Germany 191.5, France 40.1, Russia 28.8, and Belgium 22.8 million tons respectively). Taking a series of nine quinquennial averages over the period 1870-1914 inclusive, the output of coal in Great Britain has increased from 121.5 to 268.2 million tons per annum, whilst the annual consumption per head of population has increased from 3.5 to 4.3 tons. It is estimated that the available supplies within 4000 feet of the surface in Great Britain amount to about 580 times her output in 1913.

In 1920 only 229.3 million tons of coal were raised in Great Britain, at an average pithead cost of 34s. 1½d. per ton, or almost exactly four times the corresponding pre-war figure. The

amount of coal raised per person employed at British mines had fallen from 259 tons per annum in 1913 to only 190 tons per annum in 1920.

According to the Report upon the World's Coal Resources issued by the International Geological Congress in 1913, the total possible and probable reserves of coal of all kinds (anthracite, bituminous, and lignites) within 6000 feet of the surface amount to about 6000 times the present total annual consumption. Of these reserves, 6.75 p.c. are anthracites (mainly in China), 52.75 p.c. are bituminous coal, and 40.5 p.c. are sub-bituminous (lignites and Tertiary brown coals). 51.8 p.c. occur in the United States, 16.4 p.c. in Canada, 13.5 p.c. in China, 5.7 p.c. in the then German Empire, 2.6 p.c. in Great Britain, 2.3 p.c. in Siberia, and 2.2 p.c. in Australia. South America and Africa are relatively devoid of coal-fields.

For commercial purposes, bituminous coals are classified according to their suitability, or otherwise, for certain specific economic ends, *e.g.* steam raising, furnace firing, gas making, manufacture of dense metallurgical coke, and the like. The usefulness of any given coal for a particular purpose depends principally upon (1) its content of 'volatiles' expelled at 900°-1000°, which largely determines the length and character of the flame emitted during vigorous combustion; and (2) the character of the carbonaceous residue after the 'volatiles' have been expelled at high temperature, which doubtless in part depends upon the nature and mode of decomposition of a certain 'cementing' constituent of the coal, and partly also upon the character (fusibility) of the mineral ash associated with it. For economic purposes, Percy proposed to class bituminous coals as (1) non-caking, free burning, rich in O; (2) caking; and (3) non-caking, rich in C. Several classifications have been proposed based upon the ultimate composition of the dry and ashless coals. One of the most useful is that generally attributed to the French metallurgist Grüner, but in reality due originally to Regnault. In a modernised form it is as the table on p. 256.

Some authorities regard the Regnault-Grüner classification as defective, in that it is based chiefly on the 'oxygen' content of the coal, which bears all the analytical errors, and also in that it underrates the importance of hydrogen. C. A. Seyler, as the result of a special study of the coals of South Wales, has proposed a chemical classification based upon the percentages of carbon and hydrogen in the pure coal substance, and dependent on (1) the hydrogen content, and (2) the C/H ratio, as follows:—

Genus	P.c. H	Ratio C/H
1. Anthracitic . . .	under 4.0	over 22.0
2. Carbonaceous . . .	4.0-4.5	20.3-23.35
3. Semi-bituminous . . .	4.5-5.0	16.6-20.4
4. Bituminous . . .	5.0-5.8	14.6-18.2
5. Perbituminous . . .	over 5.8	12.9-14.7

The U.S. Geological Survey, independently of Seyler's work, have also adopted the C/H ratio as the best available basis for the purpose of scientific

THE REGNAULT-GRÜNER CLASSIFICATION OF COALS (AS REVISED BY THE AUTHOR).

Genus	Class	Chief uses	Percentage composition			P.c. volatiles at 900° C.	P.c. fixed carbon	Character of carbonaceous residue
			C	H	O+N+S			
A. Lignites	Non-caking	—	60 to 75	about 5·0	20 to 35	above 45	below 55	Non-coherent
B. Bituminous	[1] Non-caking long flame	Reverberatory furnaces	75 to 80	4·5 to 5·5	15 to 20	40 to 45	55 to 60	Non-coherent
	[2] Caking long flame	Gas-making	80 to 85	about 5·6	10 to 15	32 to 40	60 to 68	Very porous coke
	[3] Hard coking	Coke manufacture	84 to 89	5·0 to 5·6	5·5 to 11·0	26 to 32	68 to 74	Dense coke
	[4] Hard coking short flame	Coke manufacture and Steam raising	88 to 90	4·5 to 5·5	5·5 to 6·5	18 to 26	74 to 82	Very dense coke
B.C. Semi-bituminous	Non-caking short flame	Steam raising	90 to 92	4·0 to 4·5	4·0 to 5·5	15 to 20	80 to 85	Weakly caking or non-coherent
C. Anthracitic and Anthracites	[1] Anthracitic non-caking	Steam raising	92 to 94	3·0 to 4·0	3·0 to 4·5	8 to 15	85 to 92	Pulverulent
	[2] Anthracitic non-caking	Domestic and central heating; malting kilns	94	4·0	4·5	below 8	above 92	

All the numerical data in the above table refer to the dry ashless coal.

classification. It is, however, clear that, pending a much fuller knowledge than we now possess respecting the proximate constituents of coal, neither of the above classifications can be considered satisfactory in any final sense.

In the selection of a coal for any particular purpose, the following points should be borne in mind: (1) the best 'gas coals' are those in which the ratio O : H is approximately 2 : 0; they yield from 30 to 38 p.c. 'volatiles' (reckoned on the dry ashless coal), and a fairly porous coke of no great strength; (2) the best 'coking coals' usually yield between 20 and 30 p.c. of 'volatiles,' and are strongly caking; the best 'steam coals' yield less than 20 p.c. of volatiles, are, as a rule, non-caking and smokeless, or nearly so in their combustion; (4) for 'gas-producer' purposes it is desirable that a coal should be non-caking, and have an infusible ash. The caking properties of a coal depend upon its containing certain organic compounds (extractable by means of pyridine) which decompose when heated, yielding 'volatiles' and a small amount of a pitch-like cement which acts as a binding material in the resultant coke; *ceteris paribus*, a caking coal with a fusible ferruginous ash will yield a stronger coke than one of similar age and composition with a highly silicious ash. Non-caking or feebly caking coals are either (1) those of greatest age, high in carbon and low both in oxygen and

'volatiles'; (2) those of comparatively recent origin, with a high oxygen content; or (3) those from 'oxidised' seams which have at some period been exposed to atmospheric influence. Variations in the thickness of the overlying strata seem to influence the caking properties of a weakly caking coal-seam. For coking purposes, it is often advantageous to mix a weakly caking, short-flame coal, rich in carbon, with one which cakes well but yields much gas. Finally, it should be observed, that a caking coal loses its caking properties on prolonged exposure to the atmosphere.

Besides the elements already referred to, coal (ashless) contains two others of importance, viz. nitrogen and sulphur. The nitrogen, although present to an extent of between 1 and 2 p.c. only, is of great economic value, since it is the source of 95 p.c. of the world's entire output of ammonium salts. As the results of exhaustive tests upon some 80 Scottish coals (N=0·915-1·873 p.c.) at the Provan Gasworks, Glasgow, it has been found that under the conditions prevailing during distillation in a modern gas retort, about 58·3 p.c. of the total nitrogen remains in the coke, 19·5 p.c. appears as N in the gas, 17·1 p.c. is obtained as ammonia, 3·9 p.c. passes as organic bases into the tar, and, finally, 1·2 p.c. is evolved as cyano-compounds. Also, as the results of coking a Durham coal containing 1·57 p.c. N in Otto Hilgenstock ovens

at Blayden-on-Tyne, A. Short (J. Soc. Chem. Ind. 1907, 581) found that 43.31 p.c. of the N remained in the coke, 15.16 p.c. was recovered as NH_3 , 2.98 p.c. appeared in the tar, 1.43 p.c. as cyano compounds, the remaining 37.12 p.c. representing N in the gas. The temperature at which the evolution of ammonia begins when coal is heated seems to depend on its geological age. Carrick-Anderson, and Roberts (J. Soc. Chem. Ind. 1899, 1099) give 333° as the lowest temperature for NH_3 evolution from a young gas coal, and state that with coal of an older type it may rise to about 480° . Hilgenstock has found that the principal evolution of NH_3 occurs after the caking stage of the distillation has set in. M. G. Christie (Inaug. Diss. Aachen, 1908), in an investigation upon peat, gas coals, and anthracites, has shown that evolution of NH_3 begins at about 350° in the case of a gas coal, and at 450° in the case of anthracites, and that the principal evolution occurs between 500° and 700° ; according to Christie, also, that part of the N which remains in the coke is present in an extraordinary stable 'nitride' form, and is only slowly expelled as the temperature is raised from 900° to 1900° . From this it would appear that the N is present in at least two distinct forms, viz. (i.) as organic compounds which decompose at a temperature below 900° , and (ii.) in a stable 'nitride' form. Harger (J. Soc. Chem. Ind. 1914, 389) has suggested that the 'ammonia-yielding' N exists in a side chain in the parent molecule, whilst the more stable 'fixed nitrogen' is present in some ring formation.

Sulphur must always be considered as a deleterious element in coal; it appears in three forms, namely, (i.) as pyrites FeS_2 ; (ii.) as sulphates (gypsum); and (iii.) as 'organic' sulphur. Although partly expelled (chiefly as H_2S , CS_2 , and thiophen) on distillation, the sulphur is largely retained (chiefly as FeS and CaS) in the coke; it is impossible to produce a coke low in sulphur from a coal whose ash is rich in Fe, Ca, or Mg compounds. According to A. Short (*loc.*), in caking a Durham coal containing 0.824 p.c. S, in by-product ovens, 72.5 p.c. of the S remained in the coke, 24.0 p.c. was evolved as H_2S , 1.45 p.c. passed into the tar, the remaining 2 p.c. being accounted for as gaseous products other than H_2S .

Coal, when freshly mined, may contain much water ('pit water') and some occluded gas. Most of the water is rapidly lost on air drying, whilst the remainder (usually some 2-3 p.c.) is completely lost at 105° . The occluded gas may be withdrawn by continued exhaustion at the ordinary temperature; from a Durham coal (Hutton seam) Bedson obtained 1.6 c.c. of gas per gram of coal; the gas contained $\text{CO}_2=4.35$, $\text{CH}_4=71.15$, $\text{C}_2\text{H}_6=6.65$, $\text{O}_2=2.80$, and $\text{N}=15.05$ p.c. From a Lancashire coal (Lower Mountain Mine), R. V. Wheeler obtained 1.375 c.c. of gas per gram, containing $\text{NH}_3=0.5$, $\text{H}_2\text{S}=0.5$, $\text{C}_2\text{H}_4=0.4$, $\text{CO}=2.1$, $\text{C}_2\text{H}_6=8.10$, $\text{CH}_4=80.35$, $\text{O}_2=0.4$, and $\text{N}=7.65$ p.c.

The mineral ash in coal varies greatly in amount, colour, composition, and fusibility. A distinction must be drawn between the heavier mineral matter, 'dirt' (pyrites sp.gr. 5.0, shale sp.gr. 2.5, and gypsum sp.gr. 2.3), often mixed with freshly mined small coal (sp.gr.

1.2-1.3) from which a separation can be effected by mechanical washing, and the true or 'fixed' ash of the coal, which is disseminated throughout its entire mass, and cannot be so removed. A pure white ash which the writer once obtained from an Australian coal contained 53.4SiO_2 , $44.0\text{Al}_2\text{O}_3$, together with some 2 p.c. only of lime and the merest traces of ferric oxide. Usually the ashes of coals contain, in addition to Al_2O_3 and SiO_2 , variable proportions of CaO , MgO , Fe_2O_3 , and SO_3 (chiefly as CaSO_4); the colour varies from cream or light-buff to red-brown, according to the iron content, and, as a rule, the fusibility increases with the darkening colour. The ashes of a typical Lancashire coal will contain $\text{SiO}_2=25-40$, $\text{Al}_2\text{O}_3=19-28$, $\text{Fe}_2\text{O}_3=22-32$, $\text{CaO}=3-16$, MgO up to 3.5, and $\text{SO}_3=3-8$ p.c. A fusible ferruginous ash is a constant and prolific source of clinkering troubles in furnaces and gas producers. According to J. T. Dunn the melting-point of a coal ash may vary between 1000° and 1500° C. (or even higher) according to its chemical composition; and, although no general law can yet be formulated, the m.p. usually rises as the relative total molecular proportion of basic oxides to silica diminishes (Journ. Soc. Chem. Ind. 1918, 37, p. 171).

Whilst the majority of organic solvents (ether, alcohol, chloroform, benzene) have but little effect upon coal, Bedson has called attention to the remarkable solvent action of pyridine (b.p. 114.5°) (J. Soc. Chem. Ind. 1908, 27, 147). The coal should be ground so as to pass through a sieve of 1000 apertures per sq. in., then mixed with sand and extracted with the solvent in a Soxhlet apparatus. The residual carbonaceous material is always quite devoid of coking properties.

The pyridine solutions so obtained are dark brown in colour, with sometimes a green fluorescence, and the proportion of the coal substances extracted ranges from practically zero in the case of anthracites up to between 35 and 40 p.c. in the case of a good gas coal. The extract remaining after the solvent has been drawn off is a chocolate-brown amorphous solid, which on ignition decomposes with intumescence, yielding a large proportion of 'volatiles,' and a swollen residue of coke. From Bone and Sarjant's researches it would appear that in order to obtain any reliable results with a series of coals by the Soxhlet extraction method, attention must be paid to the purity of the pyridine, and especially to its being anhydrous, and that the whole operation should be carried out in an inert atmosphere of nitrogen. Other organic bases, such as aniline (b.p. 184°) and quinoline (b.p. 238°) have a similar solvent action to pyridine, and in general the higher the b.p. the greater and more rapid the action. Phenol also will extract (at 100°) considerable proportions of the coal substances. Mention should also be made of the recent work of F. Fischer and W. Gluud upon the solvent action of benzene upon coals at temperatures and pressures (288° and 50 atm.) approximating to the critical constants of the solvent.

The work of R. V. Wheeler and Burgess upon the volatile constituents of coal (Chem. Soc. Trans. 1910, 97, 1918; 1911, 99, 649; 1914, 105, 131) has thrown an interesting light upon the chemical nature of coal. The behaviour of

anthracitic, semi-bituminous, and bituminous coals at definite temperatures between 100° and 1100° was carefully investigated; it has been established (1) that 'occluded' gases, mainly higher paraffins, are evolved in small quantities up to 150° or even 200°; (2) that there is a copious evolution of water ('water of constitution') beginning at about 200° and continuing up to, and probably beyond, 450°; (3) that between 270° and 300° H₂S is freely evolved, after which olefines (higher than C₂H₄) appear up to 350°; (4) that a 'critical point' is reached about 350°, which is marked by a rapid increase in the gas evolution and the appearance of much viscous oil; (5) that up to 450° or 500° higher paraffins, C₂H₆, C₃H₈, C₄H₁₀, &c., as well as methane, are conspicuous decomposition products, whereas H is produced in very small quantity; (6) that the evolution of paraffins ceases entirely at about 700°, the absolute amount of CH₄ reaching a maximum at 800°–900°; and (7) that between 700° and 800° there is a 'critical point' above which the evolution of H abruptly and rapidly increases. It has been shown by D. T. Jones and Wheeler, Pictet and Bouvier, as well as by Bone and his collaborators, that the low-temperature tars obtained on distilling coal up to temperatures of 500° or 600° consist chiefly of hydrocarbons of the naphthene (C_nH_{2n}) and hydroaromatic series, together with some paraffins, but not benzene or its homologues. Certain hydroxy compounds, such as hexahydro- η -cresol C₆H₁₄O, as well as a series of homologous phenolic bodies, including C₈H₁₀O (b.p. 185°–190°), C₉H₁₂O (b.p. 198°–200°), C₁₀H₁₄O (b.p. 213°–215°), and C₁₁H₁₆O (b.p. 226°–228°) have been identified in such low-temperature tars. The results of a large number of investigations carried out in recent years by British, French, and American chemists all point to the conclusion that the 'ash-free' coal substance is a conglomerate of (a) cellulosic degradation products, (b) nitrogenous compounds of vegetable proteid origin, and (c) resinic bodies derived from gums, waxes, resins, &c., in the original vegetable *débris* from which the coal was formed. Up to recently, it has generally been supposed that the coking propensities of coals are mainly due to their resinic constituents; but this has been disproved by Bone and co-workers, who have shown that the main cause of coking are certain types of humic bodies whose softening or melting points lie below the temperature at which active decomposition sets in. For a complete discussion of the chemistry of coal, *vide* 'Coal and its Scientific Uses,' by W. A. Bone (1918).

When bituminous coal is charged into a hot furnace, it first of all undergoes a process of destructive distillation; its least stable resinous constituents decompose, and hydrocarbons are freely evolved, which, on partial oxidation or secondary decomposition, give rise to carbon, together with minute quantities of dense tarry vapours (smoke) which are difficult to burn, except in an abundant air supply and at high temperatures. The residual 'semi-carbonised' fuel, being raised to incandescence, is burnt by the air, which is drawn in through the grate. If, as in intermittent stoking, the furnace be cooled by a sudden inrush of cold air during the

introduction of a fresh charge of fuel, smoke will be freely evolved. The production of smoke may be greatly reduced by the adoption of continuous mechanical stoking, especially if it be on the 'under-feed' principle, or by making the mixture of 'smoke' and hot air impinge upon an incandescent fireclay surface; the introduction of a pre-heated secondary air supply near or at the fire-bridge of the furnace will often diminish smoke. It is never possible to burn coal in a furnace with the theoretical quantity of air; thus 1 lb. of coal containing C=80.0, H=5.5, S=0.9, N=1.5, O=5.0, and ash=7.0 p.c., would, theoretically, require 136.0 cub. ft. of dry air at 15° and 760 mm. for complete combustion, and the cooled gaseous products would contain 18.2 p.c. CO₂. It rarely happens, however, that the CO₂ content in the cooled chimney gases from a coal-fired furnace exceeds 13.0 p.c., and the more usual proportion is from 8.0 to 10.0 p.c. In large boiler installations, the adoption of mechanical stoking, together with automatic instruments for recording the temperature and CO₂ content of the chimney gases, will be found conducive to fuel economy. E. J. Constam and P. Schläpfer of the Zurich Prüfungsanstalt für Brennstoff, as the result of exhaustive boiler trials with many different coals, conclude that those yielding between 16 and 23 p.c. of 'volatiles' (referred to dry ashless fuel) have the greatest steam-raising values; with coals yielding a high percentage of 'volatiles,' there is an excessive loss on account of their incomplete combustion; whilst, on the other hand, with a coal low in 'volatiles,' and which, therefore, yields a large percentage of coke in the boiler furnace, a considerable excess of air must be used in order to maintain combustion at a rate sufficient to ensure rapid evaporation in the boiler, and this means an excessive loss as sensible heat of the chimney gases. In trials on a marine boiler with coals yielding between 16.5 and 19.1 p.c. 'volatiles,' evaporating about 3.6 lbs. of water per sq. ft. of heating surface per hour, between 73.7 and 75.1 p.c. of the heat of combustion of the fuel was transmitted to the water, about 20 p.c. was lost in the chimney gases (at 276°–303°), partly as sensible heat and partly as unburnt gases, another 3.3–4 p.c. was lost in the ashes, the balance representing radiation losses (Zeit. des Ver. deut. Ingenieure, 1909, 1857). In trials on a goods locomotive on the Furness Railway, fired with Yorkshire, Lancashire, Cumberland, Scotch, and Welsh coals, the average boiler efficiency reported was 74.5 p.c. for an average evaporation of 8.65 lbs. of water per sq. ft. of heating surface (Pettigrew, Jour. Iron and Steel Inst. 1903, ii. 206). In coal-fired Lancashire boilers the efficiency realised rarely exceeds 70 p.c., and is sometimes much lower.

Anthracite is the ultimate product of the conversion of vegetable matter into coal. Its average composition is 91.29 C, 2.91 H, 2.75 O+N, 3.05 ash. The percentage of N varies from 0.58 to 2.85; that of sulphur from 0.63 to 1.0. Anthracite is hard and brittle; it has a sub-metallic lustre, a conchoidal fracture, and a sp.gr. of 1.35–1.7. It burns with a smokeless flame. Some varieties (*e.g.* Welsh anthracites) decrepitate considerably, even when gradually

heated. This property is not exhibited by the anthracites of Pennsylvania.

2. Carbonised Fuels.

Wood charcoal. When wood is heated to 200° without access of air, it remains unaltered, at 220° it becomes brown, and at 270°–300° it suffers decomposition, torrefied wood or *Rothholz* being formed. At 350° it is resolved into volatile products and a fixed residue of charcoal. Good charcoal produced at 350°–400° is porous, black, sonorous when struck, has a conchoidal fracture and a ligneous texture. It burns without smoke, and in separate pieces without flame. Its sp.gr., exclusive of pores, is 1.5–2; inclusive of pores, 0.2–0.35 in soft charcoal, and 0.35–0.5 in hard. Dry charcoal contains on an average 90 C, 3 H, and 7 O. After storing, it contains 70.45 C, 1.68 H, 13.1 O, 1 ash, 13.76 moisture and gases. The usual percentage of ash is 3–4. The carbonisation or dry distillation of the wood may be effected in the open air in circular piles or stacks (Meiler), provided with a yielding cover; in rectangular piles; in pits (the most primitive method); in kilns of brick or stone; or in iron retorts heated externally (method used in the manufacture of gunpowder and of pyroligneous acid). The yield of charcoal varies with the nature, age, and condition of the wood, and with the method of carbonisation, from 31 p.c. by volume (branchwood of fir) to 80 (logs of the same). In Sweden, 67 p.c. of the volume of the wood was obtained in piles in which the wood was stacked vertically, and 75 when stacked horizontally. The yield by weight ranges from 15 to 28 p.c. The more slowly the charring is effected, the greater will be the yield of charcoal. Charcoal is an excellent fuel for metallurgical purposes on account of its low percentage of ash and its high calorific power.

Peat charcoal is very friable and porous, and consequently difficult to use in metallurgical operations. When sufficiently coherent, and when the percentage of P_2O_5 is low, it may be used in low, small furnaces. The carbonisation may be effected in open kilns, in pits, or in ovens in which the air for combustion passes from above downwards, or by external firing in closed vessels, in order to enable the volatile products of distillation to be collected. Peat charcoal is easily kindled, and has a calorific power of 6500–7000 cal. It is not adapted for iron making, but may be used advantageously for gas furnaces, on account of the large size of the lumps, absence of clinker, and the fact that the ash readily falls through the bars.

Coke is the solid product of the carbonisation of coal. It varies considerably in external character. For metallurgical purposes, the best coke is compact, heavy, homogeneous, with bright light-grey surface. It contains, besides carbon and ash, small quantities of hydrogen (0.2–1.2 p.c.), oxygen (traces and up to 8 p.c.), nitrogen (0.4–1.5 p.c.), and 'organic' sulphur (total S=0.8–1.8 p.c.). The best cokes contain upwards of 90 p.c. C, and less than 8 p.c. ash, and should have a metallic ring. Coke is only slightly hygroscopic, and when thoroughly dried does not absorb more than 1–2 p.c. of moisture from moist air. The moisture in coke put on the market should not exceed 3 p.c. The calorific

value of dry coke containing 90 p.c. C and 0.5 p.c. H is about 7450 K.C.U. per kilog. (cf. COKE MANUFACTURE).

Semi-Coke (coalite) is the name given to the carbonaceous residue got by carbonising a gas coal at low temperatures (450°–600°). Various attempts have been made within recent years to manufacture in this way a satisfactory smokeless fuel for domestic use, the chief difficulty being to produce on a large enough scale, and at a price comparable with that of raw coal, a fuel capable of being economically transported by rail. Attempts have been made to overcome this difficulty by either compressing the product whilst it is still hot and in a pasty or intumescent condition, or by briquetting it with a suitable binder. A complete solution of the low-temperature distillation problem would not only be the best and most economical means of abolishing the domestic smoke nuisance, but would also make available large quantities of motor spirit and fuel oils for commercial and naval purposes. Laboratory tests upon typical British bituminous coals have shown that on carbonisation at 550° to 600° C. they will yield 10 to 15 per cent. of their weight of motor spirit and fuel oil, as well as 3000 to 4000 cub. ft. per ton of rich gas. Also, it has been proved that the resulting semi-coke burns with so high a radiant efficiency in domestic fireplaces that it would probably constitute the cheapest medium of heating living-rooms by 'radiation' (*vide* W. A. Bone, Proc. Mech. Eng. 1921, p. 625).

3. Compressed Fuels.

Patent fuel (briquettes). Numerous patents have been taken out for producing a good fuel by mixing various substances with small coal in proportions sufficient to enable the mixture to be pressed into a coherent block. Various binding materials have been tried, *e.g.* soluble glass, asphalt, pitch, and turpentine. Meal made from potatoes was abandoned because the blocks were not water-tight. Coal tar (Warlick's process) was tried at Swansea, the blocks being baked after compression, whereby a quantity of tar was recovered. On the Continent, cellulose (D. R. P. 7590, 1879) and treacle (D. R. P. 31715, 1884) have been tried. Pitch made from coal tar has been used for many years with great success. Two modes of manufacture are in vogue in South Wales. In the dry process, small coal is carried by an elevator into a large bunker, whence it is lifted by another elevator to a shoot into which it is tipped with the contents of a small elevator containing pitch. The mixture then passes into a Carr's disintegrator, and the resulting product, containing 8–12 p.c. of pitch, passes to heaters, and finally to the presses, which turn out 100–200 blocks, weighing 10–30 lbs. per day of 12 hours. In the steam process, there is used a large vertical iron cylinder with arms revolving inside, constantly kept full of the mixture of pitch and coal. High-pressure steam is injected near the bottom, and allowed to percolate up through the mass, whilst the arms expose every portion to its action. Mixtures such as these described are also compressed into small ovoid briquettes of various sizes, suitable for domestic use or steam-raising purposes on boilers fitted with mechanical chain

grates. Attempts have been made to utilise peat by mixing it in a state of powder with small coal and sawdust, and pressing the mixture into blocks. Also dried lignites, or the non-coherent carbonaceous residues obtained by carbonising them at low temperatures, may be successfully briquetted with the addition of pitch as a binder. According to tests carried out by the staff of the U.S. Geol. Survey in 1904, it is possible to make good briquettes from a strongly coking coal, heated until intumescence just begins, and immediately afterwards pressed, without the addition of any binding agent. Anthracite culm or coke breeze may be briquetted without the addition of any bituminous coal, provided that good pitch be used as a binding agent. The pitch should be anhydrous, or nearly so, and should contain a certain proportion (7-14 p.c.) of creosote oils distilling below 215°, to give it good binding properties; the presence of free carbon in any quantity is objectionable, and the pitch should not flow below 70°. A good quality of powdered coal with 6 p.c. of pitch should yield a clean hard briquette, which will not disintegrate in the fire. In many cases briquetted coal will stand transportation better than the original coal, and is as good or even better as a steam-raising fuel.

The pre-war cost of briquetting coal in this country (including capital charges) was between 2s. 6d. and 3s. per ton. The world's production of briquettes amounted to upwards of 30 million tons, of which nearly three-fourths were made in Germany.

Literature.—E. Preissig, *Presskohlenindustrie*, Freiberg, 1887; Report of Coal Testing Plant of U.S. Geol. Survey, iii. 1904; A Handbook of Briquetting, G. Franke (Berlin), translated by F. C. A. H. Lantsberry, 2 vols. (Griffin & Co., London), 1916-1918.

4. Powdered Fuels.

It is well known that a mixture of coal dust and air is highly explosive, and in burning coal the excess of air actually required diminishes with the fineness of division of the fuel. The efficiency of the combustion approaches the theoretical maximum the more nearly the system attains to the homogeneity of a properly proportioned gas-air mixture. Much progress has been made in recent years in applying powdered coal to boilers and metallurgical furnaces. As long ago as 1873 Crampton (*Jour. Iron and Steel Inst.* 1873, 91) worked out a system whereby pulverised coal was fed into furnaces through an injector type of burner, air being supplied in measured quantities by a fan, so that intense heat was generated. In recent years the system has been largely applied in America to cement kilns, reverberatory and open-hearth furnaces, with considerable success, and it is also being developed in connection with boiler-firing. According to Canadian experience, the following conditions are essential for obtaining the best results: (1) that the coal shall be dried so that its moisture content is less than 1 p.c. before being pulverised; (2) that it shall be pulverised until 85 p.c. of it passes through a 200 mesh, and 95 p.c. of it through a 100 mesh; (3) that the furnace shall be properly shaped and proportioned, and be suitably equipped

with burner and feeding arrangements so that the relative deliveries of coal dust and air can be well controlled, and that special provision shall be made for the periodic removal of ashes from the flues at the far end of the furnace. In regard to steam-raising, special mention should be made of the use of pulverised coal in the Bettington boiler, which has been successfully developed in this country and in S. Africa. For particulars of recent developments of pulverised coal systems in America *vide* The Fuel Research Board's Special Report, No. 1 (1919), by L. C. Harvey.

Valuation of coals. Whilst the value of coal as a fuel depends primarily upon its calorific value, other factors must be considered in determining its suitability for any given purpose, as, for instance, (1) moisture content; (2) quantity and fusibility of ash; (3) percentage of 'volatiles' and the character of the coke residue; (4) ultimate analysis—C, H, S, and N—the N being important if the coal is to be carbonised or gasified in producers under ammonia-recovery conditions. Coal is rarely purchased in Great Britain subject to either chemical analysis or calorific test, but the practice is common in the United States and in certain European countries, the contract, in any particular case, naming a certain price for a coal of specified quality, subject to a sliding scale for variations in quality within certain defined limits. In sampling a consignment of coal for assay purposes, special care should be taken that the sample truly represents the bulk; the method adopted will obviously depend somewhat on circumstances, but the sample should contain the same proportions of large, medium, and small coal as the bulk, and, as a rule, should weigh not less than 1 cwt. On reaching the laboratory the whole should be put through a crusher and subsequently reduced to convenient bulk by successive 'quartering'; the final sample should then be further crushed to coarse powder and stored away in air-tight tins. The chemical tests may be carried out as follows: (1) *Moisture and ash.* 10 grams of sample, in a weighed porcelain basin, are dried in an oven at 105° for 1 hour, and subsequently incinerated in a muffle at bright red heat, care being taken that the initial 'distillation' is not too rapid. The colour of the ash should be recorded, and observation made as to its fusibility. (2) *Volatile matter.* The method recommended by a committee of the American Chemical Society is to determine loss in weight when 1 gram of the dry sample is heated in a covered platinum crucible of 30 c.c. capacity for 7 minutes over the full flame of a Bunsen burner, screened from draughts by a cylindrical asbestos chimney. A more useful test, however, is the 'crucible coke assay,' in which 20 grams of the dried sample are carbonised in a fire-clay crucible (lid on) at 900°-1000° in a muffle furnace; the heating is continued for 5-10 minutes after the flame, caused by the volatile matter burning at small holes in the crucible lid, has completely died away. A new method, capable of giving more accurate results of scientific as well as of commercial value, has been described by Bone and Silver (*Trans. Chem. Soc.* 1921, 119, 1145); also another improved method has been proposed by Lessing (*J. Soc. Chem. Ind.* 1912, 31, 465).

(3) *Ultimate analysis for C and H.* This may be carried out on a dried sample (0.2 gram) by the 'combustion' method ordinarily employed in the case of organic compounds, the combustion tube being packed with granular lead chromate. (4) *Sulphur.* (a) About 2 grams of the sample are ignited with three times its weight of a mixture of 2 parts MgO and 1 part pure anhyd. Na_2CO_3 in a porcelain dish or large crucible for $1\frac{1}{2}$ hours in a muffle furnace (preferably electrically heated). Afterwards the charge is washed into a beaker, excess of dil. HCl plus bromine water is added, and after boiling off the excess of bromine, the contents of the vessel are vigorously stirred and then filtered. The sulphate in the filtrate is then precipitated with a slight excess of $\text{Ba}(\text{NO}_3)_2$, and finally estimated as BaSO_4 in the usual manner. Determinations are made in triplicate, and a blank experiment is always simultaneously performed in order to determine the 'correction' to be applied on account of any traces of sulphate in the reagents employed or the fixation of SO_2 by them from the furnace gases. (b) In determining the sulphur in the ash of a coal, it is fused in a platinum crucible with an excess of Na_2CO_3 and K_2CO_3 mixture plus KNO_3 in order to convert all sulphur compounds into soluble sulphates. The fused mass is subsequently extracted with excess of hot dil. HCl, and the extracted sulphates determined as BaSO_4 in the usual way. (5) *Nitrogen* is best determined by the ordinary Kjeldahl method. Occasionally coal or coke must be examined for *arsenic*. (For details of the method recommended by the committee appointed by the Board of Inland Revenue, see T. E. Thorpe, Estimation of Arsenic in Fuel (Chem. Soc. Trans. 1903, 83, 969).)

Storage and spontaneous ignition of coal. It is well known that on storage coal deteriorates both as regards heating power and coking properties, a fact attributable to slow atmospheric oxidation, which may, in certain circumstances, give rise to spontaneous ignition of the coal. It was formerly believed that the oxidation of the iron pyrites present in coal is the principal cause of its spontaneous ignition, but it is now recognised that this is not so, the chief factor being the surface condensation of oxygen in the pores of the fuel, and subsequent oxidation of certain constituents of the coal substance. It has also been suggested, on the basis of experimental evidence, that in some cases of spontaneous combustion, the heat generated by bacterial activity is a factor to be considered. Coal readily absorbs oxygen when heated in contact with air at 150° – 200° , the process being not merely a physical absorption, but involving actual oxidation of coal substance; the weight first of all increases, and afterwards, especially if the temperature rises, steadily decreases owing to loss of moisture, slow combustion, and decomposition. According to investigations by S. W. Parr and F. W. Cressman, of the University of Illinois, the oxidation of coal is continuous over a wide range of conditions, and begins with freshly mined coal at ordinary temperatures; at some temperatures between 200° and 275° (dependent upon the nature of the coal and the fineness of division) the oxidation becomes autogenous; actual ignition does

not occur until the temperature rises beyond 350° . With regard to the influence of pyrites, it was found that the amount of 'pyritic oxidation' under given conditions is always proportionate to the pyritic content of the coal, so that an increase in the latter may therefore hasten 'the rise in temperature up to the critical point at which the absorption of O by the coal itself is rapid enough to increase the temperature up to the point of self-ignition.' Hence, pyritic oxidation may become a contributory (though not the chief) factor in the spontaneous ignition of coal, although *by itself*, and apart from the simultaneous oxidation of the coal substance, it would be a negligible one. According to Parr and Cressman, the presence of moisture increases the reactivity of the coal-air system at any temperature. The whole phenomenon is probably one of 'surface combustion.' According to Bone's investigations the absorption of O by typical British (Durham and Yorks.) bituminous coals is very slow at temperatures below 80° , and is unattended by the production of relatively insignificant quantities of the oxides of carbon. But in the neighbourhood of 80° the action becomes much quicker, and at above 100° is marked by the regular and simultaneous production of both the oxides of carbon as well as steam, all of which apparently result from the decomposition of some unstable 'oxygenated' body primarily formed by the absorption of the oxygen. An important official report upon The Spontaneous Combustion of Coal in Mines, containing a full account of recent researches by R. V. Wheeler and others, has recently been issued (Cmd. 1417 of 1921). With regard to the storage of coal, it has been proved that coal stored *under water* suffers no deterioration. The conditions most favourable to spontaneous ignition of coal when stored in heaps are (1) a certain, but not excessive, ventilation of the heap; (2) a certain degree of subdivision (e.g. small coal mixed with dust); and (3) any circumstance which tends to heat conservation in the heap. The best safeguard is either excessive ventilation (which it is practically impossible to maintain in large stores or in a ship's hold) or no ventilation at all. The extinction of fires which may break out on board ship is often a matter of great difficulty, the most effective method being that recently proposed by Harker, whereby the flue gases from the boilers of the vessel are pumped into the burning hold.

British coal-fields. The coal-fields of Great Britain may be grouped in three principal areas, each having distinctive features, namely: (a) *Southern* (S. Wales, Forest of Dean, Somerset, and Dover); (b) *Central* (Yorkshire, Lancashire, Derbyshire, N. Wales, and Midland Counties); and (c) *Northern* (Scotland, Northumberland, Durham, and Cumberland). The more important fields are as follows:—

(1) *South Wales* (Monmouth, Glamorgan, Carmarthen, and Pembrokeshire), covering an area of 850 sq. miles, of which 150 are under the sea, with seams 1–12 feet (average 2.5–3.0 feet) thick, and yielding all classes of coal, bituminous (31 p.c.), steam coals (47 p.c.), and anthracites (22 p.c.). The carboniferous strata lie in an elongated basin, which is almost com-

pletely surrounded by older formations, and complicated towards the south by an anticlinal fold running east and west. The basin is much faulted, and the rivers have cut a series of deep valleys along which the coal seams crop out. Speaking generally, and for corresponding depths below the surface, there is a gradual transition in the character of the coal from the coking varieties in the east, through the first-class steam coals of the centre, to the semi-anthracites and anthracites in the west; moreover, the seams have apparently been subjected to an increasing earth pressure in the direction east to west, a circumstance which may account for their increasing anthracitic character. This supposition has been disputed

by Strahan and Pollard (Memoirs of the Geological Survey, 1908), who, from the fact that the ash content of the anthracites is invariably much lower than that of the neighbouring bituminous seams, argue that the difference between the two classes of coals must be due to some difference in the original vegetable *débris* from which they have been derived. In the east section of the field the upper and middle coal-measures are worked, yielding good coking and bituminous coals; in the centre the middle measures predominate, the upper being found in patches only; whilst in the extreme west the lower measures only are found. The composition of the more important classes of coals usually falls within the following limits:—

Class	C	H	O and N	S	Ash	Volatiles
Anthracites . . .	91·0-93·0	3·0-3·7	1·9-3·5	0·7-1·0	0·7-1·7	5·0-6·0
Steam . . .	85·0-90·0	4·0-4·7	3·5-4·5	0·7-1·5	2·0-3·3	7·0-20·0
Bituminous (coking)	80·0-95·0	5·0-5·5	—	—	—	20·0-25·0

(2) *Forest of Dean*. A small field (34 sq. miles) between the Wye and Severn valleys, containing 31 seams, of which only 16 exceed 1 foot in thickness. The total thickness of the measure is 2765 feet, and they are completely girdled by older formations. The coals resemble in character those found in the east section of the S. Wales field; the upper and middle measures yield excellent gas and house coals, and the lower measures, which, however, are difficult to work, owing to accumulation of water therein, contain good steam coals. (3) *Bristol* (Somerset and Gloucester). The coal-fields of this region form a number of basins of varying areas (total=2385 sq. miles), the edges and outlines of which are marked by newer rocks, so that there are five or six detached 'exposed' fields and a considerable intervening area of 'concealed' fields. The upper parts of the measures (the Radstock and Farringdon series) yield bituminous house and gas coals; the lower parts (Kingswood and Volster series) yield both house and coking qualities. All these are consumed locally. (4) *Staffordshire*, divided into N. Staffs. (95 sq. miles) and S. Staffs. (150 sq. miles). In the northern area the sequence of upper, middle, and lower measures is complete, although much broken by faults; towards the south the measures thin out considerably in respect of total thickness, but the individual seams converge, finally forming the famous Dudley 10-yards seam; in the extreme south the lower measures become so attenuated that it is doubtful whether they exist at all. The northern area yields good coking as well as gas, house, and furnace coals; in the south coking and steam coals are practically non-existent, but both gas and house coals (chiefly of the Pennant series) are obtained. (5) *Leicestershire and Warwickshire*. In Leicestershire the exposed area is about 30 sq. miles, and in Warwickshire about 150 sq. miles; the seams have been subjected to igneous intrusion, and probably also to atmospheric influences, and are generally 'oxidised'; hence the coals are non-coking, with a high percentage of 'volatiles.' (6) *Yorkshire, Derbyshire, and Nottingham*. A large area,

including some 1328 sq. miles of 'concealed,' and about 808 sq. miles of 'exposed' measures; the upper measures have been proved in boring operations, but they are very thin and of no commercial importance. Throughout the area the sequence of the Carboniferous Formation is complete, the coal-bearing measures being underlaid by the Millstone Grit and the Carboniferous Limestone, and they have nowhere been affected by igneous intrusions. The chief seams belong to the Pennant (middle) series; all seams yield highly bituminous coals, with 25-40 p.c. 'volatiles.' The best house coals are obtained in this field. All the coals found north of Sheffield have marked coking properties, though few of them yield a really first-class coke; south of Sheffield the character of the coal changes, gradually losing its coking properties. Between Mansfield and Nottingham the seams have been 'oxidised,' and although the coal yields a large amount of gas, it is non-coking. (7) *Lancashire*. An irregular area, much faulted and broken by an E.-W. anticline, extending from Burnley in the north to Ashton-on-Lyne in the south (with a long tongue projecting southwards through Stockport to Macclesfield), and from Oldham in the east to St. Helens in the west; total 'exposed' area=500 sq. miles. The principal seams in the southern and central areas of the field are all formed in the middle parts of the measures, the upper parts contain no workable seams. The seams in the lower part of the measures become important in the Accrington and Burnley districts. The coals from seams in the middle parts of the measures belong almost exclusively to the 'gas-coal' class, containing 30-35 p.c. 'volatiles'; several of the seams, notably the Yard Mine, Arley, and Trencherbone, yield a fairly good coking coal. The famous 'Mountain Mine' seams of the lower measures (Burnley and Accrington) yield a coal with 26-27 p.c. 'volatiles,' which produce a coke almost, if not quite, equal to the best Durham coke. (8) *North Wales* (Flints. and Denbighs.). Similar in character to the Lancashire field, but with the upper measures rather more developed.

All the workable seams, however, are in the middle parts of the measures; the seams in the lower parts of the measures are all thin. The coals are similar to those of Lancashire; they contain 33-35 p.c. 'volatiles,' and yield a fair quality of coke. (9) *Durham and Northumberland*. In the great northern coal-field, of which Durham and Northumberland form a part, there is a development of coal-seams (more strongly marked the farther north) in the Carboniferous limestone, a feature which is absent in the Midland and Southern fields. In the Limestone series there are a few workable seams which increase in number and thickness from south to north, but in the main part of the field the coal occurs chiefly in the middle parts of the measures. The total area of the coal-field is 800 sq. miles. The S. and W. districts of Durham produce, perhaps, the finest coking coals in the world, containing 22-28 p.c. 'volatiles,' and low both in sulphur and ash. The central district (Sunderland to Newcastle) produces fine qualities of gas and house coals. The Northumberland seams are, for the most part, 'oxidised'; they contain a rather large amount of moisture, and are non-coking. They are largely used as steam coals, and they are excellent as 'producer' coals. (10) *Cumberland*. The character of the coals is similar to those obtained in N. Durham. (11) *Scotland*. The Scottish coal-fields extend from Fifeshire on the east, across a belt between the Forth and Clyde, and westwards into Lanarkshire and Ayrshire, with an isolated small area in Midlothian. The upper parts of the measures are well developed throughout the area. The middle parts of the measures attain a thickness of from 800 to 1500 feet. Below the latter is the 'edge-coal' group in the Carboniferous Limestone series, highly inclined at its outcrop (Fifeshire, Midlothian), and containing bands of cannel. Generally speaking, the coals are bituminous, with a high percentage of 'volatiles'; the best coking varieties are found in the neighbourhood of Glasgow, and the coking seams stretch as far eastward as the Firth of Forth. The Ayrshire coals are chiefly non-coking, and are excellent as 'producer' coals. In Fifeshire the seams in the Carboniferous limestone in the neighbourhood of Dunfermline yield first-class steam and house coals. The Scottish coal-fields have been subjected to igneous intrusions to an extent rarely met with in England, and, consequently, some of the bituminous seams have been locally converted into steam coals and anthracitic varieties.

German coal-fields. The principal coal-fields formerly included in the German Empire are those of (1) *Upper Silesia* (districts of Ratibor, Beuthen, Zabrze, Königshütte, Laurahütte, and Pless). The measures are 600 metres deep with seams 3-4 metres thick. The best coking coals are found near Zabrze eastwards, from which they gradually change into young gas coals, near Königshütte, and finally into non-coking flaming coals near Laurahütte. (2) *The Ruhr basin*, stretching from the neighbourhood of Hamm in the N.E. to the Rhine in the S.W.; the field is much broken by faults, and the older measures, which yield the best coking coals, are, as a rule, uppermost; the middle measures yield gas coals, and the lower

measures non-coking varieties. The coals of the Ruhr basin contain 84-97 p.c. of organic matter, of which C=83.1-87.1, and H=5.27-5.68. (3) *The Saar district*; the upper and middle measures are both thin and yield non-coking and flaming coals, the lower measures are thick, and yield (especially the deepest) very good caking and coking coals. The ash in Saar coals varies between 1.5 and 4.5 p.c. as a rule, occasionally running up to 7.7 p.c. The carbon varies between 70 and 84 p.c., and the hydrogen between 4.7 and 5.2 p.c.

American coal-fields. The following information has been abstracted from the comprehensive Report of the U.S. Geological Survey issued in 1906; the chief coal-producing states are arranged in order of their present economic importance, the figures in brackets indicating in each case the output in millions of short tons, for 1904. (1) *Pennsylvania* (73.1 anthracitic and 98 bituminous). The anthracite field lies in the N.E. and the bituminous field in the W.; the latter produces the famous Connellsville coking coals, the almost equally famous Yonghiogheny gas coals, and numerous grades of steam and domestic coals. (2) *Illinois* (36.5). This state includes the greater part of the eastern interior coal-field, which extends from Rock Island and Wilmington (Ill.) in the north to Central Kentucky in the south and from the Mississippi river in the west to Williamsport and Cannelton (Ind.) in the east. The coals are rather low grade and weakly coking, containing C=54-76, H=4.5-5.3, N=0.8-1.2, S=1.3-4.5, O=12.0-18.5, and ash=12.0-24.0 with calorific values 9929-11,907 B.Th.U. per lb. The proximity of the field to Chicago and St. Louis enhances its economic importance. (3) *West Virginia* (32.6). This state includes a large portion of the important Central Appalachian coal-field, which produces high-grade steam coals also suitable for coking purposes, and containing C=74-86, H=4.0-5.2, N=1.0-1.7, S=0.5-1.2, ash=4.6-11.3, with calorific value 13,736-15,190 B.Th.U. per lb. (4) *Alabama* (11.26) includes several fields of which the Warrior basin is the most important (23 workable seams), constituting the fuel supply of the Birmingham (Ala.) iron industry. The coal is of fair coking quality, containing C=69-72, H=4.8-5.0, N=1.55-1.66, S=0.7-1.02, ash=12.5-12.6, with calorific value 12,238-12,992 B.Th.U. per lb. (5) *Indiana* (10.9) includes the eastern section of the Eastern interior coal-field (*vide* Illinois). (6) *Kentucky* (7.5). The eastern part of the state includes part of the Central Appalachian coal-field (*vide* West Virginia) and part of the eastern interior field in the west. Both fields yield good steam and coking coals, the eastern area being in this respect superior to the western; the coke for the western field has too high a S content to be of much use as a metallurgical fuel. (7) *Colorado* (6.65). The most important coal-producing state west of the Mississippi river; the coal is a black lignite, which so rapidly disintegrates on exposure to air, that its transport over any great distance is impossible. It contains C=61.1, H=5.75, N=1.22, S=0.58, O=24.95, ash=6.37, with cal. value 10,546 B.Th.U. per lb. (8) *Iowa* (6.5) yields only low-grade coals containing high percentages of moisture, sulphur, and ash, with very feeble coking properties.

(9) *Kansas* (6.3) yields fairly good non-coking steam coals. (10) *Wyoming* (5.1) contains a number of apparently independent coal-fields in strata of the Cretaceous age; the fuel is low grade. (11) *Indian Territory* (3.04) produces good steam coal, with, in some instances, fair coking properties, but usually high in sulphur. C=63.72, H=4.8-5.2, N=1.4-1.7, S=1.5-4.0, ash=10.0-13.5, with cal. value 11,340-12,874 B.Th.U. per lb. The coke is good enough for lead smelting, but unsuitable for iron smelting.

B. LIQUID FUELS.

Whilst increasing quantities of hydrocarbon oils (crude petroleum or its distillation products, shale oil, benzol, &c.) are being used as fuel for certain special purposes, they cannot be regarded as a serious competitor of coal or as in any real sense a substitute for it; it is doubtful whether the calorific value of the world's entire output of petroleum and other liquid fuels in any given year exceeds (if, indeed, it is equal to) 5 p.c. of that of the corresponding output of coal. Nevertheless, there are certain selected purposes (e.g. for motor-car engines and the like) for which volatile hydrocarbon oils are employed without displacing coal or gaseous fuels, and other special cases, notably steam raising in ships of war, in which liquid fuel has important advantages over coal. In respect of naval requirements, these are principally (i.) economy of space and ease in replenishing supplies; (ii.) ready and immediate response to varying loads; (iii.) possibility of forcing boiler to extreme duty in case of emergency; (iv.) absence of smoke under normal working conditions; (v.) shortness of chimney stack; (vi.) abolition of stoking; and (vii.) ability to secure and maintain higher speeds than with coal firing. Some of these advantages are also of value in relation to locomotive-boiler firing, especially in countries (United States, Russia) where petroleum is abundant. In the Report issued by the U.S. 'Liquid Fuel' Board in 1904, the relative all-round efficiencies of oil and good steaming coal, from the naval point of view, are estimated to be as 18:10, whilst Mr. James Holden, locomotive superintendent of the G.E.R., in giving evidence before the Royal Commission on Coal Supplies, stated that, according to his

experience, petroleum fuel oil had, weight for weight, approx. twice the steam-raising power of coal in locomotive boilers. The latter estimate is probably based on the best rather than on the average results obtained with oil fuel, but certainly the ratio is not less than 3:2. Moreover, weight for weight, oil occupies much less space than coal, whilst oil does not deteriorate on long keeping as does coal.

Petroleum fuel oil (see also PETROLEUM). About 63 p.c. of the world's total supplies of petroleum are drawn from the United States (California, Kansas, Indian Territory, Oklahoma, Ohio, Texas, Pennsylvania, Virginia, Louisiana, and Illinois), and a further 25 p.c. from Russia (mainly the Baku oil-field); the remaining 12 p.c. is chiefly derived from Roumania, Galicia, India, and the Eastern Archipelago. The total annual output probably amounts to about 1000 million imperial gallons. Crude petroleum, in its natural state, often contains a certain amount of water in emulsified form, and also of volatile hydrocarbons. The oil should be both dehydrated and freed from volatile constituents before it can be safely transported, stored, and used as fuel. In Germany and for the British mercantile marine, the prescribed minimum flash-point for fuel oil is 150°F. (Abel test), whilst the British Admiralty require a minimum of 200°F. for warship fuel. A good fuel oil should also be sufficiently free from solid hydrocarbons to stand a temperature of 0° without solidification.

The appearance of crude fuel oil, as put on the market, varies greatly, according to its origin; some varieties have a pale colour and are mobile, others are viscous and almost black in colour. Sp.gr. varies between 0.771 and 1.06; American oil has sp.gr. 0.785-0.936; Baku oil, 0.854-0.899; Galician oil, 0.799-0.902. Whilst consisting essentially of hydrocarbons, crude oils contain small but variable percentages of N, S, and O. The nitrogen (0.25-1.0 p.c.) is present in the form of basic substances, probably of the pyridine or quinoline type; sulphur (0.5-1.5 p.c.) occurs both as alkyl sulphides (American oils) and as thiophen compounds (European oils). The following gives the ultimate composition of various crude oils:—

Origin	C	H	N	S	O	Sp.gr.
California	84.43	10.99	0.65	0.59	3.34	0.962
Texas	84.60	10.90	—	1.63	2.87	—
"	85.75	12.75	—	1.47	—	—
Java	87.1	12.0	—	—	—	0.923
Baku	85.3	11.6	—	—	—	0.940

Of the hydrocarbon constituents, members of the following series are known to be present in petroleum: C_nH_{2n+2} *paraffin*, C_nH_{2n} *naphthenes*, and C_nH_{n-2} . . . C_nH_{n-12} . Mendeleeff has concluded that all crude oils contain the same classes of hydrocarbons, but in widely different proportions. Pennsylvanian oil consists chiefly of the C_nH_{2n+2} series; Californian oil chiefly of the C_nH_{2n} (naphthene) series, together with some benzene and its homologues; Texas oil, which is dark in colour and viscous, contains principally members of the C_nH_{2n-2} and

C_nH_{2n-4} series; naphthenes C_nH_{2n} , constitute 80 p.c. of Baku oil. Of hydrocarbons, such as naphthalene, acenaphthalene, fluorene, anthracene, and phenanthrene, all of which are found in coal tar, the only one undoubtedly present in crude petroleum is naphthalene. The gross calorific value of petroleum fuel oil varies, as a rule, between 10,350 and 11,000 K.C.U.s. per kilog.; the natural oils best adapted for fuel purposes are those derived from California, Texas, Mexico, and Borneo. In Russia, where a great oil-fuel industry has been developed, the residue ('astatki') after distilling off the kerosene and burning oil, is used. In applying oil to boiler and furnace work generally, the fuel must be 'atomised' by means of a jet of high-pressure steam or compressed air in a special form of burner working on the 'injector' principle. The oil should enter the furnace as a fine spray, intimately mixed with the air requisite for its combustion. Many forms of such burners are on the market. From the chemical aspect of combustion of the oil, the use of compressed air is preferable to steam as the 'atomising' agent, although, in fact, steam is more usually employed. In other forms of burners, the 'atomising' is effected, without either air or steam, simply by forcing the oil (preheated to 130°) under considerable pressure (50 lbs. per sq. inch) through a suitable orifice.

The following typical burners may be quoted as examples: (a) the 'Carbogen' burner (Fig. 1), which may be used with either

FIG. 1.

steam or compressed air as the atomising agent: (b) the 'Kermode' hot-air burner (Fig. 2), in which the oil is partially vaporised and sprayed by means of hot air at a pressure of from $\frac{1}{2}$ to 4 lbs. per sq. inch. The oil enters at A, its further flow being regulated by a conical valve and slit. The air, suitably preheated, enters at the branches B and C; the portion passing

FIG. 2.

through C meets the oil as it passes the oil-control valve, which is regulated by the wheel E, and both travel on together through the central tube K, in which is fixed a helix, whereby complete mixture of oil vapour and air is ensured. The two air supplies, through B and C, are separately controlled by means of the rack and pinion at M and L respectively; and (c) the 'Kermode' pressure jet burner (Fig. 3), in which a supply of oil pumped into the burner through

the side tube A, and passing thence through the narrow annulus D, is 'atomised' by being forced through a series of narrow grooves cut in the plug end of B, parallel to the centre line of the burner, whilst similar grooves are cut in the face of B at right angles to the axis of the burner. The grooves, as shown in H, are tangential to the cone end of the spindle C, which regulates the size of the available opening through the cap nut E. A separate forced or induced air draught is used

FIG. 3.

with this burner. (d) A type of burner designed by Messrs. John Burden and Sons, of Bellshill near Glasgow, in which an air-injected oil spray is completely gasified and mixed with air before ignition by passage through a heated iron tube, by which means a perfectly non-luminous 'bunsen' flame of great calorific intensity is obtained.

The furnace in which the 'atomised' oil is burnt should be so constructed that the flame does not come into direct contact with cold metallic surfaces. An incandescent solid surface greatly assists the completion of combustion and prevents smoke formation. (For various forms of burners, boiler-furnaces, and the like, v. W. H. Booth, *Liquid Fuel and its Combustion*, 118-221; also Redwood's *Petroleum*, ii. 705-714.)

Petroleum oils are also employed as fuel in internal-combustion engines. With all the earlier forms of petroleum engines, as with the modern motor-car engine, it was necessary to employ a light petroleum spirit ('petrol'), but in modern types of stationary engines, kerosene and even unrefined oils of higher boiling-points may be used. These engines usually work on the four-cycle principle. A charge of vaporised oil and air is drawn into the cylinder on the out-stroke of the piston: on the return stroke it is compressed and fired by a spark at the inner dead point. The piston is then propelled outwards by the explosion, and on the return stroke the products are expelled. Part of the heat of the products is utilised in vaporising the oil or heating the air, or both. According to trials made for the Royal Agricultural Society in 1901 by Professor Ewing, the oil consumption (American kerosene, sp.gr. 0.801, flash-point 86°F. , and cal. value 10,329 K.C.U.s. per kilog.) on 5 types of engines, developing 6 to 15 b.h.p., varied between 0.69 and 1.30 lb. per b.h.p.-hour. The highest thermal efficiency indicated by these trials was 20 p.c. The Diesel oil engine, which

has a higher thermal efficiency than any other heat engine, burns ordinary unrefined fuel oil; the cycle consists of four strokes, namely, (1) out-stroke, in which air at atmospheric pressure is drawn into the cylinder; (2) compression stroke, in which the air is compressed to about 35–40 atmospheres, thereby becoming highly heated,—when the compression has reached about 10 atmospheres, part of the air is drawn out by a single-acting air pump and forced into a receiver (which is in direct communication with the admission valve chamber) at a pressure of about 47 atmospheres; (3) out-stroke, during the initial part of which oil, previously forced into the admission valve chamber, is sprayed into the cylinder by a small quantity of the highly compressed air in the receiver. The oil immediately burns in the hot compressed air in the cylinder, no sparking or other similar ignition device being required to start the combustion; the products of combustion then expand,—this is the working stroke; and (4) return stroke, the products are expelled from the cylinder. The makers of the engine guarantee that the consumption of crude petroleum will not be more than 0.452 lb. per b.h.p. per hour at full load, equivalent to a thermal efficiency of 35 p.c. Exhaustive trials by Mr. Ade Clark (Proc. Inst. Mech. Eng. 1903) on a two-cylinder 160 h.p. engine at Ghent, showed a thermal efficiency at full load of 32.3 p.c. per b.h.p.-hour; on a single-cylinder 80 h.p. engine, the corresponding efficiency was 31.2 p.c. The Diesel Engine Co. have produced a marine type of engine which can be coupled direct to the propeller shaft without the intervention of a clutch or other similar gear. The engine is reversible, and its speed is variable at will. Successful trials have been made with coal tar as fuel for the Diesel engine.

Literature.—Redwood, Petroleum (2 vols.), and W. H. Booth, Liquid Fuel and its Combustion.

C. GASEOUS FUELS.

The great advantage of gaseous over solid or liquid fuels, for heating purposes, lies in the fact that they can be completely burned in furnaces of regenerative type with only a slight excess of air, and they are therefore specially adapted for purposes where very high temperatures on a large scale are required. The absence of smoke and ash makes their extended use, from the public point of view, eminently desirable; moreover, the possibility of gasifying coal under ammonia-recovery conditions, coupled with the much higher thermal efficiency of an internal-combustion engine as compared with a steam engine or turbine, has firmly established the position of gaseous fuels in relation to power schemes.

Natural gas. In the petroleum districts of Pennsylvania and adjoining states, natural gas issues from the strata at a depth of 500–2000 feet below the surface, and when bore holes are sunk into this accumulation, the gas rises under a mean pressure of 250–400 lbs. per sq. inch. Between the years 1821 and 1883 natural gas had been used in a limited way for illuminating and heating purposes; since 1883, however, it has undergone an extraordinarily rapid development for industrial purposes. According to the Report of the British Iron Trade Association

Commission to the United States (1902), the companies engaged in the natural-gas business in the Pittsburgh district were operating nearly 3000 miles of pipe lines, and the daily consumption of gas throughout the year averaged about 50 p.c. greater. Two companies brought gas from a distance of more than 100 miles. In 1914 the total production of natural gas in the U.S. was 591,866 million cub. ft., the fuel value of which was computed at 94 million dollars. The composition of the gas varies in different wells, and even in the same well after a short lapse of time; methane (64–94 p.c.) is its principal constituent; hydrogen (3–30 p.c.), together with small percentages of ethane, ethylene, carbon monoxide, and nitrogen make up the balance. The density varies between 0.45 and 0.55. Analyses of natural gas as supplied to 25 cities in the U.S. are given in U.S. Bureau of Mines Technical Paper, No. 109 (1915), according to which five of the samples contained methane only as the combustible gas, the remainder containing in addition thereto higher paraffins (particularly ethane). Processes have been installed for extracting 'gasoline' from such 'paraffinic' gases by absorption methods, using petroleum distillates or naphtha as the wash-oil. Natural gas also occurs in the southern plains of Alberta (Canada). In the Bow Island area it is obtained at 800 lbs. pressure, and, according to the Canadian Department of Mines, Memoir 93 (1917), the possible production of this field alone amounts to 50 million cub. ft. per diem; it contains $\text{CH}_4=86.7$, $\text{C}_2\text{H}_6=1.8$, $\text{H}_2=5.4$, $\text{N}_2=6.1$ p.c. Natural gas has never been found in Great Britain except in too small quantity to be industrially important; in 1895 gas was encountered during well-sinking operations at Heathfield (Sussex), at a depth of 300 feet. In 1902 gas was issuing from the bore holes at a pressure of 140–200 lbs. per sq. inch; it contained 93.16 CH_4 , 2.94 C_2H_6 , 1.00 CO, and 2.9 p.c. N_2 , but no hydrogen.

Coal gas (coke-oven gas). Gas manufactured by the carbonisation of bituminous coals in fire-clay retorts, freed from tar, NH_3 , and H_2S , and in some instances mixed with either blue or carburetted water gas, constitutes the chief public gas supply throughout the world. Within recent years the surplus gas from by-product coking plants has been purified for public use, and in localities where metallurgical coke is largely prepared, 'coke-oven gas' will probably be more extensively used in the future. The composition of coal gas varies considerably in different localities, according to the nature of the coal, the nature and disposition of the retorts, and the temperature of carbonisation. A good 'straight' coal gas as formerly supplied to the public in this country contained 45–50 H_2 , 30–35 CH_4 , 4.0 heavy hydrocarbons (reckoned as C_3H_8), 5.0–10.0 CO, together with not more than of about 8.0 p.c. N_2 ; and it had a cal. value 575 net and 645 gross B.Th.U.s. per cub. ft. at 0° and 760 mm.

With the almost universal adoption of incandescent mantles for lighting purposes and the consistent increasing uses of gas for domestic heating purposes, the need of so rich a gas of high self-illuminating power diminished, a condition which opened the way for cheaper

production by raising the temperature of the retort settings. In 1913, the average gross calorific value of the gas supplied in six of the largest cities of Great Britain was about 580 B.Th.U.s. per cub. ft. at 60°F. and 30 in. barometer. During the war, the gas was almost universally 'debenzolisised,' whereby its gross calorific value was reduced to between 450 and 500 B.Th.U.s. per cub. ft. Long before the war, some gas undertakings had regularly mixed either 'blue' or 'carburetted' water-gas (*g.v.*) with the coal gas sent out of their works; and this practice is likely to grow considerably in future, especially as the Gas Regulation Act, 1920, has ordained that in future consumers shall be charged according to the Thermal units ('Therms' of 100,000 B.Th.U.s.) actually supplied. It is probable that post-war gas-standards will mostly be between 400 and 500 B.Th.U.s. per cub. ft.

Although the cost of manufacturing and distributing the gas militates against its use in large-scale industrial operations, where low fuel costs are of first importance, it has nevertheless made great progress in recent years (1) in the direction of supplying the needs of innumerable small-scale industrial consumers; (2) in connection with the manufacture of high-grade commodities, where the cost of the heating operation is of less consequence than the certainty of attaining a particular result within a given time (*e.g.* in the heat treatment of special steels or alloys); and (3) for brass and aluminium melting, pipe welding, glass annealing, the tempering and forging of tools, &c. Thus, for example, 13 of the principal firms in Sheffield used, in 1917, upwards of 1200 million cub. ft. of coal gas for industrial operations.

Tests carried out at the Imperial College of Science and Technology, London, have shown that a well-constituted modern gas fire, in which the columnar fire-clay 'radiant' material is properly disposed in relation to the atmospheric burners, will not only completely burn the gas without a vestige of carbon monoxide escaping into the room, but it has an unexpectedly high 'radiation' efficiency. The total 'radiation' from such a fire will vary from 45 to 50 p.c., whilst about 30 p.c. of the *net* heat generated passes directly into the flue, the balance being 'convected' into the room. Also H. James Yates has designed a 'ventilating gas fire' which combines the aforesaid high 'radiant' efficiency with a ventilating capacity nearly equal to that of an open coal fire.

Large surpluses of 'coke-oven gas,' which is little, if at all, inferior to many town gas supplies, are now available for steam raising or as gas-engine fuel. The efficiency of the gas when burnt in Lancashire boilers rarely exceeds 65-70 p.c., and with coal at 10s. per ton the cost of the gas for steam raising does not exceed 3d. per 1000 cub. ft. With the rapid extension of by-product coking plants in Great Britain, the proper utilisation of the energy represented by the surplus gas has become a problem of national importance. An average 'debenzolisised coke-oven gas' will contain $\text{CO}_2=2.0$, $\text{CO}=6.0$, $\text{C}_n\text{H}_m=2.0$, $\text{CH}_4=25.0$, $\text{H}=55.0$, $\text{N}=10.0$ p.c. In 1910 Parliamentary sanction was obtained for supplying gas from the Brackley Coke Works to the

Urban District of Little Hulton (Lancs.), and the Corporation of Middlesbrough now draws its entire public supply of gas from regenerative by-product ovens at a neighbouring iron-works.

Producer gas. For the cheap and rapid production of gaseous fuel for industrial purposes, there is no better process than the gasification of solid fuels (peat, bituminous coal, coke, or anthracite) by means of a mixed air-steam blast (sometimes air alone is employed) in some form of gas 'producer,' whereby the fuel is converted into gas containing some 35-45 p.c. of combustible constituents (CO , H , and CH_4). A modern gas producer consists of a cylindrical furnace, 6-12 feet internal diameter and 10-15 feet high, lined with fire-brick with an outer mild steel casing, and usually water-sealed at the bottom. Means are provided (1) for the introduction of the blast through some form of grate or twyer fixed immediately above the level of the water in the seal, and its regular distribution through the bed of incandescent fuel (usually 3-5 feet in thickness) which rests upon a lower bed of ashes; and (2) for the charging in of the raw fuel through (usually) some form of bell hopper fixed centrally on the top of the producer, round which are arranged a number of equidistant poking holes closed by iron balls. The gas outlet is fixed near the top of the cylindrical furnace. Taking as a typical example a producer working with a mixed air-steam blast on a common bituminous coal, the chemistry of gasification may be epitomised as follows. When a fresh charge of fuel is dropped into the furnace, it first of all undergoes a process of distillation on the top of the fire, whereby H , CH_4 , tarry hydrocarbons, CO , together with small quantities of NH_3 , H_2S , &c., are evolved, probably in much the same proportions as in the ordinary retort distillation of coal; olefines and higher paraffins are, however, so rapidly decomposed that they do not, as a rule, appear in the gas passing out of the producer. The carbonaceous residue (coke) is subsequently completely gasified in the lower layers of the incandescent fuel bed, by interaction with the ascending air-steam blast, yielding a mixture of CO_2 , CO , H , and N , together with further small proportion of NH_3 and CH_4 . The proportion of CO_2 , CO , and H leaving the incandescent coke bed depend upon the steam saturation temperature of the blast, which also largely determines the temperature gradient throughout the fire. In order to fully understand the chemistry of the process, it is necessary to separately consider the interaction between incandescent carbon and air and steam respectively. In a solid bottom producer operated with a *dry*-air blast, the initial action of the oxygen upon the incandescent carbon is rapidly succeeded by the reversible reaction $2\text{CO} \rightleftharpoons \text{C} + \text{CO}_2$ in which the state of equilibrium is a function of both temperature and the partial pressures of the CO and CO_2 . It can be demonstrated that the time required for the establishment of this equilibrium, at the temperatures which prevail in the fuel bed, is far shorter than that occupied by the gaseous mixture in traversing the fuel. According to Rhead and Wheeler's experiments (Chem. Soc. Trans. 1910, 2178), the equilibrium in the system $2\text{CO} \rightleftharpoons \text{C} + \text{CO}_2$ at

atmospheric pressure varies with temperature as follows :—

Temp.	Per cent.	
	CO ₂	CO
850°	6.23	93.77
950°	1.32	98.68
1050°	0.37	99.63
1200°	0.06	99.94

results which are in agreement with the thermodynamical equation

$$\frac{19,500}{T_{\text{abs.}}} + \log_e \frac{C^2 \text{CO}}{C \text{CO}_2} = 20.4.$$

As the change from 2CO to CO₂ involves a diminution in volume, it can be predicted on thermodynamical grounds that a lowering of the partial pressures of the CO₂ and CO, consequent on dilution with N in the producer gases, will affect the equilibrium in the same direction as an increase in temperature, i.e. it will tend to increase the ratio CO/CO₂ at any given temperature. The temperatures in the active zones of the fuel bed of an air-blown producer gasifying coal or coke may vary between 1250° and upwards of 1400°, and with good coke it is easily possible to generate a gas containing 0.5 CO₂, 33.0 CO, 1.5 H, and 65.0 p.c. N. But since the combustion of carbon to CO liberates approximately 30 p.c. of its total heat of combustion, not only would the thermal efficiency of the gasification in an air-blown producer, reckoned on the cold gas, be low, but the high temperatures in the fuel bed would cause serious clinkering troubles in cases where the fuel leaves a fusible ash. In the Thwaite cupola producer (30 feet high and 6 feet internal diameter), where a dry-air blast, forced in through a series of twyers near the bottom, is employed, it is usual to add a certain proportion

of limestone to the fuel charge in order to form a liquid slag with the ashes, which is tapped at intervals through a slag-notch. Working on a Lancashire slack coal, this producer yields a gas containing 2.0 CO₂, 29.0 CO, 5.35 H, 2.05 CH₄, 61.6 N, of cal. value 130.8 *net*, and 138.7 *gross*, B.Th.U. per cub. ft. at 0° and 760 mm.

Steam reacts with carbon in two ways, namely, (1) C+2H₂O=CO₂+2H₂, and

and both reactions are strongly endothermic. At 500°–600° (1) predominates; as the temperature rises (2) gradually asserts itself, until at 1000° and upwards it occurs exclusively. The function of the steam in a gas producer is, therefore, to absorb some of the heat liberated during the partial 'air combustion' of the carbon to CO by doing chemical work, thereby raising the potential energy of the resulting gas at the expense of some of its sensible heat. Incidentally, also, clinkering troubles with a fusible ash are greatly diminished by the admixture of steam in the blast. Where a large proportion of steam is used, the composition of the resulting gas is appreciably affected by the reversible system $\text{CO} + \text{H}_2\text{O} \rightleftharpoons \text{CO}_2 + \text{H}_2$, of which the equilibrium constant, $\frac{\text{CO} \times \text{H}_2\text{O}}{\text{CO}_2 \times \text{H}_2} = K$, increases with temperature (according to O. Hahn, $K=0.81$ at 786°, 1.54 at 986°, and 2.10 at 1205°). The operation of this reversible reaction must also be considered when a producer gas passes through the hot regenerators of an open-hearth furnace.

The influence of varying blast-steam saturation temperatures upon the composition and yield of the gas from a Lancashire bituminous coal containing C=78.0, H=5.4, S=1.0, N=1.4, O=10.0, ash=4.2 p.c., and yielding 36 p.c. 'volatiles' at 900°, is shown in the tabulated results below of a series of gas-producer

Average depth of incandescent fuel		3 feet 6 inches					7 feet

trials (each extending over a continuous period of 100-130 hours) carried out by Bone and Wheeler in 1906-7 (Jour. Iron and Steel. Inst. 1907, i. 126; 1908, ii. 206).

In these trials it was also proved (1) that on gasifying an ordinary bituminous coal by means of a mixed air-steam blast, about 92.5 p.c. of the carbon in the fuel is converted into permanent gas (CO_2 , CO , and CH_4), another 6.3 p.c. appears as tar, and the remaining 1.2 p.c. is lost in the ashes. These proportions are independent of the blast-steam saturation temperature. (2) That with blast-steam saturation temperatures up to and including 55° , the whole of the steam in the blast is decomposed in passing through the fuel bed; as the saturation temperature is raised above this limit, the proportion of the steam decomposed progressively diminishes, although the absolute quantity (per lb. of fuel) increases. (3) That increasing the effective depth of fuel bed beyond 3 feet 6 inches has no influence upon either the composition of the gas or the practicable rate of gasification. (4) That the thermal efficiency of the gasification reaches a maximum at blast-steam saturation temperatures between 50° and 60° , and that the best quality of gas for furnace purposes is produced with a saturation temperature of 50° .

In gas generated for furnace purposes it is important that the CO content should be as high as possible, and that the H content should not exceed about 12-14 p.c.; moreover, for a regenerative furnace supply the gas leaving the producer should be in a hygroscopic condition such that the proportions of CO_2 , CO , H , and H_2O shall substantially conform to the equilibrium ratio corresponding to the highest temperature of the regenerator (say 1200°), namely, $\text{CO} \times \text{OH}_2 = 2.0$. This latter requirement is fulfilled by a gas containing 2.5 CO_2 , 30.6 CO , 12.35 H (such as may be generated with blast-steam saturation temperature of 50°), and leaving the producer in a hygroscopic condition corresponding to saturation at 20° . Such a gas will leave the producer heavily charged with tarry vapours, and at a temperature of 500° - 600° ; it usually passes on to the furnace through large fire-brick lined mains, without being cleaned or cooled, accumulations of tar, soot, &c., in the mains being burnt out in a current of air at the end of each week's run (*vide* also W. A. Bone, Producer Gas, with special reference to Steel Works Requirements, Journ. W. of Scotland Iron and Steel Institute, 1911).

In gas generated for power purposes, the actual composition is not so important, provided that the total content of combustible constituents is high, and in such cases the gas may be generated under conditions permitting of the recovery of a large proportion of the N in the fuel as NH_3 . A gas supply for internal-combustion engines must be both thoroughly cleaned and cooled down to atmospheric temperature before delivery to the engine.

The main points to be considered in relation to gas-producer design are: (1) the easy and accurate control of the blast-steam saturation temperature; (2) a suitable form of grate or twyer which should permit of a rapid rate of gasification, together with uniform distribution of the blast, through the

fuel bed; (3) the contour of the furnace body; and (4) the arrangements for charging the producer and removal of the ashes. One of the earliest forms of gas producers (Ebelmen, 1840) was of the cupola type, in which charcoal or coke was gasified, with a positive blast introduced through twyers, limestone being added to the charge (if necessary) to flux the ash. In 1845 Ekman, a Swedish ironmaster, designed a furnace and producer combined, for which the fuel was charcoal. The producer itself consisted of a cylindrical fire-brick chamber, enclosed in an iron casing, a space being left between the brickwork and the casing through which the air supply was admitted and pre-heated on its way to the fire. In 1861 the Brothers Siemens patented their well-known producer for use in connection with their new regenerative furnace. This producer consisted of a fire-brick chamber, rectangular in section, the front of which was inclined at an angle of 45° - 60° , provided with a grate at the bottom, through which a current of air was induced. Below the grate was a trough of water, which, on evaporation, by heat radiated from the grate, added a certain proportion of steam to the induced air supply. Subsequently the front of the producer was closed by an iron door, and the air supply forced in under the grate by steam injection. This producer was the first to successfully gasify a bituminous coal; it was capable of generating a fairly good quality of gas, but its rate of gasification was low. In 1876 Messrs. Brooke and Wilson patented a producer consisting of a cylindrical chamber having a solid hearth, but no fine bars. The mixed air-steam blast was obtained by steam injection, and was introduced into the fuel bed by means of a box-shaped casting which traversed the middle of the hearth. In 1882 Mr. Wilson patented a form of generator on which ash and clinker were automatically removed by means of two worm screws revolving in a water seal. Water-sealed producers have now almost entirely superseded the older solid or bar-bottom types.

The Duff producer (Fig. 4) may be cited as a modern producer of simple design; it consists of a cylindrical chamber, A, 7-10 feet internal diameter, with a 9-inch fire-brick lining within an outer steel shell. At the bottom of the lining is a circular angle-iron casting, which dips into the water seal in the trough BB. The 'Duff' grate, or blast grid, C, is a \wedge -shaped structure, with transverse grids extending as a ridge across the producer immediately above the water seal; the air-steam blast enters the space beneath the grate, and the grid ensures its uniform distribution over a considerable area of the fuel bed. The latter (which, as a rule, extends to a height of about 3 feet above the apex of the grate) is supported upon a bed of ashes, which extends downwards from the grate level into the water trough. In the lower part of the shell of the producer, and on a level with the grate, are inserted cleaning doors DD. The fuel is charged intermittently into the furnace through the belled hopper E, and the gas outlet is at F; the dotted lines at GG indicate poking holes. Ashes are withdrawn from the water trough at regular intervals in quantity corresponding to the rate of accumulation in the

furnace. A producer of 10 feet internal diameter will gasify 10 cwt. of coal per hour, or about 15 lbs. per sq. ft. of fire area.

In Fig. 5 is shown the latest form of the Mond producer, which, although designed with special reference to ammonia-recovery practice, is eminently adapted to all working conditions. The chief features about this producer are (1) the annulus A between the inner fire-brick lining and outer steel shell through which the incoming preheated air-steam blast passes before reaching the grate; (2) the hanging bar grate B, which takes the shape of an inverted truncated

into producers so as to ensure a more even distribution over the fire bed, and more uniform working conditions. The 'George' feed of the

SECTION THROUGH WATER SEAL.

FIG. 4.

cone, with spaces between the bars for the admission of the blast, an arrangement which ensures an adequate grate area and a very uniform and effective distribution of the blast in the fuel bed; and (3) the large bell C at the top of the producer below the charging hopper D, which is supposed to expedite the preliminary distillation of the raw fuel. The Mond producer is usually worked with a very deep fuel bed, as indicated in the diagram, but if the bell C be dispensed with, a much shallower fuel bed may be used with advantage. In Fig. 6 is shown the B.W. producer, which, with an improved form of hanging bar grate, is specially adapted for rapid gasification with a shallow fuel bed. In a producer of this type, 10 feet internal diameter, from 20 to 25 cwt. of coal (equal to 30-35 lbs. per sq. ft. of fire area) may be gasified per hour.

Some years ago attention was drawn to the automatic and continuous feeding of the fuel

FIG. 5.

Morgan producer (Fig. 7) satisfactorily effected this purpose. The essential feature of this

FIG. 6.

device is an inclined and slowly rotating water-cooled feeding spout A, fixed immediately under the charging hopper B, the fuel being

continuously forced from B into A by the slowly revolving circular disc, C, working up against the fixed bracket D. The producer itself is water sealed, and circular in section, but tapering from the middle downwards. The blast is introduced through the central dome E, and the gas outlet is at F. The producer may be worked with a shallow fuel bed (3 feet thick), and with a fire of 10 feet diameter will gasify about 10 cwt. of fuel per hour.

The Kerperley producer (Fig. 8) embodies the latest device for the automatic and continuous removal of ashes, consisting of a revolving conical grate, A, fixed eccentrically upon the foundation, and provided with a flattened top. The cone comprises a number of plates through

Fig. 7.

which the steam-air blast reaches the fire. The grate is fixed in one piece with the shallow iron water trough BB, which is continuously rotated at the slow rate of one revolution every $2\frac{1}{2}$ –3 hours. The lower part of the producer surrounding the zone of active chemical action is water-jacketed CC, in order that no incipient clinkers can adhere to the cold side plate. The slowly revolving eccentric grate disintegrates clinkers before they attain large dimensions, and, pushing the ashes outwards into the water trough, causes them to be automatically discharged by their coming up against a fixed scraper. The Morgan producer also is now fitted with a mechanical revolving grate (Fig. 9), which, besides effecting automatic discharge of ashes, considerably increases the gasifying capacity of the producer.

A still more recent mechanical development in gas-producer practice is the employment of water-cooled rotatory poking devices of which the Chapman Floating Agitator is a typical example. This appliance combines an automatic feed with a slowly rotating water-cooled

stirring arrangement which keeps the upper layers of the fuel bed constantly agitated, whereby 'caking' is prevented; it may be fitted on to existing types of producers, no matter whether they have static or rotating grates. In the latest form of Morgan 'Gas Machine,' the coal is automatically fed into the producer, whilst continuous removal of ash is

Fig. 8.

effected by making the body of the producer to rotate slowly and automatically sweeping the entire bottom of the water-sealed ash-pan by a suitable spiral-shaped bar or plough. All need of poking is eliminated by using an adjustable water-cooled 'leveller,' which 'floats' on the slowly rotated fuel-bed and keeps it constantly levelled.

Fig. 9.

¶ All large gas producers are blown on the pressure system either by means of steam injection or preferably by a suitable fan or blower, steam or electrically driven. The pressure required is only 3–6 inches water gauge, according to the thickness of the fire. In the case of a blower-produced blast, the requisite steam is introduced through a lateral opening into the air duct a few feet before it enters the producer; perfect control and adjustment of the blast-steam saturation temperature is of great importance in relation to uniform working.

For the cleaning and cooling of producer gas for gas engines, various arrangements of plant are employed, comprising (1) a dust-catching chamber; (2) atmospheric condenser, usually of annular type; (3) water-sprayed coke or 'hurdle' scrubbers; (4) water-sprayed fans; and, finally (5) sawdust scrubbers or other equivalent devices for removal of tar fog.

For small (up to 200 h.p.) power installations, producers in which the blast is induced by the suction of the engine cylinder ('suction producers') are now largely employed with anthracite or coke as fuel. The first successful attempt to operate a producer by suction in conjunction with a gas engine was made by Léon Bénier, in 1896, who employed a suction pump, placed side by side with the engine cylinder and driven by means of a connection with the fly-wheel axle. Soon afterwards the suction of the engine itself, on the out-stroke of the piston, was substituted for the Bénier suction pump, thus cheapening construction, and at the same time reducing fractional losses. By 1901 'suction' power plants were established on the market, and their use has since steadily extended. Such a plant (as illustrated in Fig. 10) consists of the

FIG. 10.

following essential parts: (1) A fire-brick-lined generator, A, of cylindrical section, in which the fuel is gasified by means of an air-steam induced draught; the fuel is introduced through an air-tight feeding hopper, B, which drops it into a storage and distillation bell, C, situated within the generator. The fire rests upon a horizontal grate under which is a shallow chamber, D, with a solid bottom, and a lateral opening communicating with the air and steam supplies. (2) A vaporiser, E, which may be either within or without the upper part of the shell of the generator, in which a regulated water supply is vaporised, usually at the expense of some of the sensible heat of the hot gas leaving the generator, or sometimes by the heat of the fire. (3) A water-sprayed coke scrubber, F, for cooling and washing the gas; and (4) an expansion box, G, which serves the double purpose of a gas reservoir for the engine, and, on the suction stroke, of minimising the jerkiness

of the suck. The generator is started up by kindling a wood fire on the grate with a layer of coke or anthracite above. The fire is blown up by means of a hand fan, which is a necessary auxiliary to the apparatus. During the starting-up period, the products of combustion are sent into the atmosphere through a vent pipe, but as soon as a rich enough gas is generated (about 20-30 minutes from the start), the engine is started and the fan shut off. A typical 'suction gas,' generated from gas coke with air saturated with steam at 51.7°, contains $\text{CO}_2=5.10$, $\text{CO}=25.45$, $\text{H}=13.10$, $\text{CH}_4=0.28$, and $\text{N}=55.32$ p.c., its net calorific value being 127 B.Th.U.s. per cub. ft. at 0° and 760 mm. The thermal efficiency of the gasification, allowing for the power required to draw the gases through the system, and based on the net calorific values of coke and gas respectively, is about 78.5 p.c. The fuel consumption on a suction plant is about 1 lb. or even slightly less, per b.h.p. developed, the water consumption for scrubbing the gas being about 1.2 gallons per b.h.p.

Ammonia-recovery systems. The solution of the problem of the gasification of coal under conditions which permit of the recovery of a large proportion of its nitrogen as ammonia, was due to the late Dr. Ludwig Mond. The best practical results are obtained by working the producer with a blast-steam saturation temperature of 85°, the mixture of air and steam being preheated to about 250° before it enters the fuel bed. There is carried into the producer by the blast about 2 lbs. of steam for every 1 lb. of coal gasified; one-third only of this steam is decomposed, by interaction with carbon, in passing through the fuel bed, the remaining two-thirds passing with the hot gases out of the producer. The outstanding features of the process are (1) that, owing to the cooling influence of the large proportion of steam in the blast upon the fuel bed, the low temperature interaction $\text{C} + 2\text{H}_2\text{O} = \text{CO}_2 + \text{H}_2$ predominates over the high temperature 'water-gas' reaction, $\text{C} + \text{H}_2\text{O} = \text{CO} + \text{H}_2$, so that the resulting gas (e.g. 17.0 CO_2 , 11.0 CO , 24.0 H , 3.0 CH_4 , and 45.0 N) has a high hydrogen and low carbon monoxide content as compared with ordinary producer gas; and (2) that for economical working it is necessary that the large proportion of steam leaving the producer shall be conserved to the system by some efficient recuperative arrangement. From a coal containing between 1.2 and 1.6 p.c. N it is possible to obtain up to 90 lbs. per ton of ammonium sulphate, together with about 150,000 cub. ft. of gas (at 0° and 760 mm.) of calorific value about 150 gross and 135 net, B.Th.U.s. per cub. ft. at 0° and 760 mm. According to the Mond system of ammonia recovery and steam recuperation, as originally designed, the gas leaves the producer heavily charged with steam and tarry vapours at a temperature of 500°-600°. It then traverses the central tubes of a series of three annular 'superheaters,' indicated by B in the diagram (Fig. 11), each about 20 feet long. The incoming steam-air blast passes through the annulus between the central and outer tubes in the reverse direction. The temperature of the gas is thus reduced to about 300°, whilst that of the blast is raised to about 250° (further 'superheating' of the blast occurs as it subsequently

traverses the annulus between the fire-brick lining and the outer steel casing of the producer itself). The partly cooled gas next passes through a long rectangular and water-sealed chamber (the 'mechanical washer'), C, where it encounters a water spray thrown up by a series of revolving dashers, by which means dust, soot, and a large amount of heavy tar are removed, and the gas itself further cooled to about 100°. It next passes up the lead-lined scrubbing tower D, packed with perforated bricks or tiles, down which an acid liquor containing 36-38 p.c. of ammonium sulphate *plus* 2.5 p.c. of sulphuric acid is sprayed, the volume of liquor being so adjusted in relation to the upward flow of gas that the latter leaves the tower at a temperature of 80° and free from ammonia. The tarry liquor from the tower is passed into an open tank provided with suitable partitions, in order to eliminate any small quantity of surface tar in it. To the main bulk of the clear liquor is added a regulated quantity of sulphuric acid, after which it is again pumped up to the top of the acid tower D. A portion of the clear liquor is, however, removed from the circuit, and, after treatment with heavy oils (if necessary) to remove tar, is evaporated to crystallising-point in a special lead-lined vacuum evaporator furnished with steam coils. After separation of ammonium sulphate, the mother liquor is pumped back into the main-liquor circuit. The ammonia and tar-free gas, on leaving the acid tower at 80°, is passed up the 'gas cooling tower' E, where it encounters a downward spray of cold water, so regulated that whilst the gas is cooled down to about 60°, and rendered substantially free from tar, the water is heated up to 75°-78°. The gas passes onwards to the place of consumption through a second water-sprayed cooling tower in which it is further cooled to 30°, at which temperature it contains only 4 p.c. by volume of water vapour. But if it is intended for gas engines it should be further cooled down to within a few degrees of the atmospheric temperature, and be also passed through a sawdust scrubber to remove the last traces of tar.

The hot water from the 'gas-cooling tower' is passed through a far separator, after which it is pumped up to the top of the 'air-saturating tower', κ down which it is sprayed. The air blast for the producer is forced up this tower by means of a blower; in this way the blast is heated up to and saturated with steam at 75° at the expense of the hot water. A further quantity of live steam is added to the air blast as it passes forward to the superheaters in order to raise its steam-saturation temperature to 85°.

The chief drawback to the original Mond system was the large capital outlay involved, which rendered ammonia recovery unprofitable unless the coal gasified exceeded 180-200 tons per week. Moreover, the gas, being rich in hydrogen and poor in carbon monoxide, is not well suited for open-hearth steel or glass-melting regenerative furnaces.

Successful efforts have been made to simplify the mode of ammonia recovery by the substitution of rectangular horizontal washers, constructed of steel or iron work and rendered resistant to the acid liquor by special treatment, for the expensive lead-lined vertical

acid tower, and by making the sulphate liquor play the double rôle of an absorbent for the ammonia in the gas and an agent for the transfer of undecomposed steam back to the producer blast. As an example of this type

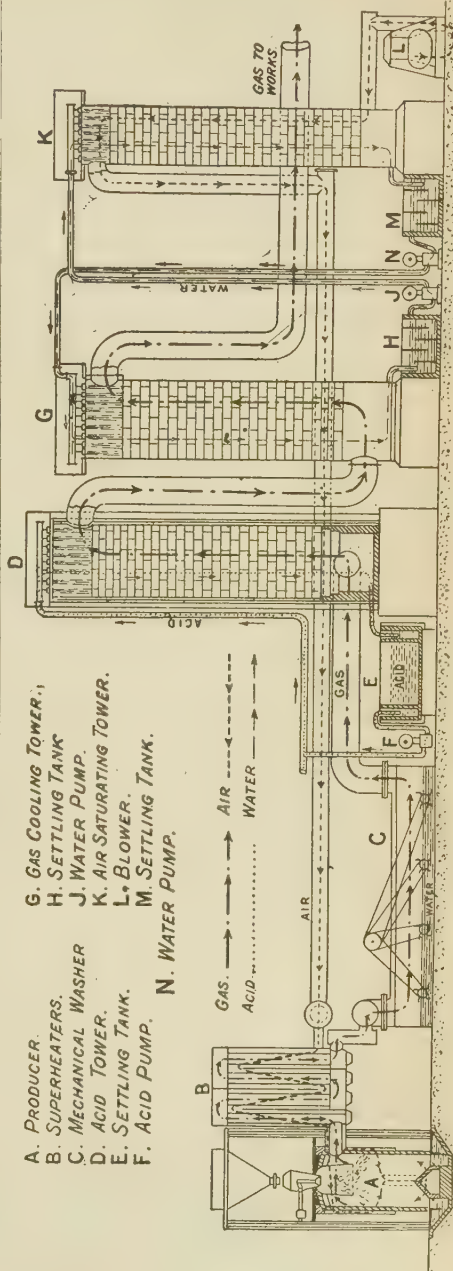

FIG. 11.

of plant, the Crossley and Rigby system may be described with reference to Fig. 12. The generator A is central blown with a special rotary conical grate (1 revolution in 4 hours), which gives an even distribution of blast

through the deep fuel bed and minimises clinker formation. The blast enters the fuel bed preheated to 280° and with a steam-saturation temperature of 85° . The gas, on leaving the producer, passes through the tubular 'superheater' B, so designed as to give a maximum of heating surface combined with facility of cleaning. The latter operation may be effected whilst the plant is running by means of a corkscrew cleaner inserted through holes provided at the top. The function of the superheater is to effect a transfer of part of the sensible heat of the outgoing hot gas to the incoming steam-air blast. The partly cooled gas next passes onwards to the 'washer condenser' C, consisting of five compartments, in the first two of which it meets with a water spray whereby it is freed from dust and heavy tarry vapours; the steam generated is subsequently recovered. In the remaining three compartments the gas is washed with a spray of sulphate liquor containing 0.5 p.c. of free acid, which is circulated by gravity flow in a direction contrary to that of the gas. The absorption of ammonia is complete, whilst at the same time the gas is satisfactorily cooled and most of the undecomposed steam leaving the producer is condensed. After leaving the washer condenser, the gas is slowly filtered through the dry coke scrubber D whereby all trace of sulphate liquor spray is removed. The hot liquor from the washer condenser passes by gravity flow into the well E whence it is pumped into the air-saturating chamber F where it flows and is sprayed by paddles in a counter direction to the cold-air blast created by the blower G. The liquor is thereby cooled and flows by gravity back to the washer condenser C, whilst the air blast is warmed and leaves the chamber (via the coke scrubber H) saturated with steam at 75° . A constant proportion of sulphate liquor is withdrawn from circulation and delivered into the closed evaporator K, where it is concentrated to crystallising-point. A portion of the concentrate is run off at frequent intervals into the crystallising trough L, where, after cooling and draining, the sulphate is dried and the mother liquor returned by gravity flow to the washer condenser C. The steam from the evaporator is conveyed by an overhead pipe to the base of the coke scrubber H, where it enters the air blast already saturated with steam at 75° . The steam-air blast then passes forward, via the coke scrubber H and the superheater B, to the producer. Owing to a special treatment of the iron and steel used in the construction of the plant, all leadwork is eliminated, except in the acid storage tank and the sulphate concentrating and crystallising apparatus. In consequence of the greatly reduced capital cost, as compared with the original Mond system, it is now possible to carry out ammonia recovery when gasifying only 100 tons per week. From a producer coal of average quality, containing 1.20-1.25 p.c. N, and up to 10 p.c. ash, it is possible to recover 90-100 lbs. of sulphate per ton, together with 140,000 cub. ft. of gas (at N.T.P.) containing 16.5-17.0 CO_2 , 10.5-11.0 CO , 26.5-27.0 H_2 , and 2.6-2.8 CH_4 .

Among the most recent developments in regard to ammonia-recovery practice may be mentioned (1) an interesting attempt to economise steam by gasifying the fuel in a water-

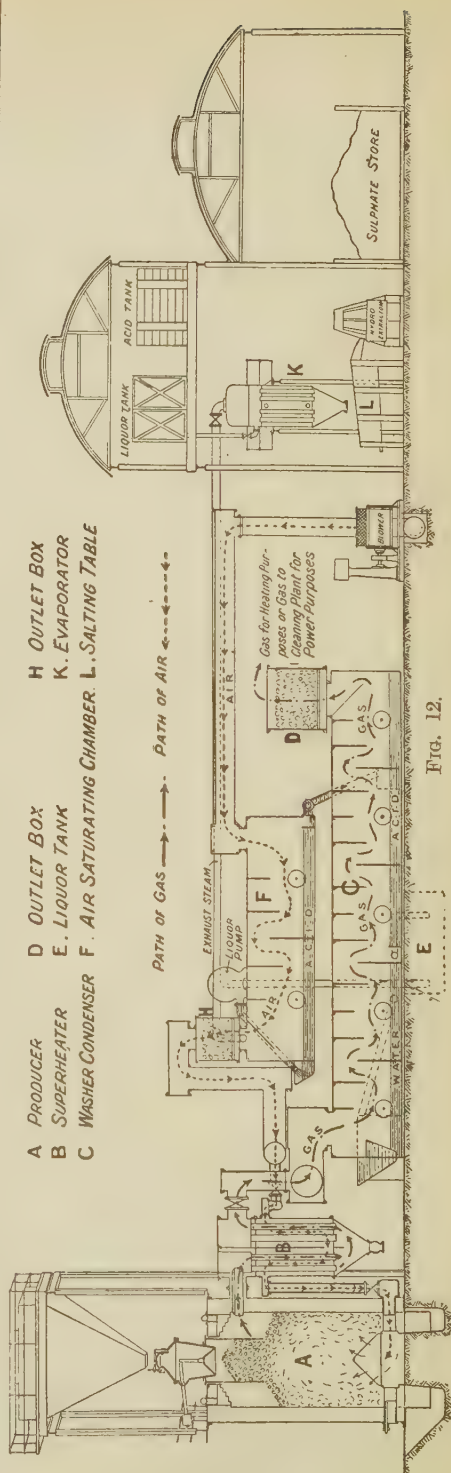

FIG. 12.

jacketed generator, as embodied in the Moore system, whereby it is claimed that the steam required to produce from 80 to 90 lbs. of ammonium sulphate from a ton of coal need not exceed the weight of fuel gasified, the resulting gas containing $\text{CO}_2=10.0$, $\text{CO}=20.0$, $\text{H}=20.0$, $\text{CH}_4=3.0$, and $\text{N}=47.0$ p.c. (*vide* Iron and Coal Trades Review, February 21, 1913); and (2) the Lymn system, in which the plant has been entirely re-modelled with a view to reducing its capital cost (*vide* the writer's book on Coal and its Scientific Uses, pp. 366-370).

Blast-furnace gas. Within recent years the problem of better utilising the waste gases from iron blast-furnaces as a source of power has assumed great industrial importance. A furnace smelting an average grade of ore, with coke as fuel, will yield per ton of iron produced about 185,700 cub. feet of gas at 15° and 760 mm. containing approximately 10.0 CO_2 , 30.0 CO (this may include from 0.5 to 1.0 H) and 58.0 N , of calorific value approximately 95-100 B.Th.U. per cub. ft. For a furnace with an output of 1000 tons of pig iron per week, the production of gas will average 1.114 million cub. ft. per hour, the potential energy of which is rather more than half that of the coke charged into the furnace. Until the year 1837, when the French ironmaster Dufaur drew attention to the matter, this immense amount of energy was entirely wasted. The classical investigations of Bunsen at Verkerhagen in 1838, and of Bunsen and Playfair at Alfreton in Derbyshire in 1844-5 (Brit. Assoc. Reports, 1845; reprinted, 1903, by the Iron and Steel Inst.), finally led to the utilisation of the gases for (1) heating the blast for the furnace, and (2) boiler firing. Special 'hot-blast' stoves, on the regenerative principle, were designed to effect the first purpose by E. A. Cowper and by Thomas Whitwell in 1865, whilst for steam raising the gas was burnt in a fire-brick-lined combustion chamber attached to a Lancashire boiler. In this way about 40 p.c. of the gas was utilised for heating the blast, another 10 p.c. would be lost at the bell, leaving 50 p.c. to be used to raise steam for driving the blowing engines, the furnace hoists, and other mechanical appliances in connection with the plant. But the combined efficiency of boiler *plus* steam engine was always very low; thus in 1902 it was estimated by a Cleveland engineer that with the best type of water-tube boiler only about 54 p.c. of the heat developed by the combustion of the gas is actually transmitted to the water, and that the combined efficiency of boiler and blowing engine was somewhat less than 7 p.c. All this has been changed by the rapid development of the large gas engine during 1895-1905, which has increased the efficiency of power production from blast furnace gas something between three- and fourfold as compared with the old steam plants. Gas engines developing up to 2000 b.h.p. per unit have now been installed in most of the German and many British and American ironworks, realising in actual practice a thermal efficiency of conversion 'gas-b.h.p.' of 25 p.c., and of 'gas-e.h.p.' of 20-22 p.c. As an illustration of what this improved practice implies, the following figures may be quoted for a plant of five furnaces

smelting 5000 tons of iron per week from calcined Cleveland ironstone; the hourly production of gas is 5,500,000 cub. ft., of which not more than 1,100,000 would be required for generating the blast in a gas-driven blowing engine, another 1,650,000 for heating the blast, leaving a surplus of about 2,750,000 cub. ft. for employment in the steel works (heat and power).

Indeed the time has now arrived when, with a proper concentration and arrangement of the various producing units (by-product coke ovens, blast furnaces, gas-power house, steel furnaces, soaking pits, and electrically-driven rolling mills), and utilising to the best advantage all the surplus coke-oven and blast-furnace gases, ironstone may be brought in at one end of the plant and finished steel sections turned out at the other, with no more expenditure of fuel than the amount of coal that is required to make sufficient coke to smelt the ironstone in the blast furnace (*vide* T. C. Hutchinson, Jour. Iron and Steel Inst. 1913, ii. 110; and W. A. Bone's 'Coal and its Scientific Uses,' pp. 409-421).

The gas, as it leaves the furnace at a temperature of 300° or thereabouts, is heavily charged with dust, which must be reduced by washing to infinitesimal proportions before it is fit for delivery to the engines. The cleaning of the gas is usually accomplished in two or three stages, namely: (1) 'dry cleaning' (by means of any ordinary type of dust catcher), which may reduce the dust down to between 2 and 8 grams per cub. metre; (2) preliminary water washing (*e.g.* in the Bian washer, consisting of a cylindrical steel chamber along the axis of which there slowly revolves a horizontal shaft carrying a series of circular discs of thick wirework with a coarse mesh, the lower half of which is submerged in water; the dusty gas is partly cleaned by passing through the films of water between the wire meshes); this may reduce the dust down to 0.5 gram per cub. metre; and (3) a final cleaning in some form of centrifugal apparatus in which the gas is violently churned up with a fine spray or stream of water (*e.g.* the Theisen washer). Most frequently the cleaning is carried out by the combination of processes (1) and (3) only. In any case, the dust in the gas should be reduced down to about 0.01 gram per cub. metre, and the temperature to 18° - 20° , before delivery to the engine. The power expended in cleaning the gas to this degree amounts to between 5 and 6 p.c. of that generated by its explosion in the engine cylinder.

Processes of dry-cleaning (*e.g.* the Beth-Halberg system, in which the gas is filtered through a special fabric) have been successfully developed within recent years; but probably the best solution of the cleaning problem lies in some electrostatic system whereby the whole of the dust can be successfully eliminated with a minimum expenditure of energy and without using water or sensibly cooling the gas. A description of the Lodge Electrostatic Process for gas-cleaning as recently installed at Skinningrove Ironworks is given in a paper by A. Hutchinson and E. Bury, in Journ. Iron & Steel Inst. cii. (1920), p. 65.

Water gas. The need of a cheap gaseous

fuel of high calorific intensity for certain industrial purposes (*e.g.* steel welding) has led to the utilisation of the well-known endothermic interaction of steam and incandescent carbon at high temperatures. For such a process to be continuous, heat would have to be transmitted from an external source through the walls of the reaction chamber or retort, which would

necessarily be constructed of refractory material of low conductivity. As such procedure would certainly be very uneconomical, all idea of it has been abandoned in favour of an intermittent process, in which a bed of fuel (usually coke) is alternately blown with (1) air, until the mass attains a sufficiently high temperature, and (2) with steam, so long as the high temperature

FIG. 13.

interaction $C + H_2O \rightleftharpoons CO + H_2$ can proceed without undue occurrence of the low temperature interaction $C + 2H_2O \rightleftharpoons CO_2 + 2H_2$.

The use of water gas was first introduced in the United States about the year 1875, as the result of the pioneering efforts of J. S. C. Lowe, but it was not until 1888 that the British Water Gas Syndicate installed the first plant in Great Britain at the Leeds Forge. This plant embodied the now obsolete idea of, during the 'air blow,' manufacturing a low grade 'producer gas' (a mixture of CO_2 , CO , and N , in which CO was the predominating carbon constituent) for furnace purposes by blowing a thick fuel bed with an air blast at moderate pressure. This operation was alternated with the usual 'steam blow' for the production of 'water gas.' The 'air blow' occupied 10 minutes, and the 'steam-blow' only 4 minutes, and each ton of gas coke yielded about 34,000 cub. ft. of 'water gas,' and about 140,000 cub. ft. of 'producer gas,' some 25 p.c. only of the carbon in the fuel appearing in the 'water gas.'

Some ten years later the process was much improved by Dellwik and Fleischer, who proposed, during the air blow, to heat up a comparatively thin bed of fuel as rapidly as possible by means of a blast supplied in such quantity as to burn the carbon as completely as possible to the dioxide. In the Dellwik-Fleischer system (Figs. 13 and 14), the generator is of cylindrical section with a fire-brick lining encased in a steel shell. The fuel bed rests on a flat bar grate on a level with which are clinkering bars, and below which are doors for the removal of ashes. The air blast always enters the fuel bed from below through a valve, and the products of the 'air blow' leave the generator by the central stack valve, through which also the fuel is charged from a small hopper wagon. During the 'steam blows' superheated steam from a boiler working at a pressure of 150–160 lbs.

per sq. in. is blown through the incandescent fuel bed in either an upward or a downward direction, the direction being reversed in each successive blow. Accordingly, there is one 'water-gas' outlet at the top of the generator, and another below the grate, each provided with a valve leading to the annular 'superheater,' which serves to effect a heat exchange between the outgoing hot gas and the incoming steam blast, thus superheating the latter. At the

FIG. 14.

bottom of the 'superheater' is a water seal through which the gas passes onwards to a coke scrubber, where it is cooled and cleaned from dust by means of a water spray; from thence the cold gas passes into a holder. The various valves of the generator are operated by an interlocking gear which makes it impossible for the operator to make a mistake or get an explosive mixture in any part of the plant. A set of water gauges and a test flame on the

operating platform indicate the working conditions in the generator at any moment and also the quality of the gas during the 'steam blow.' Towards the end of the 'steam blow,' when the temperature of the fuel has fallen below the point at which the low temperature interaction $C + 2H_2O \rightleftharpoons CO_2 + 2H_2$ comes seriously into play, the steam and gas valves are shut off, the stack and air valves being simultaneously opened, for the commencement of the 'air blow.' Each 'air blow' lasts about 1 minute, and the subsequent 'steam blow' about 4 minutes. With an average quality of gas coke the plant will produce about 32 cub. ft. at 0° and 760 mm. of water gas per lb. of carbon charged into the generator, which means that as nearly as possible

is introduced from below each fire. The hot products (CO_2 , CO , and N), on leaving the top of the generators, pass upwards through the 'double regenerator,' a cylindrical structure filled with fire-brick chequer work and divided vertically into two chambers or compartments by a central fire-brick wall. As the hot products enter in parallel streams at the base of one or other of the two chambers, they meet a secondary air supply sufficient to burn completely all the CO which they may contain. The chequer work in the chambers absorbs part of the heat of the burnt gases which eventually make their exit into the outer atmosphere through the stack valve D at the top of the double regenerator. As soon as the fires in the two generators have attained the necessary high temperature, the air and stack valves are shut, and the steam valve simultaneously opened. The steam, entering the base of the first generator, traverses the fire contained therein in an upward direction.

FIG. 15.

50 p.c. of the carbon is converted into water gas. The average composition of the gas is 4.0 CO_2 , 43.0 CO , 49.0 H , 0.5 CH_4 , and 3.5 p.c. N , and its calorific value about 320 gross and 290 net B.Th.U. per cub. ft. at 0° and 760 mm. The ratio of the net calorific value of the gas to that of the coke charged into the generator is about 0.60.

Another system of water-gas making is that embodied in the Kramers and Aarts patents (the 'K and A' system), according to which two generators, A and B (Figs. 15, 16, and 17), connected through a double 'regenerator,' C, are operated in parallel during the 'air blow' and in series during the 'steam blow,' somewhat as follows:—

During the 'air blow' the fires (5–6 feet in thickness) in both regenerators are simultaneously blown in parallel by a powerful blast, which

FIG. 16.

The products (CO_2 , CO , H , and some undecomposed steam) passing out at the top traverse in a \nearrow direction the two chambers of the 'double regenerator,' after which they enter, in a highly 'superheated' condition, the top of the second generator, through which they pass in a downward direction. In this way, it is claimed, the gases, just prior to leaving the system, come into contact with a bed of highly incandescent carbon, the temperature of which has not been sensibly lowered by the main endothermic steam-carbon interaction, which principally occurs in the first of the two generators. In alternate 'steam blows,' the direction of the steam and gases is reversed, in order to ensure the maximum of uniformity in the working conditions. The plant is operated by means of an interlocking valve gear, which prevents mistakes on the part of the workman. The hot gas produced passes from the bottom of the second generator upwards first of all through the annular 'steam superheater' E (Fig. 17), whereby part of its sensible heat is transmitted to the in-going steam blast, and then through a coke scrubber, where it is cleaned and cooled by a downward water spray. The process works smoothly and is very efficient, the average duration of each air blow being about 70 seconds, and of each steam blow about

5 minutes. The yield of gas, from an average gas coke, is nearly 38 cub. ft., at 0° and 760 mm., per lb. of carbon charged into the generator, about 60 p.c. of which appears in the 'water

that of the coke charged into the generators is about 0.70.

With coke at 12s. per ton, the pre-war cost of making 'blue water gas,' including fuel, wages, interest, and depreciation, was about 4d. per 1000 cub. ft., which was equivalent to coal gas at about 8d. per 1000 cub. ft. Post-war costs cannot well be estimated until prices of coal and labour are more stabilised, but they are now (1921) probably not less than 3 to 4 times the pre-war figure.

The most important industrial application of water gas is undoubtedly steel-plate welding, and a large industry has grown up, especially in Germany, for the manufacture of welded steel tubes of large dimensions. The overlapping joint to be welded is heated simultaneously from both sides by special burners (Fig. 18) fed with both

FIG. 18.

water gas and air under pressure, which on mingling produce aerated flames of great heating power. As soon as the joint attains the proper welding heat, it is quickly passed through special rolls which bring about a perfect weld.

Water gas is also used for mixing with ordinary town coal gas, but for this purpose it usually first of all undergoes a process of 'carburetting,' (For the production of 'Carburetted Water gas,' see GAS, COAL; also GAS, WATER.)

The combustion of gaseous fuels. The following table, relating to the various forms of gaseous fuels described in this article, may be found useful for comparative purposes; the figures for calorific values are approximate only:

Gas	Net cal. value B.Th.U. per cub. ft. at 0° and 760 mm.	Vol. air required to burn 1 vol. of gas	Vol. gas + air required per 100 B.Th.U.Us. cub. ft.	Vol. products incl. H ₂ O per 100 B.Th.U.Us. cub. ft.
Blast-furnace gas . . .	100	0.715	1.715	1.565
Producer gas . . .	150	1.216	1.480	1.357
Water gas . . .	290	2.200	1.100	0.953
Coal gas . . .	590	5.440	1.100	1.050

For information as to the present state of science in gaseous combustion, see article on FLAME (this vol. p. 206) and also reports by W. A. Bone to the British Association, Sheffield, 1910 and 1915. Attention is also drawn to the recent revival of the subject of 'surface combustion' by W. A. Bone and C. D. McCourt (*vide* Proc. Roy. Institution, xxi. No. 108 (1917), pp. 41-62; and Howard Lectures, Roy. Soc.

gas.' The composition of the gas is 3.75 CO₂, 43.70 CO, 45.1 H, 0.5 CH₄, and 6.95 N, its calorific value being about 310 gross and 285 net B.Th.U. per cub. ft. at 0° and 760 mm. The ratio of the net calorific value of the water gas to

Arts, 1914) whereby numerous economies in the industrial application of gaseous fuels (including steam raising by means of blast furnace gas, producer gas, or surplus gas from by-product coking plants) may be realised. During the war the 'Bonecourt' system was successfully developed for large gas-fired boilers (with 'superheat') for power stations, and it has also been extensively applied to industrial furnaces in America. Also, their method of 'diaphragm heating' by radiation has recently been successfully applied in the manufacture of confectionery, etc.

W. A. B.

FUKUGI. The Japanese dyestuff fukugi (botanical origin unknown) has, at least until recently, been employed to a considerable extent as a mordant dyestuff in Japan. It consists of the wood of a tree, which, when ground, forms an almost colourless powder, the extract of which is sold in the form of brittle rectangular cakes of a yellowish-brown colour.

Fukugetin $C_{17}H_{12}O_6$, the colouring matter, forms minute canary-yellow prismatic needles, melting at 288° – 290° (Perkin and Phipps, Chem. Soc. Trans. 1904, 85, 58). It dissolves in alkaline solutions with a yellow colour and gives with alcoholic lead acetate an orange-yellow precipitate, and with alcoholic ferric chloride a brown-black coloration.

Crystalline acetyl and benzoyl derivatives of this colouring matter could not be obtained, but the bromine compound $C_{17}H_{10}O_6Br_2$, minute flat needles, m.p. 280° , is readily prepared by the action of bromine on fukugetin in the presence of acetic acid.

Fukugetin dyes mordanted fabrics shades which are almost identical with those given by luteolin:

Chromium	Aluminium	Tin	Iron
Dull orange-yellow	Orange-yellow	Bright yellow	Olive-brown

and resembles this colouring matter in that its alkaline solution is not oxidised on exposure to air. By fusion with alkali, fukugetin gives *phloroglucinol* and *protocatechuic acid*.

The dyeing properties of 'fukugi' are analogous to those of weld. The similarity in shade, indeed, is so marked that, except in point of strength—for fukugi is a stronger dye than weld—it is impossible to distinguish between them.

A. G. P.

FULLER'S EARTH. (Fr. *Terre à foulon*; Ger. *Walkerde*.) A term applied to a variety of clay-like materials which possess in common the property of absorbing grease and oil, and hence are used by fullers for cleansing woollen goods. They vary in colour with dull shades of grey, yellowish, bluish, or greenish, and are soft, with an earthy appearance. They are greasy and unctuous to the touch, and do not adhere to the tongue. When a lump of the dried earth is placed in water, it presents a very curious appearance as it crumbles down to a fine powder; and is not plastic like ordinary clays. Mineralogically they appear to be mixtures; some approximate to kaolinite ($Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$) in composition, and many may be referred to the 'smectite' of A. Breithaupt (1841), a greenish-grey clay from Cilly in Styria. A microscopical examination of English fuller's earth, made by G. P. Merrill (The Non-metallic Minerals, 1904), showed the presence of colourless and greenish-

yellow particles with very feeble birefringence, ranging from 0.002 to 0.07 mm. in diameter: very little quartz could be detected, although the presence of free silica is suggested by the analyses. The chemical composition varies widely, and is, in fact, no guide to the commercial value of the material, which depends rather on the physical state of aggregation. Sp.gr. 1.75–2.5.

The following analyses are of: I, smectite from Cilly, Styria (Jordan, 1849); II, bluish-grey fuller's earth from Nutfield, Surrey (P. G. Sanford, Geol. Mag. 1889, 456, 526), on material dried at 100° with a loss of 27.47 p.c. water; 13.33 p.c. of all the solid constituents except silica, are soluble in acid; III, yellowish fuller's earth from Nutfield, Surrey (P. G. Sanford, 1889), on material dried at 100° with loss of 29.56 p.c. water; 10.73 p.c. solids, soluble in acid; IV, from Fairborn, South Dakota; V, from south-east of River Junction, Florida; VI, from Decatur Co., Georgia (anal. IV–VI by E. J. Riederer, quoted by H. Ries, 17th Ann. Rep. U.S. Geol. Survey, 1896, iii. 880).

Fuller's earth occurs as beds in sedimentary rocks belonging to various geological periods, ranging from the Silurian to the Eocene. The most important deposit in England is a bed 8–12 feet in thickness, lying between sandstones in the Lower Greensand division of the Cretaceous system. This is worked in open pits at Nutfield and Redhill in Surrey. Nearer the surface, where oxidised, it is yellowish, but lower down it is bluish in colour. In Somersetshire, Gloucestershire, and Dorsetshire, the 'fuller's earth formation' of geologists, lying between the limestones of the Great Oolite and the Inferior Oolite, consists of a thick deposit of clays and marls, with beds 2–3 feet in thickness of fuller's earth of good quality. This was formerly extensively worked for use in the cloth mills of the west of England, but now is obtained only on the Downs to the south of Bath. Still smaller quantities are yielded by the Lower Greensand strata near Woburn in Bedfordshire.

For many years the English fuller's earth was considered the best, and until recently large quantities were exported to America. Deposits have now been opened up at several places in the United States, chiefly in Florida, and to a lesser extent in Georgia, Alabama, Arkansas, and California. In Gadsden Co., Florida, it occurs as a bed 4–12 feet in thickness in bedded clays and sandy clays of Oligocene (Tertiary) age. Small outputs are also recorded from India and Australia (Wingen, New South Wales).

The English output amounts to about 15,000 tons per annum, whilst double this quantity is now obtained in America. The price at the pits ranges from 25s. to 2l. per

drops of sodium nitrite solution. The course of the reaction is as follows:—

Wieland and Semper (Ber. 1906, 2522) have shown that phenylmethylnitrolic acid readily decomposes into nitrous acid and the unstable benzonitrile oxide.

Hence, if a similar decomposition occurs in the case of methyl nitrolic acid, the hitherto unknown nitrile oxide $\text{H} \cdot \text{C} : \text{N} : \text{O}$ or the products of its decomposition would be obtained. Wieland (*l.c.*) has shown that the products of the decomposition of methylnitrolic acid are fulminic acid, formic acid, and hydroxylamine, the decomposition being analogous to that of chloroformoxime. The unstable nitrile oxide is probably formed first and then undergoes an isomeric change into fulminic acid.

Wöhler (Ber. 1905, 1351) has determined the molecular weight of fulminic acid by means of the sodium salt, which can be prepared in a pure anhydrous state by the action of sodium amalgam on mercury fulminate suspended in alcohol. The numbers obtained by the cryoscopic method and by determining the equivalent conductivities of dilute solutions correspond closely with the numbers required for the monomolecular formula $\text{C} : \text{NONa}$.

In the ordinary method of preparing fulminates by the oxidation of ethyl alcohol, the following changes are supposed to occur (Wieland, Ber. 1907, 418):—

The experimental evidence in favour of the above hypothesis is as follows: Wieland and Theodorovits (Ber. 1905, 1345) found aldehyde to be a more suitable agent than alcohol for the preparation of fulminates, the formation of methylnitrolic acid from *isonitrosoacetic acid* has been accomplished by Ponzo (Chem. Soc. Abstr. 1903, i. 453), Wieland has prepared mercuric fulminate from methylnitrolic acid (*v. supra*); and lastly by treating fulminic acid with nitrous acid, Palazzo (Chem. Soc. Abstr. 1907, i. 489) has obtained methylnitrolic acid as one of the products of the reaction.

The older view of Kekulé as to the constitution of fulminic acid has now been finally abandoned, and the carbonyl oxime formula of Nef has taken its place.

Hodgkinson (J. Soc. Chem. Ind. 1918, 37, 190, T) has pointed out that mercury fulminate cannot be formed in the absence of nitrous acid or a mixture of nitric oxide and nitrogen peroxide; he, therefore, represents the formation and constitution of fulminic acid by the equation:

Mercuric fulminate or fulminating mercury $(\text{C} : \text{NO})_2\text{Hg}$. To prepare this substance on a small scale, 3 parts of mercury are dissolved in 36 parts nitric acid of sp.gr. 1.34, without warming. The solution is then poured into a flask capable of containing 18 times the quantity, in which there has been placed 17 parts alcohol of from 90–92 volumes p.c. The liquids are well mixed, poured back into the first vessel, which is of the same size, shaken to absorb nitrous fumes, and the whole then allowed to stand. In a short time gas is given off and a highly refracting liquid separates at the bottom of the flask. On shaking the flask to mix this liquid with the rest, the whole becomes black, metallic mercury separates, and a violent reaction takes place, which is moderated by the gradual addition of 17 parts of alcohol. Crystals of mercuric fulminate separate on cooling (Liebig).

For methods of production on the large scale, see EXPLOSIVES.

Mercuric fulminate may also be produced by using mercuric oxide for mercury in the above preparation; by boiling silver fulminate with mercury and water, or by precipitating the zinc salt with mercuric chloride. Wöhler and Theodorovits (Ber. 1905, 1345) state that mercuric fulminate is also formed when mercuric nitrate in dilute nitric acid is mixed with methylal, acetal, or lignone obtained by the dry distillation of wood, but the acid must contain nitrous fumes.

For its preparation from oximino acetic acid, see Wieland, Ber. 1910, 43, 3362.

It crystallises from hot water in white or greyish silky needles of sp.gr. 4.42; its gravimetric density varies from 1.3 to 1.6, depending upon the size of the crystals; its formula is $(\text{C} : \text{N} \cdot \text{O})_2\text{Hg} \cdot \frac{1}{2}\text{H}_2\text{O}$; by carefully regulating the temperature and the amount of alcohol, it can be obtained anhydrous. It is nearly insoluble in cold water, but soluble in alcohol, pyridine, potassium cyanide, and, with decomposition, in sodium or ammonium thiolsulphate solution. Nicolardot and Boudet (Bull. Soc. chim. 1919, 25, 119) employ the last-named aqueous solutions in 5 p.c. strength to dissolve mercury fulminate for purposes of analysis, the impurities it commonly contains remaining undissolved.

When heated to 180° or when forcibly struck, mercuric fulminate detonates with great violence. The electric spark, or the spark from flint and steel, or contact with nitric or sulphuric acids also bring about explosive decomposition. Large crystals are more sensitive to impact than small ones. When moist it may be handled without danger, and when heated to 100° it does not explode if the crystals contain no enclosed mother liquor. The disruptive force of the explosion within a small space is greater than that of gunpowder, but too sudden for its use in guns. The pressure exerted by the gases evolved in the decomposition of the fulminate is less than that caused by the explosion of an equal weight of guncotton, the greater action of the former being attributed to the density of the compound and the great rapidity of the decomposition. Fulminate of mercury is used in the manufacture of percussion caps and of the various detonators used for exploding guncotton, dynamite, and other nitro-glycerin compounds (*v. EXPLOSIVES*).

Concentrated hydrochloric acid reacts with perfectly dry mercuric fulminate to produce formic acid and hydroxylamine hydrochloride. Thus :

If the acid be dilute and of a certain strength, chloroformoxime is produced (*v. supra*).

Moderately dilute sulphuric acid decomposes mercuric fulminate without explosion; hot nitric acid converts it into mercuric nitrate, acetic acid, and carbon dioxide. If sulphuretted hydrogen be passed through ether in which mercuric fulminate is suspended, ammonium thiocyanate is formed (*v. supra*); but if the system is kept free from moisture, nitrothioacetamide

is also produced, and is decomposed by a further quantity of sulphuretted hydrogen into ammonium thiocyanate, oxalic acid, and sulphur (Steiner, Ber. 1874, 1244; 1875, 518; 1879, 779). Heated with aqueous ammonia, mercuric fulminate yields urea, guanidine, and complex nitrogenous substances; with alcoholic ammonia fulminuric acid is the main product (Steiner).

Potash, lime, and strontia decompose mercuric fulminate on boiling, with the separation of mercuric oxide and the formation of double salts, which detonate on percussion (Liebig).

Finely divided zinc, copper, or silver (the last in contact with platinum) displace mercury from the fulminate, forming salts of zinc, copper, or silver. (For the action of mercuric fulminate on various metals and alloys see Langhans, Zeitsch. ges. Shies. u. Sprengstoffen. 1921, 16, 108.) Mercuric fulminate readily forms double salts with potassium cyanide and potassium and ammonium thiocyanates (Steiner).

Bromine reacts with mercuric fulminate to produce first of all the unstable additive compound $(\text{CBr}_2 : \text{N} \cdot \text{O})_2\text{Hg}$, which loses mercuric bromide, giving the unstable bromoformonitrile

reacts similarly, but the oxidising power of the halogen is so strong as to completely destroy the molecule, with the evolution of carbon dioxide (Wieland, Ber. 1909, 4192).

For the electrolytic estimation of mercury in mercury fulminate, see Losanitsch, Monatsh. 1914, 35, 307.

Silver fulminate, Fulminating silver

In preparing this substance 1 part silver is dissolved in 20 parts nitric acid of sp.gr. 1.36 and 27 parts of 86 p.c. spirit of wine added, and the whole gently heated till it froths up. The liquid is then removed, and 27 parts or more of spirit added in order to moderate the action. Silver fulminate separates out on cooling (Liebig).

Silver fulminate is not formed, as was stated by Liebig (Annalen, 5, 287), when nitrogen trioxide is led into an alcoholic solution of silver nitrate (Divers and Kawakita, Chem. Soc. Trans. 1884, 27), and is only produced by the energetic oxidation of alcohol by nitric acid in

presence of silver nitrate. Great caution must be exercised in the preparation of this substance. Capacious vessels must be used, so that the liquid may not boil over, as in that case the salt might dry on the outside and then explode; all flame must be kept at a distance, lest the vapours should take fire; and the mixture should be stirred with wooden rods, not with glass rods or other hard bodies. When dry it should be transferred on paper shovels, and kept in paper or cardboard vessels, loosely covered, to prevent explosion from the friction of stoppers or lids.

Silver fulminate crystallises in white opaque glistening needles, scarcely soluble in water, and having a bitter metallic taste. Given in certain doses, it produces violent convulsions (Pagot-la-Forêt), while in doses of 0.3 gram it acts as a narcotic (Ittner).

Silver fulminate is an exceedingly dangerous body, as it explodes much more violently than the mercury salt, by the action of heat, by the electric spark, by friction or percussion, or by contact with oil of vitriol. It even explodes in the moist state, sometimes under water, by friction with a glass rod. It may be rubbed to powder in a mortar with the finger or with a cork. The light accompanying the explosion, which is best seen in the dark, is reddish-white with a tinge of blue (Liebig). When ignited under a pressure of about 2 or 3 mm., it burns slowly with a visible flame. If silver fulminate be thrown into a bottle containing chlorine, it deflagrates before it reaches the bottom, and does not fracture the bottle (E. Davy). Silver fulminate dissolves in hot aqueous ammonia, and the solution, on cooling, deposits crystalline grains of ammonium silver fulminate

This salt is sparingly soluble in water, and explodes with much greater violence than the silver salt, even under liquid, when touched with a glass rod (Liebig). Aqueous solutions of the hydroxides of the metals of the alkalis or alkaline earths, or of the sulphides or chlorides of the alkalis, yield similar double salts when boiled with silver fulminate. Copper or mercury can displace silver wholly or in part from silver fulminate. Zinc, even on boiling for several days, displaces only half of the silver, forming silver-zinc fulminate. The normal zinc salt is prepared by the action of zinc on mercuric fulminate. By acting on this salt with baryta water, and exactly precipitating the barium from the zinc barium fulminate thus produced with sulphuric acid, zinc hydrogen fulminate is obtained. By saturating this salt with metallic bases, many double salts of zinc fulminate are obtained.

Cadmium fulminate $\text{Ca}(\text{CNO})_2$ is a white powder, stable when dry, but readily decomposed by water, in which it is very soluble. It is one of the most violent explosives, and is nearly as sensitive to shock and heat as mercury fulminate. *Thallous fulminate* becomes yellow on exposure to light, and is the most susceptible of all known fulminates to shock and increased temperature, but the heat of detonation is not high, and its explosion is not violent. *Cuprous fulminate* is insoluble in water, and is almost as violently explosive as cadmium fulminate, although not so sensitive to shock (L. Wöhler and Martin, Ber. 1917, 50, 586).

Fulminic acid gives rise to a series of polymerisation products. If mercuric fulminate is boiled with ammonium chloride, a salt of fulminuric acid is formed, as was discovered by Liebig. When the ethereal solution of fulminic acid is allowed to stand, metafulminuric acid, a triple polymer, is produced. When metafulminuric acid is warmed with water, it yields cyanisnitrosoacetohydroxamic acid, and the latter can be converted into the isofulminuric acid of Ehrenberg, the constitution of which is still unknown. Finally, on long standing metafulminuric acid changes into the β -isofulminuric acid of Scholzein.

FULMINURIC ACID $C_3H_3N_3O_3$. This compound was discovered independently by Liebig (Annalen, 95, 282) and Schischkoff (*ibid.* 97, 53; 101, 213). It is produced by boiling a solution of a metallic chloride or iodide with water and mercuric fulminate

60–75 grams of well-washed mercuric fulminate are boiled with 700–800 c.c. of water, 60 c.c. of a saturated solution of ammonium chloride are then added, and the whole heated to the boiling-point. As soon as a yellow deposit of oxydimercuric ammonium chloride separates, the flame is removed, and ammonia added till all the mercury is precipitated. On filtering, evaporating the filtrate, and recrystallising the first crop of crystals, pure ammonium fulminurate is obtained. By converting this into the basic lead salt by treating with lead acetate and then precipitating with sulphuretted hydrogen, an aqueous solution of fulminuric acid is obtained. This, on evaporation and standing in a warm place, solidifies to an indistinctly crystalline mass, which, dissolved in alcohol, deposits on evaporation colourless prisms of fulminuric acid. The potassium or ammonium salt may be converted into the silver salt, which may be decomposed by hydrochloric acid, yielding free fulminuric acid. Another method of preparing fulminuric acid is that of Ulpiani (Gazz. chim. ital. 1905, iii. 357). Succinamidedinitrosoperoxide, obtained by the action of fuming nitric acid on ethylacetacetate and subsequent treatment with concentrated ammonia, yields an acid which Ulpiani has proved to be identical with the fulminuric acid of Liebig, and also β -isofulminuramide. The latter yields β -isofulminuric acid on hydrolysis. Fulminuric acid decomposes on heating with a slight deflagration at 145° (Steiner, Ber. 1872, 381), and by heating with dilute acid or alkalis decomposes into oxalic acid, ammonia, and carbon dioxide. It appears to be monobasic. The constitution of fulminuric acid is still uncertain. Nef regards it as nitrocyanacet-

amide $CN \cdot CH \cdot NO_2$ (Annalen, 280, 329); while

Ulpiani (*l.c.*) represents it as isonitrocyanacetamide $HO \cdot C \equiv NH$
 $CN \cdot C : NO_2H$

amide $O : C \equiv NH_2$

Ammonium fulminurate forms anhydrous monoclinic crystals, which blacken on heating and give off hydrocyanic acid, ammonia, and cyanic acid, which latter partially unite to form urea (Liebig).

Potassium fulminurate. To prepare this salt two parts of mercuric fulminate are gradually added to a saturated solution of one part of potassium chloride, and the mixture gently boiled till the whole is dissolved. The liquid is filtered through a hot funnel from a yellowish precipitate which appears, and the compound of mercuric oxide and potassium fulminurate, which separates in the filtrate, is freed from mercury by sulphuretted hydrogen. On recrystallising from water, potassium fulminurate separates in long glistening prisms, which decompose with incandescence when heated to 225° (Schischkoff).

Silver fulminurate may be obtained by heating ammonium or potassium fulminurate with silver nitrate. It is almost insoluble in cold water, but may be recrystallised from boiling water in long very thin needles. Heated with concentrated hydrochloric acid in sealed tubes, at 110° , traces of the oxides of carbon are produced; one-third of the nitrogen goes to form hydroxylamine hydrochloride, and the other two-thirds ammonium chloride (Ehrenberg). Under ordinary pressures at 100° the action is complicated.

The fulminurates of calcium, barium, strontium, iron, and lead may be obtained by double decomposition from ammonium or potassium fulminurates. On heating an ammoniacal solution of copper sulphate with fulminuric acid, dark-blue prisms of ammonium copper fulminurate are deposited on cooling. By passing hydrochloric acid gas through alcohol containing potassium fulminurate in suspension, Schischkoff obtained an oil which he considered to be ethyl fulminurate. This body is, however, not an ethyl salt of fulminuric acid, but has the composition $C_4H_5EtNO_5$. It readily forms additive compounds with ammonia and the amines (Ehrenberg, *l.c.*). According to Siedel (Ber. 1892, 2756), fulminuric acid forms two series of esters, the oxygen ethyl ester melting at 133° and the nitrogen ethyl ester at 155° .

Metafulminuric acid, Isocyanuric acid $C_3H_3N_3O_3$. It is obtained by the spontaneous polymerisation of fulminic acid (*q.v.*). It is best prepared by treating chloroformoxime with a small quantity of sodium hydroxide or with aqueous ammonia in the cold (Wieland and Hess, Ber. 1909, 1346). The hydrated acid, containing probably 2 molecules of water, melts at 85° – 86° , and the anhydrous acid at 102° . On standing, metafulminuric acid changes into β -isofulminuric acid. The constitution of metafulminuric acid is still under discussion. Wieland and Hesse (*l.c.*) consider the hydrated acid to be isonitroso-iso-oxazolone

whilst Palazzo and Tamburello (Chem. Zentr. 1907, i. 26) assign to it the constitution

Cyanisnitrosoacetohydroxamic acid, or oximinocyanacetohydroxamic acid

is obtained by warming metafulminuric acid with water. It is prepared by treating an

ethereal solution of chloroformoxime with small quantities of ammonia, until the odour of the latter remains. The ammonium salt is decomposed with hydrochloric acid, and the acid, which crystallises from ether in colourless cubes, melts at 117° – 118° (Nef, *Annalen*, 280, 324). Cf. Ulpiani (*Gazz. chim. ital.* 1916, 46, i. 1), who discusses the constitution of the fulminuric acids and describes a number of their derivatives.

Isotofulminuric acid $C_3H_3N_3O_3$ of Ehrenberg is obtained by treating cyanisonitrosoacetohydroxamic acid with ammonia. It is a powder, and chars without melting when heated (Nef, *l.c.*; Ehrenberg, *J. pr. Chem.* [2] 30, 55).

β-Isotofulminuric acid was obtained by Scholzein (*ibid.* [ii.] 32, 461). He treated sodium fulminate with dilute sulphuric acid, and allowed the metafulminuric acid thus formed to stand for some time. Ulpiani (*Gazz. chim. ital.* 1905, iii. 35, 7) obtained the amide of this acid by treating succinamidedinitrosoperoxide with concentrated ammonia. The amide has the constitution

$$\begin{array}{c} \text{NH}_2\text{C}:\text{N} \\ | \\ \text{NH}_2\text{CO}\text{C}:\text{N} \end{array} \text{O}, \text{ and the acid is}$$
 obtained from it by hydrolysis. When anhydrous, the acid melts at 196° with decomposition; the hydrated acid melts at 188° .

FUMARIC ACID and MALEIC ACID

These two unsaturated acids are regarded as stereoisomers, and because of the readiness with which maleic acid forms an anhydride, maleic acid is represented as the *cis*-modification, and fumaric, which forms no anhydride, as the *trans*-modification. Interesting confirmation of this is shown by the formation of maleic acid on oxidising benzoquinone with nascent silver peroxide (Kempff, *Ber.* 1906, 3715). Maleic acid chloride is a very reactive compound, and an asymmetric structure is attributed to it, $\text{H}\cdot\text{C}\cdot\text{CO}$

$\parallel > \text{O}$. The chloride of fumaric acid is much less reactive (Ott, *Ann.* 392, 245). These two unsaturated dibasic acids may be obtained by heating maleic acid:

maleic anhydride $C_4H_2O_3$ distils over, and fumaric acid remains behind in the retort. By rapid distillation at 110° – 140° , maleic anhydride is obtained as chief product; by heating for about 40 hours to 150° , fumaric acid is mainly formed.

Both acids when treated with nascent hydrogen yield succinic acid. Both unite with hydrobromic acid to form monobromosuccinic acid. But fumaric acid unites with bromine to form dibromosuccinic acid, whilst maleic acid gives isodibromosuccinic acid. Potassium permanganate oxidises fumaric acid to racemic acid; maleic acid is converted into mesotartaric acid. Fumaric acid is much less soluble in water than maleic acid.

Fumaric acid occurs in various plants, as in the common fumitory (*Fumaria officinalis* [Linn.]), in *Corydalis bulbosa*, *Glauclium flavum* (Crantz), *Cetraria islandica* (Ach.), *Euphor-*

biaceae *Clytia similis*, and in varieties of *Agaricus*. It is also formed during the growth of *Rhizopus nigricans* in dextrose-containing media. It occurs in fresh beef, as an oxidation product of succinic acid (*Zeitsch. physiol. Chem.* 90, 301). It can be prepared by heating halogen substituted succinic acids (Brunner and Chuard, *Ber.* 1897, 201; Swarts, *Zeitsch. Chem.* 1868, 25); by reduction of tartaric acid (D. R. P. 254, 420); by condensing malonic with glyoxylic acid in presence of pyridine; and from maleic acid (*v. infra*). When heated in a sealed tube it melts at 286° – 287° (Michael, *Ber.* 1895, 163); sp.gr. 1.625 (Tanatar, *Chem. Soc. Abstr.* 1893, i. 11). It crystallises in small prisms, which sublime at 200° without decomposition, but by distillation is converted into maleic anhydride and water. Fumaric acid forms no anhydride of its own; all processes of dehydration convert it into maleic anhydride, which unites with water to form maleic acid.

Fumaric acid is converted into maleic acid by ultra-violet light, and also under the influence of radium rays. Fumaric acid on heating in aqueous solution is converted to maleic acid, the change being a reversible one (James and Jones, *Trans. Chem. Soc.* 1912, 1158).

Maleic acid has never been found to occur in nature, and is best obtained by heating maleic acid with acetyl chloride, and decomposing the acetyl maleic anhydride into maleic anhydride and acetyl chloride, and then heating the anhydride with water. It can also be prepared by heating fumaric acid (*v. supra*), or by treating a mixture of the vapours of benzene and benzoquinone by oxygen under pressure in presence of vanadium oxide (Weiss and Downs, *U.S. Pat.* 1318632). It forms large prisms or tabular crystals, very soluble even in cold water, m.p. 130° , b.p. 160° , decomposing for the most part into anhydride and water. Maleic acid is converted into fumaric acid when it is heated for some time at 130° or in sealed tubes at 200° , when it is treated in the cold with dilute mineral acids and certain organic acids, with sulphuretted hydrogen followed by sulphur dioxide, or with bromine in sunlight. Even at ordinary temperatures, and in the dark, its aqueous solution is slowly converted into fumaric acid. By heating the esters of maleic acid with iodine, the esters of fumaric acid are produced.

Maleic anhydride is a white crystalline solid, melting at 56° and boiling at 196° .

FUMARINE. Protopen (*q.v.*).

FUNGICIDES v. DISINFECTANTS and PLANT-SPRAYS.

FUNGISTEROL v. ERGOT.

FURFURAL, *Furfurol*, *Furfuraldehyde*, *Pyro-*

mucic aldehyde $C_5H_4O_2$, $\begin{array}{c} \text{CH}=\text{CH} \\ | \\ \text{CH}=\text{C}\cdot\text{CHO} \end{array} \text{O}$ first ob-

tained by Döbereiner by distilling sugar with manganese dioxide and dilute sulphuric acid. It may be prepared in small yields by heating sugar with dilute tartaric or lactic acids, or simply by heating with water; hence it occurs in brewers' wort and sometimes in the finished beer, also forming a constituent of fusel oil from the distilleries. Is produced during the heating of madder with dilute sulphuric acid in the preparation of garancin; during the dry

distillation of oak timber; and by heating starch at 200°. It is a constituent of many essential oils (Schimmel). Best prepared by distilling bran with dilute sulphuric acid and fractionating the distillate.

Colourless liquid; b.p. 161°; smelling of oil of bitter almonds and oil of cinnamon; sp.gr. 1.1594 at 20°/4°; $\mu_a = 1.5186$; soluble in 11 parts of water at 13°.

Reduces silver oxide with formation of pyromucic acid. Shows a striking similarity to benzaldehyde in its reactions, forming furfural-alcohol and pyromucic acid with caustic potash, furfural with potassium cyanide, dyestuffs with derivatives of aniline, &c.

The *urethane* is a very characteristic derivative, crystallising in needles, m.p. 169°, which may be sublimed. The *semicarbazone* melts at 202°-203°.

Owing to the presence of furfural in beer and spirits, many methods have been devised for its detection. One of the most sensitive tests is with colourless aniline, absolute alcohol, and either hydrochloric or glacial acetic acid, a cherry-red coloration being produced, the amount of furfural present being estimated by the depth of colour (J. Amer. Chem. Soc. 1906, 1629). Other methods of estimation are: precipitation with phloroglucin and hydrochloric acid (Weibel and Zeisel), and the preparation of the insoluble semioxamazine.

FURFURAN, Furan, Tetrol, Tetraphenol

Is a fairly stable ether compound, obtained by the distillation of the barium salt of pyromucic acid with soda-lime; by the distillation of calcium succinate; or by heating succinic dialdehyde with water at 180°. Best prepared by heating pyromucic acid alone in a tube at 260°-275°, as the barium salt produces also the hydrocarbon C_8H_4 and CO (Freundler, Compt. rend. 124, 1157).

Appears to be contained in the volatile portions of pinewood tar. Colourless liquid, boiling at 32°; insoluble in water, readily soluble in alcohol and ether. Acids convert it into pyrrole-red; metallic sodium and alkalis do not attack it. Colours a chip of pinewood moistened with hydrochloric acid an emerald green.

By nitration in presence of acetic anhydride, a monoacetin of nitrosuccinaldehyde is formed, which reacts with pyridine, producing nitrofurfuran; m.p. 28°;

FURFURINE $\text{C}_{15}\text{H}_{13}\text{N}_2\text{O}_3$. Prepared from furfural by first making the amide with the aid of ammonia. Furfuramide is boiled for 15 minutes with very dilute caustic potash, and the furfurine which separates is dissolved in excess of boiling dilute oxalic acid. The so-formed dioxalate is collected, and again dissolved in 100 parts boiling water, and precipitated with ammonia (Bahrmann, J. pr. Chem. [2] 27, 313); white needles; m.p. 116°; very sparingly soluble in cold water, but appreciably soluble in hot; readily soluble in alcohol or ether. It is a mono-acid base, and the crystals turn brown in moist air. Expels ammonia from boiling solutions of

ammonium salts, but is itself precipitated by ammonia from its salts in the cold.

When heated with sodium, *isofurfurine* is formed. Forms a nitrosamine $\text{C}_{15}\text{H}_{11}(\text{NO})\text{N}_2\text{O}_3$ by acting on the sulphate with very dilute potassium nitrite, and this exists as golden triclinic crystals; m.p. 112° (Schiff, Ber. 11, 1250).

FURFUROIDS are a group of compounds closely related to the pentoses and pentosans, distinguished by yielding furfural as a characteristic product of decomposition on treatment with acids (Cross, Bevan, and Smith, Chem. Soc. Trans. 1897, 1001).

FURFUROL v. FURFURAL.

FURNACES FOR GENERAL LABORATORY USE. Fig. 1 shows a Fletcher's gas muffle

FIG. 1.

furnace affording high temperatures without an air blast. With the use of a suitable pressure governor, fairly constant temperatures may be obtained. The furnace can be used for heat-

FIG. 2.

ing precipitates, fusions, roasting of ores, and similar laboratory operations. When crucibles which have to be weighed are heated, a sheet of asbestos cloth should be placed on the floor of the muffle.

A Fletcher's muffle furnace (Fig. 2), in which petroleum is used as fuel, is designed for use

where gas is not available. With the burner shown, the necessary air-blast may be obtained by a foot blower; or an automatic petroleum burner may be used, which dispenses with the use of an external supply of compressed air.

Fig. 3 shows a Fletcher's injector furnace,

FIG. 3.

which is efficient and rapid in working. For ordinary purposes, a foot blower is used, but for very high temperatures a blower driven by power is preferable. Cast iron can readily be fused in this furnace.

A furnace of similar shape to that shown in Fig. 3, but with a modified burner, is used where extremely high temperatures are required, a stream of oxygen being employed instead of

the usual air blast. In order to prevent the perforation of crucibles by a small but extremely hot flame, the burner is so designed that the oxygen is mixed with air before it enters the furnace, a more diffused flame being thus obtained.

FIG. 4 (a).

An exceedingly useful furnace designed by Fletcher is shown in Fig. 4 (a and b). This furnace works either as a draught or blast furnace with the same burner, and may be used for any temperature up to the fusing-point of the casing. It is adapted for crucibles, muffles, tubes, cupels, distillation by descension, treatment of refractory substances with gases at high temperatures, small forgings, roasting of

FIG. 4 (b).

ores, &c. When used as a blast furnace as shown in the figure, an empty crucible can be raised to the fusing-point of cast iron in 2 minutes, starting all cold. For use as a draught furnace, the plug c is removed and replaced by a chimney, when a crucible may be heated to bright redness in 10 minutes. The furnace may also be turned on its side, when the doors A and B become the front of a muffle furnace.

A furnace in which magnesia is used as the refractory material, and designed to employ the oxygen-coal gas flame is made by Merck. The burner is provided with a water jacket; and the mixed gases, which are projected through the bottom of the furnace, are so directed that the flame does not play directly on the substance in the crucible. The employment of magnesia for the parts most exposed to the flame, admits of the use of a very high temperature.

Fig. 5 shows a Fletcher's reverberatory furnace available for all general laboratory work, and capable, when working with a draught, of producing a clear yellow heat above the fusing-point of fine silver, and when worked

with a blast, for which the same burner is employed, of melting cast steel. It may be employed as shown, or one or both doors may be arranged to receive a muffle, so that the furnace may be used for muffle or crucible

FIG. 5.

operations, or for both simultaneously. Perrot's furnace for heating crucibles by gas is described fully in Bull. Soc. chim. 1867, 7, 332.

A furnace designed by Rössler (Zeitsch. anal. Chem. 1886, 95; Dingl. poly. J. 253, 79; J. Soc. Chem. Ind. 1884, 512) for intensely heating small

crucibles employed in chemical analysis is shown in Fig. 6. Cold air, admitted in carefully regulated quantity at *e* to the burner *a*, becomes heated during its passage around a jacket, *d*. Combustion takes place within a muffle, *c*, surrounding the crucible *b*, and the combustion products pass out through the cover of the muffle and through a chimney, *g*, the draught in which is assisted and regulated by a second burner. A somewhat similar arrangement has

Fig. 6.

been described by Hempel (Zeitsch. anal. Chem. 1877, 454). A simple form of crucible furnace using gas has been described by Roberts and McDermott (J. Amer. Chem. Soc. 1911, 33, 507).

Fig. 7 shows a Fletcher's furnace, which, although primarily designed for organic analysis,

Fig. 7.

will be found very useful for many other laboratory operations. The burners are placed in front of the furnace, and clear from all falling dirt, and since these are made of brass, there is no ironwork to rust. The furnace is made in 6-inch sections, and can, therefore, be

Fig. 8.

built up to any length. The body of the furnace is made entirely of fire-clay.

Sefström's portable furnace for use with charcoal is shown in Fig. 8. It consists of an outer cylinder forming an air chamber around a cylinder, *b*, fixed in position by a flange, *g*.

The cylinder *b* is perforated with holes containing small tapering nozzles, *e*, and is lined with fire-clay shaped as shown. When greater space is required for fuel, &c., a hoop, *h*, may be placed around the top of the cylinder *b*. It consists of a strip of sheet iron, in one end of which are two holes, *i*, whilst in the other end is a button which may be inserted in either of the holes, so that the hoop may fit over the cylinder *b*, or, when not in use, over the outer cylinder. The blast is supplied at *f* by a small bellows.

The electric furnace shown in Fig. 9 is specially adapted for fusions on a small scale, and for the production of high local temperatures. The process can be watched from beginning to end through the mica doors, the eyes being protected by blue spectacles. The furnace consists of an iron muffle lined with fire-clay. The block *b* can be raised or lowered by means of the set-screw *c*. On this block stands the crucible, made of lime, magnesite, &c., according to the purpose required. The

Fig. 9.

cables *f* and *f'* convey the current to the electrodes, *a* and *a'*, which can be adjusted by means of the regulating wheels *e* and *e'*. The mica doors permit of easy access to the interior of the furnace. In this type of furnace the heat is generated in a chamber of practically non-conducting material, and since no cold gases are introduced, extremely high temperatures may be produced in the crucible.

In the tube furnace shown in Fig. 10, the heating body consists of a tube of highly refractory porcelain, around which is coiled a ribbon of very thin platinum, which makes a closer contact with the porcelain and lasts much longer than platinum wire. A temperature of 1400° can easily be reached, but above this the porcelain begins to conduct electricity, and an electrolytic action is set up between the platinum and the tube, which will eventually cause breakage. In the figure the furnace is shown mounted on a tilting frame for use in any position. It may be obtained wound for any supply between 65 and 250 volts. In using the furnace it is necessary to pay attention to the following points: (1) No cold object must

be brought into contact with the tube while it is incandescent. (2) The furnace should not be kept at its maximum temperature longer than is necessary. (3) A suitable resistance should be connected up with the furnace in

FIG. 10.

order to ensure gradual heating, and to provide a means of regulating the temperature.

Fig. 11 shows an electrically heated crucible furnace, in which the heating resistance consists of platinum wire embedded in a suitable fire-clay. The furnace is designed for crucibles of a capacity not exceeding 30 c.c., and the temperature obtained is about 1050° – 1100° . Inside

FIG. 11.

the furnace the crucible rests upon a small stand of refractory porcelain; but if the contents of the crucible are moist, and it is required to heat them slowly, the crucible is suspended in such a way that only the lower part is within the furnace. For quantitative work, the furnace cover can be coated with platinum foil in order to prevent chips of fire-clay from falling into the crucible, and in special cases the whole of the interior may be

so lined. The temperature obtained is more uniform than that produced by the gas blow-pipe, and the use of this furnace entirely prevents the damage, which, particularly in the analysis of phosphates, is caused by the reducing gases, to a platinum crucible heated by gas. The consumption of current at 110 volts is 2.3 amperes, and the platinum resistance has an average life of about 850 burning hours.

An electrical crucible furnace in which the platinum resistance is replaced by a common metal is described by Askenasy (*Zeitsch. Elektrochem.* 1914, 20, 253). The metal is prevented from oxidising by a packing of powdered charcoal, which is placed in the space between the actual furnace and the outer casing. The furnace is 50 mm. diameter and 80 mm. deep, and can be connected directly with the lighting circuit without any resistance in series. The efficiency of the furnace is high, and a temperature of 800° can be obtained in 10 minutes, and one of 1100° in 30 minutes.

A crucible furnace in which the heat is generated by the passage of an electric current through a resistance of granular carbon, is made by Merck (Fig. 12). In order to withstand very high temperatures, the parts most exposed to

FIG. 12.

a, b, Case; *c*, copper plate; *d*, bolt; *e*, terminal; *f*, carbon block; *g*, resistance; *h*, crucible stand; *i*, magnesite ring; *l*, heating chamber; *m*, *n*, rings of magnesia; *o*, annular electrode; *p*, large cover; *q*, small cover.

the heat are made of magnesia, which is also used as a packing to minimise loss of heat. When using the maximum amount of energy (about 8000 watts), the temperature approaches the melting-point of corundum.

An electrically heated tube furnace (Fig. 13) is described by Blount (*Analyst*, 1905, 30, 29), in which the resistance consists of loosely packed retort carbon mixed with a suitable quantity of siloxicon. The essential parts of this furnace

are two concentric fire-clay tubes, surrounding, but not actually touching, that part of the porcelain tube to be heated. The resistance material is packed between these two fire-clay tubes, the current being led in by means of an

FIG. 13.

A, clamps; B, asbestos cloth; C, copper terminals; F, fire-clay tubes; D, pieces of fire-clay; R, resistance mixture; P, porcelain tube; U, uralite discs.

annular copper disc at each end, which is provided with a short cylindrical projection fitting closely in between the two tubes so as to make good contact for the resistance material. The two tubes which form the furnace proper are surrounded by two other wider fire-clay tubes which serve merely to insulate the heat. They may be covered with asbestos wrapping still further to retain the heat. The ends of the furnace are made of uralite discs, which also support the tube to be heated. With this apparatus, a piece of copper weighing from 15 to 20 grams can be fused in about 18 minutes.

A simple electric laboratory furnace with resistor of ductile tungsten or molybdenum wound on an alundum cylinder has been described by Winne and Dantsizen (*Met. & Chem. Eng.* 1911, 9, 537; *J. Soc. Chem. Ind.* 1911, 30, 1264). The temperature can be raised to 1700°, at which a current of 25 volts and 45 amperes is required.

For temperatures up to 2100°, electrically heated furnaces are made in which a current of 500 amperes and 5 volts is led through a thin-walled tube of pure iridium, but the extremely high price of this metal greatly limits the use of these furnaces.

For other forms of electric furnaces, see *Pring, The Electric Furnace*, Longmans, 1921.

For descriptions of electric vacuum furnaces, see Goecke, *Metallurgie*, 1911, 8, 667; also Slade, *Proc. Roy. Soc.* 1912, A, 87, 519; Wolf and Müller, *Zeitsch. Elektrochem.* 1914, 20, 1; Ruff, *ibid.* 1914, 20, 177; Oosterheld, *ibid.* 1915, 21-54.

Furnaces employed for particular purposes will be found described under special headings, as ASSAYING; ALUMINIUM; &c., &c.

FURUNCULINE v. SYNTHETIC DRUGS.

FUSEL OIL. *Fermentation amyl alcohol, Potato oil, Grain oil, Marc brandy oil.* (Ger. *Fuselöl*; Fr. *Huile de pommes de terre*.) The mixture of alcohols constituting this substance is produced in comparatively small quantity in the alcoholic fermentation of most bodies containing sugar, the largest proportion being contained in the alcohol prepared from potatoes, while in the alcohol from the 'marc' of grapes and from beetroots, grain, &c., smaller quantities are found.

Fusel oil consists mainly of two alcohols, one

of which, *iso*-butyl carbinol, or *iso*-amyl alcohol, or inactive amyl alcohol $(CH_3)_2CH \cdot CH_2 \cdot CH_2 \cdot OH$, is optically inactive, while the other, secondary butyl carbinol or active amyl alcohol

rotates the plane of polarised light to the left sufficiently to render fusel oil strongly laevorotatory. The following alcohols are said to have been separated from fusel oil:—

Ethyl alcohol	$CH_3 \cdot CH_2 \cdot OH$.
Normal propyl alcohol	$C_3H_7 \cdot CH_2 \cdot OH$.
<i>iso</i> Propyl	$(CH_3)_2CH \cdot OH$.
Normal butyl	$C_4H_9 \cdot CH_2 \cdot OH$.
<i>iso</i> Butyl	$(CH_3)_2CH \cdot CH_2 \cdot OH$.
Tertiary butyl	$(CH_3)_3C \cdot OH$.
Active amyl	$C_5H_9 \cdot CH_3 \cdot CH \cdot CH_2 \cdot OH$.
Inactive amyl	$(CH_3)_2CH \cdot CH_2 \cdot CH_2 \cdot OH$.
Methyl normal propyl carbinol	$CH_3 \cdot (C_3H_7) \cdot CH \cdot OH$.
Normal primary amyl alcohol	$C_5H_{11} \cdot OH$.
A primary hexyl alcohol	$C_6H_{13} \cdot OH$.
" heptyl	$C_7H_{15} \cdot OH$.

Formic, acetic, propionic, butyric, valeric, caproic, cœnanthic, caprylic, pelargonic, and capric acids have been found in fusel oils, and ethyl acetate and other esters and various aldehydes are also present.

The composition of fusel oil depends on the source of production, the nature of the ferments (*vide infra*), and the method of distillation. That from grain or potatoes consists largely of amyl alcohols with ethyl alcohol, the inactive amyl alcohol being the principal constituent. The fusel oil prepared in the South of France from the marc of brandy contains normal propyl alcohol in considerable quantities, while that obtained from the beet contains a larger proportion of *isobutyl* alcohol. Also the ferment in brewer's yeast (*Saccharomyces cerevisia* [Meyer]) appears to favour the production of *isobutyl* alcohol, whilst *Saccharomyces ellipsoides* (Reess.) (from the grape) tends to produce normal butyl alcohol. Higher alcohols are said to be rapidly produced after fermentation ceases, and, therefore, the higher alcohols tend to increase the longer the interval between fermentation and distillation. This may be due to some organism other than yeast becoming active after the yeast has done its work.

The proportion of fusel oil obtained during fermentation is also modified by the condition of the mash. Alkaline liquids, particularly when warm and containing large quantities of sugar, promote its formation, while acid liquids, especially when containing tartaric, racemic, or citric acids, are said to prevent its production. The presence, in any quantity, of tartar or certain bitters such as that of hops also prevents its formation, so that wines, &c., are usually free from fusel oil. According to Le Bel (*Compt. rend.* 96, 1368), pure sugar fermented with beer yeast yields less of these alcohols than wine or beer. Obviously a larger proportion of higher alcohols is likely to occur in spirits distilled from a pot-still than when highly rectifying appliances are used, as in patent stills.

Fusel oil is contained principally in the alcoholic distillates commencing to come off at 105°–125° and ending at 132°–137°. Between 105° and 120° most of the *isobutyl* alcohol is obtained,

while the amyl alcohols distil principally between 128° and 132°.

According to Rabuteau (Compt. rend. 87, 500), the following represents the percentage by volume of the principal constituents of *potato oil* :—

isoPropyl alcohol . . .	15.0
Propyl " . . .	3.0
Normal butyl alcohol . . .	6.5
isoButyl " . . .	5.0
Inactive amyl " . . .	27.5
Active " " . . .	6.0
Products boiling above 132° and retaining amyl alcohol . . .	17.0
Ethyl alcohol, ethyl acetate, and aldehyde . . .	7.5
Water . . .	12.5
	100.0

Later observations, however, do not confirm Rabuteau's statement that fusel oil contains *isopropyl alcohol*.

According to Ulex, the distillation of fusel oil produced from (1) beet, (2) potatoes, (3) grain, gives (roughly) the following percentage by volume :—

	(1)	(2)	(3)
80°–100° (principally propyl alcohol) . . .	13	13	31
100°–130° (butyl and amyl alcohols) . . .	53	30	26
Above 130° (amyl alcohol) . . .	34	57	43

By careful fractional distillation of wine brandy 25 years old, Ordonneau (Compt. rend. 1886, 102, 217) obtained the following substances :—

	P.c. by volume
Aldehyde . . .	0.003
Ethyl acetate . . .	0.035
Acetal . . .	traces
Enanthylic ester . . .	about 0.004
Propionic, butyric, and caproic esters . . .	0.003
Normal propyl alcohol . . .	0.040
" butyl " . . .	0.218
' Amyl alcohol ' . . .	0.0838
Hexyl " . . .	0.0006
Heptyl " . . .	0.0015
Amine bases (probably of the pyridine series) . . .	traces

Commercial alcohols from maize, beet, and potatoes, showed the presence, in addition to other substances, of propyl alcohol, active and inactive amyl alcohol, pyridine, a base which appeared to be collidine, and *isobutyl alcohol*, without a trace of normal butyl alcohol. Ordonneau attributes the disagreeable difference in flavour between wine brandy and that from a mash to the presence in the former of normal butyl alcohol, while the latter contains the disagreeably smelling *isobutyl alcohol*, but no normal butyl alcohol. He recommends that the fermentation of a mash should be performed with the elliptic wine yeast instead of the globular beer yeast, as he finds by experiment that the former produces the normal butyl alcohol, while the latter tends to form the *iso*- variety.

The *iso*-amyl alcohol (inactive amyl alcohol) may be separated from fusel oil by agitation with a saturated solution of common salt. The amyl, butyl, and propyl alcohols, which are less

soluble in that medium than in water, separate as an oily layer, while the ethyl alcohol remains in the brine. The separated oil is distilled, the portion coming off between 105° and 120° consisting principally of *iso*-butyl alcohol, while that distilling between 125° and 140° contains the amyl alcohols. This is collected separately, agitated with hot milk of lime, dried over calcium chloride and redistilled, the portion coming off between 128° and 132° being collected separately. In this way the *iso*-amyl alcohol is obtained almost free from butyl alcohol and from valeric aldehyde. The barium amyl sulphate produced from active amyl alcohol is $2\frac{1}{2}$ times as soluble in water as that from the inactive variety, so that these salts may be separated by careful fractional crystallisation, and afterwards treated for reproduction of the alcohols.

The composition of fusel oil from various sources has been carefully studied by Karl Windisch (v. Arbeiten aus dem Kaiserlichen Gesundheitsamt, 1892, Bd. 8), his principal results from (1) potato and (2) corn fusel oil, expressed in grams per kilog., and excluding ethyl alcohol and water, being as follows :—

	(1)	(2)
Normal propyl alcohol . . .	68.54	36.90
isoButyl alcohol . . .	242.50	157.60
Amyl " . . .	687.60	758.50
Hexyl " . . .	—	1.33
Heptyl " . . .	—	trace
Free fatty acids . . .	0.11	1.60
Fatty acid esters . . .	0.20	3.05
Furfural and bases . . .	0.05	0.21
Terpenes . . .	—	0.33
Terpene hydrate . . .	—	0.48

The free fatty acids and acid esters were also analysed with the following results expressed in percentages, the acids and esters being taken together in the potato fusel oil, and separately in the fusel oil from corn :—

	Potato. Free fatty acids and acid esters	Corn Free fatty acids	Esters
Capric . . .	36	44.1	40.7
Pelargonic . . .	12	12.9	14.2
Caprylic . . .	32	26.7	34.8
Caproic . . .	14	13.2	9.6
Butyric . . .	0.5	0.4	0.4
Acetic . . .	3.5	2.7	0.3

The terpene $C_{10}H_{16}$, which is present, together with its hydrate $C_{10}H_{16}O$, has not been exactly identified, but it has a close resemblance to phellandrene.

The injurious effect of raw or recently manufactured spirits is attributed (*inter alia*) to the presence of fusel oil produced during the fermentation and not thoroughly separated. Bell considered it to be due rather to furfural and other empyreumatic bodies, and this view was supported by Lauder Brunton, who thought that the toxic effect of spirit may also be attributed, in some cases, to the presence of traces of alkaloidal bodies, arising from the decomposition of albuminous substances in the mash. Schidrowitz also found in new whisky substances such as pyrrol, phenolic bodies, traces of nitriles, &c., which disappear as the spirit matures (J. Soc. Chem. Ind. June, 1905). The actual adulteration of alcoholic liquors with fusel oil is improbable, but spirits containing 0.3 p.c. of that

substance are usually deemed to be injurious, although the general tendency of the evidence given before the Royal Commission on Whisky and Potable Spirits, was to show that the evil effect of spirits is due to the ethyl alcohol itself, rather than to fusel oil or other secondary products present.

Samples of spirits examined by Dupré (Analyst, 1, 6) contained for 100 parts by weight of ethyl alcohol:

Scotch whisky containing 54.5 p.c. of alcohol	0.9 p.c. amyl alcohol
Cape smoke	0.24 "
Common Samshoe	0.18 "
Fine	0.13 "

According to Le Bel (Compt. rend. 96, 1368), natural white wine contains 0.2 p.c. amyl alcohol per litre, and, according to Hamberg (Schmidt's Jahrb. der Medicin, 201, 27, 1885), beer contains about 0.00114 p.c. of fusel oil.

Beer recommends a maximum permissible limit to the fusel oil in brandy, liqueurs, &c., of 0.3 p.c.; but Bödlander and Traube (Rep. Anal. Chem. 7, 167), who have examined a number of commercial spirits, propose a limit of 0.10–0.15 p.c.

The separation of fusel oil from spirit is extremely difficult. Among the various substances proposed or used for its destruction or removal, are charcoal, soap, oil, and fatty substances, potash ('grey salts'), pearl ash ('white salts'), lime, sulphuric, nitric, and hydrochloric acids, bleaching powder, and potassium permanganate.

Charcoal, soap, and oil are supposed to separate the fusel oil unchanged. When rectified over potassium permanganate or bleaching powder, the amyl alcohols are converted into valerates, but a portion of the ethyl alcohol is also decomposed. Bleaching powder, when used, is made into a milk at the ordinary temperature and permitted to digest for a time, after which the spirit is drawn off and rectified. According to Klezensky, if the spirit be distilled from *hard soda soap*, the fusel oil remains with the soap, from which it may be separated by subsequent distillation at a more elevated temperature.

The most approved method of separation, however, is by well-burnt granulated vegetable charcoal or bone-black. The charcoal is placed upon perforated trays in a vessel surrounded by a cooling jacket, and the spirit, usually diluted to about 160°Tr., is caused to pass through several layers. The operation should not be performed above the ordinary temperature, as the fusel oil is again dissolved from the charcoal near the boiling temperature. From 3 to 5 vols. of charcoal are required for the successful treatment of 100 vols. of brandy. The whole of the fusel oil is evolved from the charcoal on treatment by superheated steam, and the charcoal may be repeatedly used after heating to redness to drive off the occluded gases, &c. It is noticeable that the fusel oil obtained by steaming the charcoal does not represent the whole of that removed from the spirit, nor are sufficient compounds which might be produced by the decomposition of the fusel oils found to account for this loss.

Raw brandy, produced in Switzerland from

potatoes, maize, and the residues from breweries, by the continuous process, has been found to contain 1.32 p.c. of fusel oil. Raw Swiss brandy filtered through charcoal showed 0.2 p.c. of fusel oil; that rectified by distillation, 0.06; and that filtered through charcoal and afterwards rectified contained none. Cf. F. Pampe (Chem. Zeit. 11, 313).

Apart from the desirability of removing the excess of fusel oil from spirits intended for human consumption as a beverage, the oil is recovered for its own sake, as a valuable by-product in the manufacture of spirit, its price before the war being about 6 times that of ordinary alcohol. During the war, owing to the great demand for fusel oil for the manufacture of amyl acetate and other purposes, the price increased fourfold, viz. from about 50*l.* to over 200*l.* per ton.

By means of patent stills, the fusel oil may be rapidly and almost completely removed, and with suitable rectifying apparatus, alcohol at 95° and fusel oil may separately be obtained in the proportions of 130 to 1, or nearly 0.8 p.c. (by volume) of fusel oil.

The amyl alcohols of fusel oil dissolve in about 40 parts of cold water. According to Balbiano (Ber. 9, 1437), the inactive variety is soluble in about 50 parts of water at 14°, and is less soluble at 50°. Isobutyl alcohol dissolves in 10 parts of water at 15°. One part of inactive amyl alcohol takes up about 0.08 part of water, while isobutyl alcohol dissolves nearly twice that amount.

Fusel oil dissolves freely in ether, chloroform, alcohol, benzene, and carbon tetrachloride.

It is largely used for the manufacture of amyl acetate (*v.* ACETIC ACID), which has numerous applications in the arts and manufactures, as flavouring essences (pear oil, &c.), for confectionery, as a solvent for cellulose, and in making lacquers, varnishes, artificial leather, waterproofing, and sanitary sheeting for hospitals, &c. It is also used in toxicology as a solvent for alkaloids, for which purpose it should be carefully purified by agitation with dilute acid to remove an alkaloidal body which it is liable to contain. On account of its strong affinity for chlorine, fusel oil has been employed in chlorine generators for laboratory purposes as an absorbent for that gas, to prevent its escape into the atmosphere when the supply is no longer required; whilst its principal constituent (amyl alcohol) is employed in the estimation of fat in milk by the centrifugal methods.

For a description of the method of valuation of fusel oil used in the Institut für Gärungsge- werbe, Berlin, see Heinzelmann, Z. Spintusind. 1912, 35, 612; J. Soc. Chem. Ind. 1912, 31, 1142.

Synthetic fusel oil.—Synthetic commercial amyl acetate and fusel oil can be prepared by the following operations: A gasoline, boiling at 25°–45°, and consisting chiefly of saturated hydrocarbons, as, for instance, that obtained by cooling natural gas, is chlorinated by introducing chlorine at one end of a body of the hydrocarbon whilst illuminating the other end with a source of actinic light, and causing the gas to approach the light. By this means monochloro- derivatives are obtained, and as

soon as these have accumulated to the extent of 20 p.c. the mixture is fractionated, and the unchanged hydrocarbons are recovered for re-treatment. The fraction, b.p. 95°–140°, consisting mainly of pentyl and hexyl chlorides, is heated with an equal weight of anhydrous sodium acetate (with or without acetic and amyl acetate) for 5 hours at 200° under pressure in an autoclave rotated 30 times per minute. In this way 580 lbs. of the crude chlorides gave 384 lbs. of crude amyl acetate, from which fusel oil may be obtained by hydrolysis (Essex, Hibbert, and Brooks, J. Amer. Chem. Soc. 1916, 38, 1368). Another method consists in heating the chlorides with methyl alcohol and a formate under pressure at 140°–190° (Brooks and Essex, U.S. Pat. 1221667, 1917; Pyman, Reports, &c., 1917, ii. 471).

Detection of fusel oils.—When a sample of spirit is poured on filter paper or on the hand, and allowed to evaporate spontaneously, the characteristic suffocating odour of fusel oil may be recognised towards the close of the evaporation. So small a quantity as $\frac{1}{2000}$ part of amyl alcohol in gin may thus be detected.

On dissolving 1 gram of caustic potash in 150 c.c. of the spirit, concentrating slowly to 15 c.c., and adding an equal volume of dilute sulphuric acid, a powerful odour is given off, which is frequently sufficiently distinctive to show the nature of the mash from which the spirit was obtained. Betali (Ber. 8, 72) adds to the alcohol 6–7 volumes of water, and agitates with sufficient chloroform to produce a small layer on subsidence. This layer is drawn off and evaporated, and the residue is tested by digestion with potassium acetate and sulphuric acid. In presence of fusel oil the characteristic pear-like odour of amyl acetate is observable.

Marquardt dilutes 40 c.c. of the spirit with sufficient water to raise the density to about 0.980, and agitates the mixture with 15 c.c. of pure chloroform, which, after settlement, is drawn off, shaken with an equal volume of water, and evaporated spontaneously. The residue is treated with a little water, one or two drops of sulphuric acid, and sufficient of a strong solution of potassium permanganate to ensure that the liquid shall remain red after standing for 24 hours in a closed tube. The odour of valeric aldehyde is frequently noticeable shortly after the addition of the permanganate, but the characteristic smell of *valeric acid*, on which this very delicate test is based, is not appreciable until after standing.

Determination.—Fusel oil containing not more than 15 p.c. of proof spirit is allowed to be delivered from distilleries in the United Kingdom or to be admitted on importation from abroad duty free.

Numerous methods have been suggested for the estimation of ethyl alcohol in fusel oil, but none is free from objection. The following method can be recommended as being sufficiently accurate for all practical purposes.

75 c.c. of the sample, with 150 c.c. of water, are shaken vigorously in a separator (A) for 4 or 5 minutes, and allowed to stand. If an emulsion forms, a few grains of salt are added. The aqueous layer is drawn off into a second separator (B) saturated with salt, and extracted with 150 c.c. of petroleum ether. The brine

layer is then drawn off into a third separator (C) and extracted with a further 150 c.c. of petroleum ether, and the brine run off into a distilling flask.

The oil remaining in (A) is treated a second time with 150 c.c. of water, the aqueous layer drawn off into the petroleum ether in (B), saturated with salt, and extracted. The brine layer is drawn off into (C) and there extracted with the petroleum ether, from which, after separation, it is run into the distilling flask. The procedure described in this paragraph is then repeated.

The 450 c.c. of brine are distilled and the first 75 c.c. of distillate collected. This portion is saturated with salt and extracted with 150 c.c. petroleum ether. The brine is run off, distilled, 75 c.c. collected, and the specific gravity and refractometer (Zeiss immersion) reading of this fraction determined.

The refraction will be somewhat higher than that of ethyl alcohol of the same density. The difference is multiplied by the appropriate factor (1.1 is taken in ordinary cases), and the product is deducted from the percentage of proof spirit as deduced from the density of the distillate.

The accurate estimation of fusel oil in spirit is extremely difficult. A very rapid and simple process introduced by Traube is said to give satisfactory results where great accuracy is not required. The specific gravity of the spirit having been determined, sufficient water is added to reduce the proportion of alcohol to 20 p.c. The liquor is sucked up and allowed to fall a few times in a carefully dried, thin-sided capillary tube, 20 cm. long, and about 0.8 mm. in diameter, fastened to a graduated scale, and terminating at the zero in two points, which are set by a stand moved upon screws, to the surface of the liquid in the vessel into which the capillary tube dips. The height to which the liquid rises decreases with a rise in the proportion of fusel oil. From the observed height of the liquid in the capillary tube (temperature 21°), the percentage of fusel oil may be ascertained from the following table (Girard and Cuniasse, l'Analyse des Alcools):—

Height in tube	P.c. of fusel oil	Height in tube	P.c. of fusel oil
53.6 mm.	0.0	48.85 mm.	0.6
52.7 "	0.1	48.20 "	0.7
51.85 "	0.2	47.45 "	0.8
51.0 "	0.3	46.75 "	0.9
50.3 "	0.4	46.15 "	1.0
49.6 "	0.5		

This process is said to be largely affected by accidental conditions, such as temperature, moisture in the tube, &c., and by the presence of nitrobenzene, oils of peppermint, fennel, orange, and carraway, amyl acetate, &c.

Further information on this process is given by Traube (Bied. Zentr. 15, 559; Ber. 19, 892; Chem. News, 53, 302; Rep. Anal. Chem. 6, 659); Stutzer and Reitnair (*ibid.* 6, 606); Dingl. poly. J. 268, 126; and Girard and Cuniasse.

An improved apparatus, which he calls a *stalagmometer*, has been introduced by Traube (Ber. 20, 2644) for this estimation. The liquid, diluted as above to 20 p.c., is filled to a mark

in a vessel, and is allowed to fall drop by drop through a capillary tube at the base of the vessel, the number of drops in a certain time being noted and compared with the number of drops of pure alcohol of the same strength falling in the same time from the same apparatus. A smaller proportion of fusel oil than 0.05 p.c. may thus be determined.

The following table serves to indicate the percentage of fusel oil corresponding with the number of drops observed (Girard and Cuniassé):—

Number of drops	P.c. of fusel oil	Number of drops	P.c. of fusel oil
100	0.0	108.5	0.6
101.8	0.1	109.9	0.7
103.6	0.2	111.5	0.8
105.0	0.3	113.1	0.9
106.3	0.4	114.7	1.0
107.5	0.5		

If the temperature of the spirit is higher or lower than that for which the instrument has been calibrated, the number of drops observed is increased or diminished by 0.1 drop for every 30 drops for each degree of difference.

Another process, first introduced by Röse (Pharm. Centr. 1886, 9), depends on the alteration produced by the presence of fusel oils in the solubility of 50 p.c. alcohol in chloroform, and is said to be scarcely affected by the bodies which influence the results obtained by Traube's method. This process, which is official in Germany and Switzerland, has been modified at various times by Stutzer, Reitmair, Herzfeld, Windisch, and others (*vide* Zeitsch. anal. Chem. 34, 1895). Bromwell's modification of Röse's fusel-oil apparatus (*v.* U.S. Dept. Agric. Bur. of Chem. Bul. 46, 59) consists of a pear-shaped bulb holding about 200 c.c., stoppered at the upper end, and having at the lower end a graduated stem of about 4 mm. internal diameter leading to another bulb of about 20 c.c. capacity, and terminating in a tube provided with a stop-cock. The narrow stem is graduated in 0.02 c.c. from 20.0 to 22.5 c.c.

Fusel-free alcohol is first prepared by fractional distillation over caustic alkali to resinise aldehydes, saponify esters, and saturate acids, and is diluted to exactly 30 p.c. by volume (sp.gr. 0.965 at 15.6°); a quantity of chloroform is dehydrated and redistilled, and a solution of sulphuric acid of sp.gr. 1.2857 at 15.6° is prepared.

Of the sample under examination, 200 c.c. are taken, made alkaline, and distilled until about 175 c.c. are over. After cooling, 25 c.c. of water are added to the distilling flask, and the distillation resumed until 200 c.c. are collected. The distillate is diluted to exactly 30 p.c. by volume (sp.gr. 0.965 at 15.6°), and this, together with the Röse apparatus and the flasks containing the reagents (fusel-free alcohol, chloroform, and sulphuric acid), is placed in a water-bath kept exactly at 15° until all have acquired a uniform temperature.

The apparatus is then filled to the 20 c.c. mark with chloroform (through the lower tube by suction), and 100 c.c. of the fusel-free alcohol and 1 c.c. of sulphuric acid added. The apparatus is inverted and shaken vigorously for 2 or 3 minutes, the stop-cock being momentarily opened once or twice to equalise pressure. The

apparatus is then allowed to stand for 10 or 15 minutes in the water-bath at 15°, with occasional turning to hasten the separation of the reagents, and the volume of the chloroform is noted.

The apparatus is then thoroughly cleaned and dried, and the operation repeated, using the distillate from the sample instead of the fusel-free alcohol. An increase in the volume of the chloroform is observed due to the fusel oil present, and this difference, multiplied by the factor 0.663, gives the volume of fusel oil in 100 c.c., or the percentage of fusel oil by volume in the 30 p.c. distillate. This is then calculated to the percentage of fusel oil by volume in the original sample according to the alcoholic strength of the latter.

For example, in a sample containing 50 p.c. of alcohol by volume, the increase in the chloroform volume with the distillate from the sample diluted to 30 p.c. being 1.62 c.c., and that in the fusel-free alcohol also at 30 p.c., 1.42 c.c., the difference is 0.20 c.c. The volume of fusel oil in 100 c.c. of the 30 p.c. distillate is, therefore, $0.20 \times 0.663 = 0.1326$ c.c., and the percentage of fusel oil by volume in the sample (50 p.c. alcohol by volume) is $0.1326 \times 50 \div 30 = 0.221$.

In France, the official method is that of *Savalle* as modified by Girard and Cuniassé, and is based upon the depth of colour obtained by the action of strong sulphuric acid upon the higher alcohols. The method, which at best gives only comparative results, and these only when conducted under conditions so strict as to be almost unattainable in practice, is as follows:—

50 c.c. of the brandy, after distilling to free from colouring and extractive matters, and adjusted to contain 50 p.c. of absolute alcohol, are placed in a flask of about 250 c.c. capacity, and 1 gram of metaphenylenediamine is added, together with a little pumice.

The flask is adjusted to a reflux condenser and the contents boiled gently for an hour and then allowed to cool. The contents of the flask are then distilled to near dryness, and the distillate made up to the original volume of 50 c.c. with a few drops of distilled water. 10 c.c. of the spirit thus prepared are placed in a thoroughly clean flask of about 75 c.c. capacity, and 10 c.c. of pure concentrated sulphuric acid are carefully run into the flask so that it forms a layer under the spirit. The contents of the flask are quickly mixed and heated over a Bunsen flame, with constant agitation for 15 seconds after the commencement of ebullition. The liquid is set aside to cool, the mouth of the flask being covered with a small watch-glass. One or more samples of standard alcohol of 50 p.c. strength, and containing known quantities of isobutyl alcohol (50 mg. or less per 100 c.c.) are treated in exactly the same way. When cold, the coloration given by the sample under examination is compared with those given by the standard samples.

Beckmann's method depends upon the separation of the higher alcohols from the spirit by means of calcium chloride and carbon tetrachloride, the conversion of the higher alcohols into their nitrites by the action of sodium nitrite and sodium bisulphite, removing the excess of nitrous acid with sodium bicarbonate, decomposing the nitrites with sulphuric

acid, and final titration of the nitrous acid thus obtained with permanganate.

The details of this process are as follows :—

25 to 50 c.c. of the spirit, after distillation to free it from any colouring or extractive matter, are taken and diluted with water, so that the mixture shall contain not more than 20–25 p.c. of absolute alcohol. The solution is then saturated with sodium or calcium chloride, and extracted four times successively by vigorously shaking with 40 c.c., 25 c.c., 25 c.c., and 10 c.c. of carbon tetrachloride. The carbon tetrachloride extracts are mixed, and then washed three times successively by shaking with 50 c.c., 25 c.c., and 25 c.c. of saturated salt solution, and once with 25 c.c. of saturated sodium sulphate solution. The washings of each are extracted with 25 c.c. of fresh carbon tetrachloride, and this after separation is added to the first carbon tetrachloride extract. The mixed carbon tetrachloride solution is then dried by shaking vigorously with freshly heated calcium chloride in powder.

To the dried tetrachloride solution 3 grams sodium nitrite and 3 grams of sodium bisulphite are added, and the mixture is shaken occasionally during an hour. It is then filtered through glass wool, and to the filtrate 3 grams of sodium bicarbonate are added, and the mixture shaken occasionally during half an hour. Then 20 c.c. of water are added, and the whole gently shaken and allowed to stand till the mixture separates into two layers. The separated carbon tetrachloride is then run off. To the remainder, 10 c.c. of pure concentrated sulphuric acid are added; and, after shaking gently to mix, the mixture is poured into 100 c.c. of ice-cold water. The solution thus formed is titrated with standard permanganate (1 in 1000) until the pink colour becomes permanent. (The end reaction is not very sharp.)

(1 c.c. permanganate solution = 0.00278 gram amyl alcohol.)

According to Schidrowitz (*v. infra*), this method, as published, is unreliable, owing chiefly to the extraction of ethyl alcohol by the carbon tetrachloride.

The best method hitherto suggested is that of Marquardt, as modified by Allen and Schi-

drowitz. It is based upon the oxidation of the higher alcohols into the corresponding acids, and the estimation of the latter by titration or by converting them into and weighing their barium salts.

The extraction is carried out as in the Beckmann process just described. To the washed carbon tetrachloride solution 5 grams of pure powdered potassium dichromate, 2 c.c. of concentrated sulphuric acid, and 10 c.c. of water are added. The mixture is shaken and gently boiled for 8 hours under a reflux condenser. It is cooled, a little pumice and 50 c.c. of recently boiled distilled water are added, and it is then distilled to near dryness. The residue is cooled, 50 c.c. water added, and again distilled.

The distillates are mixed and titrated with N/10-baryta solution, first with methyl orange as indicator, and then with phenolphthalein. The acid indicated by the methyl orange is regarded as 'mineral acid,' and the difference as organic acid, which is calculated into amyl alcohol by multiplying the number of c.c. of N/10-baryta solution by 0.0088, and the figure indicating the dilution of the alcohol.

To obtain the combining weight, the solution containing the barium salt of the acid is separated from the carbon tetrachloride, evaporated, filtered, and finally dried in a platinum capsule and weighed. The weighed residue is then treated with a slight excess of sulphuric acid, again evaporated, and the barium sulphate ignited and weighed. From the weights found the combining weight of the acid is calculated.

By this method also some ethyl alcohol is extracted by the carbon tetrachloride, but apparently it does not appear as acetic acid after oxidation, and, according to Schidrowitz, the effect attributed to 'mineral acid' (of the presence of which there is no proof) may be due to some action between the methyl orange and certain aliphatic acids present.

(For a detailed criticism of the last three methods described, see Schidrowitz and Kaye, *Analyst*, June, 1905, and June, 1906.) J. C.

G-ACID. 2-Naphthol-6 : 8-disulphonic acid.

GABBRO. A holocrystalline igneous rock composed essentially of basic plagioclase-felspar and augite, and containing less than about 50 p.c. of silica. It is the plutonic equivalent of the finer-grained dolerite and basalt, having crystallised slowly under considerable pressure from large bodies of molten material within the earth's crust. The felspar is the soda-lime labradorite or the lime-felspar anorthite; the augite is usually the laminated diallage variety; apatite, iron-ores (magnetite and ilmenite) are usually present in small amount. When the rhombic pyroxene hypersthene is present in addition to plagioclase and augite the rock is

called a norite. The more acid quartz-gabbro forms a passage to diorite, whilst the more basic olivine-gabbro grades into the peridotites. The rock is dark grey, black, or greenish-black in colour, medium to coarse grained in texture, and very hard. Sp.gr. 2.7–3.0 (weight per cubic foot 170–190 lbs.); crushing strength 640–2200, averaging 1830 tons per sq. ft.

Analysis I of olivine-gabbro from Skye; also Cr_2O_3 trace (W. Pollard, 1900). II, olivine-gabbro from Lizard, Cornwall; also Cr_2O_3 0.08, V_2O_5 0.02, Li_2O trace, FeS_2 0.11 (E. G. Radley, 1912). Gabbro forms large masses and is of wide distribution, occurring, for example, in the Highlands of Scotland, Lendalfoot in Ayrshire, Carrock Fell in Cumberland, North and South Wales, the Lizard district in Cornwall, and in Guernsey. Owing to its dull colour and difficulty of working, it is not very extensively employed as a building stone; and it is reputed not to weather well, especially those varieties containing more felspar. In the trade it often passes under the name of 'black granite' (on the other hand, the trade name 'Norwegian gabbro' is sometimes applied to the augite-syenite—laurvikite—from the south of Norway). Medium-grained varieties are used for road metal and paving-sets. Olivine-gabbro is extensively quarried for export at Herrestad near Kärda in prov. Jönköping, Sweden, and on the Pleasant river near Addison in Maine. The 'black granite' of the Kentallen quarries in Argyllshire is a dark bluish-grey, medium-grained alkali-gabbro containing orthoclase, olivine, and biotite in addition to the usual constituents, and has been named kentallenite. It is used principally for paving-sets, and on a polished surface it displays bright plates of mica.

Gabbro takes a good polish and is sometimes used for ornamental purposes. The diallage often displays a metallic sheen, and in the gabbro of Volhynia and near Kiev in Russia the labradorite sometimes shows blue reflections. Coarse-grained gabbros when partly altered show the light- and dark-coloured minerals in marked contrast, and have been used as far back as Roman times as ornamental stones. In some cases the felspar is altered to saussurite and the diallage to emerald-green smaragdite, the rock being then known as euphotide; this beautiful ornamental stone occurs in the Alps, Corsica ('Verde di Corsica'), and Elba. A dark-coloured orbicular gabbro from Dehesa, San Diego Co., California, has also been used as an ornamental stone.

Magmatic segregations of iron-ores, metallic sulphides (nickeliferous pyrrhotite and copper-pyrites), and apatite sometimes occur in connection with gabbro masses. L. J. S.

GADININE *v.* PTOMAINES.

GADOLINITE. A rare mineral consisting of silicate of yttrium earths, glucina, and ferrous oxide $\text{Gl}_2\text{FeY}_2\text{Si}_2\text{O}_{10}$. Analyses show about 40–45 p.c. of yttrium earths of molecular weight 250–290; the amount of erbia has been separately determined as 10–15 p.c. It occurs in

much larger masses than the other rare-earth minerals, forming rough, black, and opaque crystals, sometimes exceeding 20 kilos. in weight. The crystals are monoclinic with an orthorhombic aspect; but in thin sections the material is optically isotropic. When heated, the mineral suddenly glows brightly, a molecular transformation taking place; the material then becomes optically birefringent, increases in sp.gr. (from 4.1–4.4 to 4.3–4.7), and changes in colour (as seen in sections) from greenish to reddish. Gadolinite occurs in some abundance as masses of considerable size in pegmatite veins at a few localities; notably, at Ytterby and near Fahlun in Sweden; in the felspar quarries of Sætersdalen and Hitterö, and elsewhere in the south-east of Norway; in Llano Co., Texas, Mohave Co., Arizona, and Western Australia. The locality (Barringer Hill, five miles south of Bluffton) in Llano Co. has yielded masses of gadolinite weighing 200 lbs., in association with several other rare-earth minerals. These have been worked for the supply of yttrium and erbium earths used in the 'glower' of the Nernst lamp (W. E. Hidden, Amer. J. Sci. 1889, 38, 474; 1905, 19, 425). L. J. S.

GADOLINIUM. $\text{Gd} = 157.3$ (*cf.* Urbain, Compt. rend. 1905, 140, 583). This element was first identified by Marignac in 1880, who separated its salts from those of other rare-earth metals present in samarskite by fractional precipitation with potassium sulphate (Arch. de Genève, 1880, [3] 3, 413; Compt. rend. 1880, 90, 899). With europium and terbium, gadolinium forms the small group of terbium metals, and as the solubilities of its salts are intermediate between those of the other two members of the family, the final separation of gadolinium from these elements is a matter of considerable difficulty. The older methods of separation, precipitation by ammonia, crystallisation of the oxalates, formates, and double sulphates, or combinations of these processes, did not, in all probability, lead to the complete purification of gadolinium. *Cf.* Meyer and Müller, Zeitsch. anorg. Chem. 1919, 109, 1, who have examined the efficiency of the various methods of separation. The presence of small quantities of terbium is indicated by a faint yellow discoloration of the colourless gadolinia. Europium is indicated spectroscopically in the arc spectrum.

Sources. The crude yttrium earths from monazite sand, samarskite, ytterbite (gadolinite), xenotime, aeschynite, &c.

Extraction and separation of the terbium earths. The first four methods outlined below serve rather to concentrate the terbium earths than to separate them from one another, gadolinium being the only one of the three which is obtained by these processes in a moderately pure condition.

A convenient starting-point for the separation of the terbium earths is the most soluble fraction of the ammonium or magnesium double nitrate separation of the rare earths. The preliminary elimination of the cerite metals with sodium or potassium sulphate is less preferable, since it involves a co-precipitation of a portion of the terbium group.

1. *Fractional precipitation with ammonia.*—In this process, terbia accumulates in the first fractions, followed successively by samaria and

gadolinia. Accordingly, samaria is a weaker base than gadolinia, and this relationship forms an exception to the rule that the more electro-positive earths yield less soluble double sulphates and nitrates than the less electro-positive oxides (*cf.* Lecoq de Boisbaudran, *Compt. rend.* 1890, 111, 394; Bettendorf, *Annalen*, 1892, 270, 376; Benedicks, *Zeitsch. anorg. Chem.* 1900, 22, 393).

According to Katz and James (*J. Amer. Chem. Soc.* 1914, 36, 779), in separating gadolinium from samarium by fractional precipitation with ammonium hydroxide the samarium would be concentrated in the last fractions, instead of in the early fractions, as stated by Boisbaudran and Benedicks.

Jordan and Hopkins (*J. Amer. Chem. Soc.* 1917, 39, 2614) recommended first to remove cerium by the bromate method and fractionally crystallise the residue. The less soluble fractions contain only europium, samarium, gadolinium, and neodymium, which are converted into the dimethyl phosphates and again fractionated. The least soluble fractions will then consist mainly of gadolinium. The last traces of samarium can be removed by precipitation with sodium glycolate.

2. *Fractional crystallisation of the sodium and potassium double sulphates.*—In isolating gadolinia from samarskite, Marignac (*l.c.*) separated the less basic constituents of the yttrium earths by partially decomposing the nitrates, dissolved the oxides, consisting chiefly of yttria, samaria, and the terbium earths in nitric or hydrochloric acid, and precipitated fractionally with potassium sulphate solution. After a systematic course of fractionation, he obtained the following four fractions in descending order of solubility: (i.) yttrium, terbium; (ii.) gadolinium, purified by further fractionations with potassium sulphate; (iii.) samarium, didymium; (iv.) didymium (*cf.* Delafontaine, *Arch. de Genève*, 1878, 61, 273; *Ann. Chim.* 1878, [5] 14, 238; Lecoq de Boisbaudran, *Compt. rend.* 1883, 97, 1463; Bettendorf, *l.c.*).

3. *Fractional crystallisation of formates and oxalates.*—The sparing solubility of the formates of the terbium group has been utilised in the separation of these metals, these salts separating as white microcrystalline powders from the concentrated solutions (*cf.* Delafontaine, *l.c.*; Marignac, *l.c.*; Hofmann and Krüss, *Zeitsch. anorg. Chem.* 1893, 4, 27; Feit, *ibid.* 1905, 43, 267).

The terbium earths can also be separated from erbium and yttrium by precipitation with oxalic acid in nitric acid solution (Marignac and Delafontaine, *l.c.*).

4. *Fractional crystallisation of the ethyl sulphates.*—The systematic crystallisation of the ethyl sulphates of the rare earths from water or alcohol leads to a separation of the three principal groups; cerite earths, terbium earths, and yttrium earths, arranged in descending order of solubility (Urbain, *Ann. Chim.* 1900, [7] 19, 184).

5. *Fractional crystallisation of the nitrates.*—The more complete separation of the constituents of the terbium group has been accomplished by the use of the nitrates and double nitrates. By fractionating the nitrates of terbium earths containing samaria, the sparingly soluble gadolinium nitrate and the more readily

soluble samarium nitrate were separated as well as a middle fraction rich in europium. The solubility of the rare-earth nitrates falls from lanthanum to samarium, attaining a minimum at gadolinium, and rises again till it reaches ytterbium.

By a lengthy fractionation of the nitrates from nitric acid (*sp.gr.* 1.3), Demarcay isolated small quantities of europium and gadolinium in a highly purified condition (*Compt. rend.* 1900, 130, 1469; 131, 343; 1901, 132, 1484). A further improvement in the separation was effected by Urbain and Lacombe (*v. EUROPIUM*), who crystallised the double magnesium nitrates of the rare earths in the presence of magnesium bismuth nitrate.

After crystallisation of the samarium and bismuth double salts, the mother liquor contains europium and gadolinium, the former being the first to separate on further fractionation. The gadolinium is then separated from the other remaining earths by fractionating the simple nitrates in the presence of bismuth nitrate. The latter salt now causes a separation to occur between gadolinium and dysprosium, the middle fraction consisting of bismuth and terbium nitrates. In this way, gadolinium is completely freed from terbium, dysprosium, and erbium earths. The fractional crystallisation of the nickel double nitrates of the terbium earths has led to a similar separation (*cf.* *Compt. rend.* 1903, 137, 568, 792; 1904, 138, 84, 627; 139, 736; 1905, 140, 1233; 141, 521).

The best starting materials for the preparation of gadolinium compounds are euxenite, samarskite, or the monazite residues, beginning with several kilos. of material.

The following method of procedure is recommended for the purification of gadolinium compounds: (1) If the rare earth mixture contains little cerium earths and much yttrium earths the gadolinium is separated with the cerium earths in one operation by the potassium double sulphate method. (2) If the mixture contains much cerium earths the major portion of these is separated by the double nitrate method. In either case a fraction very much richer in gadolinium is obtained. This is converted into the bromates and the yttrium earths removed by fractionation. The ytterbium earths first pass into the mother liquors, then follow the erbium earths, and last of all yttrium. It is essential that the yttrium should be removed at this stage, for it is scarcely possible to separate it at any of the remaining stages. The main fraction contains samarium, gadolinium, neodymium, terbium and europium; it is converted into acetate and fractionated, the fractionation being combined with the fractionation of the double bismuth nitrates. The cerium earths are rapidly separated, and a brown mixture of oxides, containing gadolinium and terbium is obtained. These salts are rapidly separated by fractional precipitation with ammonia (Meyer and Müller, *Zeitsch. anorg. Chem.* 1919, 109, 1).

Compounds. The oxide and chloride of gadolinium are colourless; the solutions of the latter have no selective absorption in the visible region of the spectrum, but show four strong bands in the ultra-violet end. (For spark-spectrum, *v. Compt. rend.* 1890, 111, 472; 1896, 122, 728; 1900, 131, 343; 1905, 140, 1233; 141, 521, 954;

Ber. 1901, 34, 2460; Annalen, 1891, 263, 164. For arc-spectrum, *v.* Eberhard, Zeitsch. anorg. Chem. 1905, 45, 394; Exner and Haschek, Die Wellenlängen der Bogenspektren, 1904.)

The spectrum of gadolinium contains seven groups of lines which are characterised by constant differences between the wave-lengths of corresponding members of the several groups (Poulson, Physikal. Zeitsch. 1915, 16, 7).

Gadolinia (*Gadolinium oxide*) Gd_2O_3 , a white amorphous hygroscopic powder, absorbing carbon dioxide from the air; sp.gr. 7.407 at 15° .

Gadolinium chloride and bromide $GdCl_3 \cdot 6H_2O$ and $GdBr_3 \cdot 6H_2O$, soluble deliquescent salts, the former yielding the yellow double chlorides, $GdCl_3 \cdot PtCl_4 \cdot 10H_2O$, and $GdCl_3 \cdot AuCl_3 \cdot 10H_2O$.

Gadolinium fluoride GdF_3 , a white gelatinous precipitate becoming granular on heating on the water-bath; somewhat soluble in hot hydrofluoric acid.

Gadolinium cobaltcyanide

Sparingly soluble in 10 p.c. solution of hydrochloric acid. 1000 parts of saturated solution contain 1.86 part of the salt.

Gadolinium platino-cyanide

separates in red rhombic crystals with a green reflex; it resembles the isomorphous platino-cyanides of yttrium and erbium, and differs from the corresponding double salts of the cerium group, which are yellow with a blue reflex.

Gadolinium nitrate $Gd(NO_3)_3 \cdot 6H_2O$ or $5H_2O$, m.p. 91° – 92° , is of all the nitrates of the rare earths the least soluble in nitric acid (*cf.* Demarçay, Compt. rend. 1900, 131, 343; *v.* Lang and Haitinger, Annalen, 1907, 351, 450). The following double nitrates:

and $2Gd(NO_3)_3 \cdot 3Ni(NO_3)_2 \cdot 24H_2O$, have been utilised in the isolation of gadolinium; the former melts at 77° .

Gadolinium sulphate $Gd_2(SO_4)_3 \cdot 8H_2O$ separates from hot solutions in monoclinic crystals, isomorphous with yttrium sulphate.

Gadolinium hydrazine sulphate

separates in colourless, sparingly soluble crystals when a solution of the mixed sulphate is boiled for some time.

Gadolinium sulphide Gd_2S_3 , a yellow hygroscopic mass, sp.gr. 3.8, is produced by heating the sulphate in hydrogen sulphide; it is slowly decomposed by water.

Gadolinium acetate $Gd(H_3C_2O_2)_3 \cdot 4H_2O$ forms moderately soluble triclinic crystals; the **Oxalate** $Gd_2(C_2O_4)_3 \cdot 10H_2O$ separates from nitric acid solution in monoclinic crystals (*v.* Brauner, Chem. Soc. Trans. 1898, 73, 951); the **Malonate** $Gd_2(H_2C_2O_4)_3 \cdot 8H_2O$ is obtained in refractive yellow needles (*v.* Erdmann and Wirth, Annalen, 1908, 361, 190).

Dimethyl phosphate, long, white needles, solubility 23.0 at 25° and 6.7 at 95° .

For other salts of gadolinium, *see* Bissell and James, J. Amer. Chem. Soc. 1916, 38, 873; Jantsch and Grünkraut, Zeitsch. anorg. Chem. 1913, 79, 305; Armstrong and Rodd, Proc. Roy. Soc. 1912, 87, 204; Katz and James,

J. Amer. Chem. Soc. 1913, 35, 872; Morgan and James, *ibid.* 1914, 36, 10. G. T. M.

GAHNITE or **ZINC-SPINEL**. Zinc aluminate $ZnAl_2O_4$, crystallised in the cubic system and belonging to the spinel group of minerals. According to the formula it contains 44.3 p.c. ZnO (35.6 p.c. Zn), but this is usually partly replaced isomorphously by ferrous oxide, manganous oxide, and magnesia, whilst the alumina may be partly replaced by ferric oxide. The mineral usually occurs as grey or dark greenish-black, opaque octahedra. Sp.gr. 4.5–4.9; H. 7½–8. It occurs as crystals embedded in talc-schist at Fahlun in Sweden, and more abundantly in crystalline limestone with other zinc ores (willemite and franklinite) at Franklin Furnace and Sterling Hill in New Jersey. It is also found at Bodenmais in Bavaria (with pyrrhotite), in Massachusetts, and a few other localities; and has also been observed in the muffles of zinc furnaces. The mineral was named in 1807 after the Swedish chemist, J. G. Gahn (1745–1818). L. J. S.

GALACTIN *v.* GUMS.

GALACTOSE *v.* CARBOHYDRATES.

GALAFATITE. An aluminium potassium sulphate, named after the discoverer, found, amongst other places in Spain, at Benahabux near Almeria, where it occurs in parallel veins from 5 to 6 mm. thick. It is white when pure, has a sp.gr. 2.75, and hardness 3.5. It is treated by calcination, followed by lixiviation with water, whereby a solution of potassium sulphate and a residue of nearly pure alumina are obtained. The calcined ore contains 65–70 p.c. of alumina and 25–30 p.c. of potassium sulphate (Preuss, Eng. and Min. J. 1911, 91, 261; J. Soc. Chem. Ind. 1911, 30, 282).

GALALITH or **ERINOID**. Artificial horn prepared by the action of formaldehyde on casein. Skim milk is treated with caustic alkali or alkali carbonate, the casein is precipitated by the action of rennet, pressed, impregnated with formaldehyde and dried (J. Soc. Chem. Ind. 1909, 101). Is used as an insulator and as a non-inflammable substitute for ivory, amber, tortoise-shell, coral, bone, ebony, &c. Is employed in electrical work, for aeroplanes, in the manufacture of buttons, pianoforte keys, &c. (*see* CASEIN).

GALANACK. A mixture of sulphur, tar and oil used as a cement or lute.

GALANGA ROOT. Galanga root is the rhizome of *Alpinia officinarum* (Hance), and is a native of China. It is employed in the form of a decoction as a remedy for dyspepsia.

Galanga root was first examined by Brandes (Arch. Pharm. [2] 19, 52), who isolated from it a substance which he named kampferride, but this, according to Jahns (Ber. 1881, 14, 2385), was a mixture of three substances, kampferride, alpinin, and galangin. The subject was later examined by Gordin (Dissert. Berne, 1897), and by Ciamician and Silber (Ber. 1899, 32, 861) and Testoni (Gazz. chim. ital. 1900, 30, ii. 327), and it is now clearly demonstrated that galanga root contains kampferride, galangin, and galangin monomethylether. According to Testoni, the alpinin of Jahns is a mixture of galangin and kampferride.

Kampferride $C_{16}H_{12}O_8$ consists of yellow needles, m.p. 227°–229°, soluble in alkaline

solutions with a yellow colour. Sulphuric acid gives a blue fluorescent yellow solution.

Triacetylkæmpferide $C_{16}H_8O_6(C_2H_3O)_3$, colourless needles, m.p. 193° – 194° (Ciamician and Silber and Testoni) (cf. also Jahns), **tribenzoylkæmpferide** $C_{16}H_8O_6(C_7H_5O)_3$, m.p. 177° – 178° (Testoni), **kæmpferide diethylether**

(Testoni), yellow needles, m.p. 137° – 139° , and **dibromkæmpferide** $C_{16}H_{10}Br_2O_6$, yellow needles, m.p. 224° – 225° (decomp.) (Jahns) have been prepared. In the presence of acetic acid, kæmpferide yields, by means of mineral acids, yellow crystalline compounds, and alcoholic potassium acetate gives **monopotassium kæmpferide** $C_{16}H_{11}O_6K.H_2O$, yellow needles, which is decomposed by boiling water (Perkin and Wilson, Chem. Soc. Trans. 1903, 83, 136). Kæmpferide is in reality **kæmpferol monomethylether** (v. Kostanecki and Rozycki, Ber. 1891, 24, 3723)

For a detailed description of kæmpferol, see *Delphinium consolida*.

Galangin $C_{15}H_{10}O_5$, the second constituent of galanga root, crystallises in yellowish-white needles, m.p. 214° – 215° , soluble in alkaline solutions with a yellow colour. With acetic anhydride, it gives a **triacetyl** derivative

m.p. 140° – 142° (Jahns), and by means of methyl iodide a **dimethylether** $C_{15}H_9O_5(OCH_3)_2$, m.p. 142° .

Galangin gives crystalline compounds with mineral acids in the presence of acetic acid, and reacts with alcoholic potassium acetate, yielding **monopotassium galangin**, yellow needles (Perkin and Wilson). When fused with alkali, **phloroglucinol** and **benzoic acid** are obtained. Galangin is a **dihydroxyflavonol**

and has been synthesised by v. Kostanecki and Tambor (Ber. 1899, 32, 2260) by a series of reactions similar to those employed in the preparation of kæmpferol.

2-Hydroxy-4 : 6-dimethoxychalkone

was converted into the corresponding flavanone, and the latter into its **isonitroso** derivative. This compound, on boiling with dilute sulphuric acid, gave **1 : 3-dimethoxyflavonol** which, when heated with hydriodic acid, was transformed into galangin. Galangin dyes with mordanted woollen cloth the following shades :—

Chromium	Aluminium	Tin	Iron
Olive-yellow.	Yellow.	Lemon-yellow.	Deep olive.

Galangin monomethylether $C_{15}H_9O_5(OCH_3)$, was first isolated from galanga root by Testoni (l.c.). It crystallises from methyl alcohol in bright yellow prisms, melts at about 300° , and dissolves in strong alkaline solutions with a yellow colour. **Diacylgalangin monomethylether** $C_{16}H_{10}O_5(C_2H_3O)_2$ forms yellowish-white leaflets, melting at 175° – 176° .

When air is aspirated through an alkaline solution of galangin monomethylether, it is oxidised with formation of **benzoic acid** and **phloroglucinol** (Perkin and Allison), and therefore possesses the constitution

A. G. P.

GALBA v. RESINS.

GALBANUM v. GUM RESINS.

GALAGINE $C_6H_{13}N_3$, is a crystalline alkaloid, m.p. 60° – 65° , obtained by G. Tanret (Compt. rend. 1914, 158, 1182, 1426; Bull. Soc. chim. 1914, [iv.] 15, 613) from the seeds of *Galega officinalis*. It is optically inactive, and splits on heating with barium hydroxide solution into equal molecules of urea and 3-methylpyrrolidine. The constitution suggested is:

Galagine is moderately poisonous (Tanret, Compt. rend. 1914, 159, 108), and *Galega* has occasionally caused cattle poisoning. G. B.

GALENA (Ger. *Bleiglanz*; Fr. *Galène*). Native lead sulphide (PbS), the principal ore of lead (86.6 p.c.). It crystallises in the cubic system, and possesses three directions of perfect cleavage parallel to the faces of the cube. Well-developed crystals, with the form of the cube or cubo-octahedron, are not uncommon. The massive mineral is always readily recognised by its rectangular stepped cleavages with smooth and brilliant surfaces and a lead-grey colour; small broken fragments have the form of cubes or dice. Further, it can be readily scratched with a knife (H. $2\frac{1}{2}$) yielding a black powder, and it is very heavy (sp.gr. 7.5). Ore with a very fine-grained texture may present somewhat the appearance of steel.

The presence of small quantities of silver in galena is of importance; though usually not more than a few ounces per ton in amount, it may reach 1 p.c. It is probably present in solid solution as silver sulphide, since argentite (*q.v.*) is isomorphous with galena. Examining polished surfaces of galena by reflected light under the high powers of a microscope, A. M. Finlayson (Quart. J. Geol. Soc. 1910, 66, 319) was able to detect fine strings of native silver running along the cleavage cracks of the galena. This was, however, only detected in specimens taken from the higher levels within reach of surface waters; specimens taken from deeper levels, where there has been no secondary alteration, showed no native silver. F. N. Guild (Econ. Geol. 1917, 12, 297) found that galena containing 0.10 to 0.35 p.c. silver shows definite spots of tetrahedrite and argentite; whilst

specimens containing more silver show evidence of later addition of ruby-silver, etc., in the form of veinlets.

Galena occurs chiefly in veins traversing rocks of various kinds, and also filling cavities in limestone. It is abundant in all lead-mining districts, and by its alteration it gives rise to cerussite, anglesite, and other secondary lead-bearing minerals. The use of galena for glazing pottery gave rise to the names 'potters' ore, alquifoux (Fr.), and archifoglio (Ital.). The powdered mineral is used as a cosmetic by the natives of Nigeria.

L. J. S.

GALIPOT v. RESINS.

GALIUM. The roots of various species of galium have been employed to some extent for dyeing red on aluminium mordant, and Bancroft, in his *Philosophy of Permanent Colours* (vol. ii. 303), mentions six of these plants, the roots of which gave an excellent red in this manner. More especially he refers to the *Galium tinctorium*, the roots of which, about 2 feet in length, are of a dark reddish colour, and which were employed by the French inhabitants of Canada to dye their cloths red.

This product is also referred to by Hellot as a species of madder brought from Canada which possesses an extremely slender root and produces nearly the same effect as European madder.

According also to Bancroft, the roots of the nearly allied species of *Asperula*, of which he specially mentions the *Asperula tinctoria* known as 'Dyer's woodruff,' were at one time used for dyeing red instead of madder.

Of others may be mentioned the *Galium mullugo*, Great Ladies' bedstraw or Wild madder, *Galium verum*, Yellow Ladies' bedstraw, and *Galium aparine*, the well-known Cleaver's or Goose grass, the two latter of which are common to this country. The roots of this last certainly give a small amount of dye soluble in alkali with a purple colour, and there seems to be little doubt that all contain dyes which are fast to light and of the alizarin type, though they appear to give a somewhat yellower shade than alizarin itself. An examination of these in case they yield either anthrapurpurin or flavopurpurin would be interesting.

A. G. P.

GALL-NUTS or GALLS or Oak Apples. (*Noix de Galle*, Fr.; *Gallen*, *Gallapfeln*, Ger.)

Galls are excrescences induced on plants by the attacks of animals (especially insects) or of other plants (especially fungi), which stimulate plant tissue that is capable of growing and cause hypertrophy. When an insect is the organism responsible, it usually infects very young parts (of roots, stems, or leaves), in which it deposits eggs from which there develop inside the gall larvae and eventually mature insects.

The oak apples are thus caused by various species of gall wasps (*Cynipida*). The most important of these are those of north-temperate Europe and of the Levant. Of the former, one of the commonest on the common oak *Quercus sessiflora* (Salisb.) and *Q. pedunculata* (Ehrh.) is caused by *Cynips kollari*, and is like a yellowish-brown marble in size and shape, contains one central chamber, and eventually shows one little exit hole through which the insect has escaped.

More important are the Levant galls, induced on scrubby oaks belonging to the species *Q.*

lusitanica (Lam.) [*Q. infectoria* (Oliver)], which occurs in the region extending from Greece, through Asia Minor, to Persia. The insect responsible is *Cynips tinctoria* (Htg.); this causes a gall by laying an egg in the young stem, which thereafter, by cell division and growth, swells into a gall in which the larva develops. The resultant insect may die inside the gall, or may bore its way out and escape through an exit hole. Levant galls are spherical to pear-shaped; the half near the stalk usually has a smooth surface, often inclined to be glossy, whereas the distal half is raised into lumps which are often conical in shape.

The Levant gall is very rich in tannin. Manceau found that the chemical composition in percentages was: water 12.05, ligneous substances 19.2, tannin 58.52, other constituents 10.21.

Levant galls vary in quality according to the region of origin, time of collection (including the condition as to whether gathered before or after the insects escape). The best kinds come from the Aleppo district: those gathered first, namely, in August or September, are of the highest quality, and are green, but subsequently become dark-coloured and harder: those gathered somewhat later are white, while the galls allowed to hang until winter are reddish-brown. Three qualities of Levant galls may be distinguished: (i.) Aleppo galls, small (2.5 cm. in diameter), dark-green to black in colour; (ii.) lighter-coloured galls, presenting the appearance of having been powdered on the surface; (iii.) Smyrna galls, larger (3-5 cm. in diameter), usually yellowish in tint. In water, the dark-hued galls sink, whereas the inferior lighter-tinted galls (even when dyed to imitate the former) float.

Galls (oak apples) of the same type are obtained in Southern Europe from scrubby specimens of *Quercus sessiflora* (Salisb.) and *Q. pubescens* (Willd.).

GALLACETOPHENONE v. KETONES.

GALLAMINE BLUE, GALLANILIC BLUE, -VIOLET v. OXAZINE COLOURING MATTERS.

GALLÉIN. *Anthracene violet* (v. ALIZARIN AND ALLIED COLOURING MATTERS).

GALLIC ACID. 3:4:5-*Trihydroxybenzoic acid* $C_6H_3(OH)_3COOH$, occurs in sumach, divi divi, Chinese tea, and various other plants (Stenhouse, *Annalen*, 45, 9; Hlasiwetz and Malin, *Zeitsch. Chem.* 1867, 271; Kawahier, *J.* 1852, 683; Perkin and Gunnell, *Chem. Soc. Trans.* 1896, 1307; Easterfield, *ibid.* 1901, 122; Grüttner, *Arch. Pharm.* 236, 293). Formed from tannin by boiling with dilute sulphuric acid, or when solutions of tannin become mouldy (Nierenstein, *Chem. Zeit.* 33, 126; Ber. 1910, 628), or by heating tannin with zinc (Iljin, *J. pr. Chem.* 80, [2] 332). In order to prepare it, finely powdered gall-nuts are macerated for some days with cold water, and the decanted liquid is exposed to the air and allowed to become covered with mould. An addition of yeast is advantageous. The gallic acid, which separates, is purified by recrystallisation from boiling water (Wittstein, *J.* 1853, 435; Tieghem, *Zeitsch. Chem.* 1868, 222; Scheele and Steer, *J.* 1856, 482). Heinemann (Fr. Pat. 314863; *J. Soc. Chem. Ind.* 1902, 415) boils the aqueous extract of galls with 5 p.c. by weight of sulphuric

acid for about 5 hours. The reaction is complete when a drop of the solution gives no precipitate with a gelatin solution (*v. also* Soc. Anon. Manuf. de Prod. Chimiques et Pharm. J. Soc. Chem. Ind. 1900, 553). It is soluble in 3 parts of boiling, in 130 parts of cold water; crystallises in silky needles or triclinic prisms from water with 1 mol. H_2O , which it loses at 120° ; is most readily soluble in acetone (Rosenheim and Schidrowitz, Chem. Soc. Trans. 1898, 882); melts at 222° – 240° ; and when heated to a higher temperature decomposes into carbon dioxide and pyrogallol (Braconnot, Annalen, 1, 26; Pelouze, *ibid.* 10, 159; Liebig, *ibid.* 101; 47; de Luynes and Esperandieu, Zeitsch. Chem. 1, [2] 702; Thorpe, Pharm. J. 11, [3] 990). By heating equal weights of gallic acid and aniline, gallanilide is formed, which may be used as a germicide. It is non-toxic. When gallic acid is heated with twice its weight of aniline, and the aniline pyrogallate thus formed is boiled with benzene, pure pyrogallol is obtained (Cazeneuve, Bull. Soc. chim. 7, [3] 549; 11, 81, 82; Compt. rend. 117, 47). By the destructive distillation of ethyl gallate, pyrogallol, ethyl alcohol, and *rufigallic acid* (hexahydroxyanthraquinone) are produced (Perkin, Chem. Soc. Proc. 1902, 254). *Rufigallic acid* is also formed when gallic acid is heated with concentrated sulphuric acid (Robiquet, Annalen, 19, 204; Wagner, Chem. Zentr. 1861, 47; Löwe, J. pr. Chem. [i.] 107, 296; Jaffé, Ber. 1870, 694; Klobukowski and Noeltig, *ibid.* 1875, 819; 1876, 1256; 1877, 880; Widmann, *ibid.* 1876, 856), and on reduction with sodium amalgam yields *alicarin* (Widmann, *l.c.*; Bull. Soc. chim. 24, [2] 359). By heating a mixture of gallic and benzoic acids with sulphuric acid, *anthragallol* (trihydroxy-anthraquinone) is produced (Seuberlich, Ber. 1877, 39).

Gallic acid, on oxidation with nitric acid, chlorine, or copper sulphate and alkali, yields oxalic acid as the main product (Boettinger, Annalen, 257, 248; 260, 337; Biétrix, Compt. rend. 122, 1545); oxidation with persulphates in the presence of acetic and sulphuric acids, yields *ellagic acid* (Perkin, Chem. Soc. Trans. 1905, 1412), and in the presence of dilute sulphuric acid, *flavellagic acid* (Perkin, *ibid.* 1906, 252); electrolytic oxidation with potassium ferricyanide in the presence of sodium acetate or other electrolytes, yields purpurogallincarboxylic acid (A. G. and F. M. Perkin, *ibid.* 1904, 254; 1908, 118; Perkin and Nierenstein, *ibid.* 1905, 1429); oxidation in alkaline solution yields *galloflavin*. Gallic acid is not reduced appreciably in acid or neutral solution, but in alkaline solution, benzoic acid is formed (Gardner and Hodgson, Chem. Soc. Proc. 1908, 272; Guignet, Compt. rend. 113, 200). Gallic acid and its derivatives undergo condensation with nitrosodialkylanilines to form dyestuffs of the *oxazine* or *gallo-cyanine group* (Patent Literature, Frdl. i. 267–270; ii. 158, 167–173; iv. 485, 506; *v. also* OXAZINE COLOURING MATTERS); with *o*-nitrosonaphthols or *o*-aminonaphthols to form brown dyestuffs used in tanning (Ashworth and Sandoz, Ger. Pat. 75633, 75634; Frdl. iv. 504, 505); with salicylic acid by means of phosphorus oxychloride to produce *salitannol*, an antiseptic used for dressing wounds (Bayer & Co., Eng. Pat. 9898; J. Soc. Chem. Ind. 1898,

487; Döbner, Ger. Pat. 94281; Chem. Zentr. 1898, i. 229); with acetaldehyde and benzaldehyde, yielding compounds which become coloured when dissolved in acids (Kahl, Ber. 1898, 151); with acetic acid and acetic anhydride to yield mono- and di- acetyl derivatives of gallic anhydride. These substances are insoluble in alkali, and so can be used instead of tannin for medicinal purposes, as the latter is soluble in the stomach juices (Bayer & Co., Eng. Pat. 1228; J. Soc. Chem. Ind. 1895, 297). Gallic acid is also used in the preparation of *thionine* dyestuffs (Nietzki, Ger. Pat. 73556, 76923, 79172; Frdl. iii. 360; iv. 455, 456).

Gallic acid condenses with formaldehyde to yield four distinct methylenedilgallic acids, yielding dyestuffs on treatment with nitrosulphuric acid in sulphuric acid solution (Möhlau and Kahl, Ber. 1898, 259). It forms compounds with albuminoids (Wörner, Ger. Pat. 189334; J. Soc. Chem. Ind. 1908, 644), and with ferments (Ger. Pat. 198305; J. Soc. Chem. Ind. 1908, 713). It is absorbed by organic colloids, this being of interest, since it bears on the theory of dyeing and tanning processes (Dreaper and Wilson, J. Soc. Chem. Ind. 1906, 515). Complex salts of gallic acid (*v.* Silbermann and Ozorovitz, Chem. Zentr. 1908, ii. 1024). Derivatives of gallic acid (*v.* Power and Shedden, Chem. Soc. Trans. 1902, 73).

Basic bismuth gallate (*Dermatol*)

is prepared from bismuth hydroxide and gallic acid, or from bismuth nitrate and gallic acid in the presence of potassium nitrate and acetic acid. It is a yellow powder, but is obtained crystalline by the second method given above (Thibault, J. Pharm. 14, [vi.] 487; 25, [vii.] 268; May, Amer. J. Pharm. 80, 208; Causse, Compt. rend. 117, 232; Fischer and Grützner, Arch. Pharm. 231, 680). *Bismuthhydroxydigallate* (*Airol*) is a greenish-grey powder (Haegler, Chem. Zentr. 1896, i. 764; Torelli, *ibid.* 1898, i. 857; Hoffmann, Traub & Co., Ger. Pat. 80399, 82593; Frdl. iv. 1122, 1123). Both compounds are inodorous antiseptics, and may be used as substitutes for iodoform.

Methyl ester $(HO)_3C_6H_2 \cdot CO_2CH_3$. Prepared by dissolving gallic acid in hot methyl alcohol, and treating the solution with hydrogen chloride. The alcohol is distilled off, the residue dried and recrystallised from hot water (Kern, Eng. Pat. 5953; Ger. Pat. 45786; Frdl. ii. 167; Hamburg, Monatsh. 19, 594); m.p. (anhydrous from methyl alcohol) 202° ; from hot water, crystals contain water of crystallisation, which is driven off at 100° – 110° .

Detection and Estimation.—Gallic acid gives a bluish-black precipitate with ferric chloride, but does not precipitate gelatin. On adding 1 c.c. of (1:30) potassium cyanide solution to a 1 p.c. solution of gallic acid and agitating, a ruby-red colour is produced, which disappears on standing, but is regenerated by agitation. Pyrogallol and tannic acid give yellowish-red solutions (Griggi, Boll. Chim. Farm. 38 5). Boettinger (Annalen, 256, 341; J. Soc. Chem. Ind. 1900, 450) heats gallic acid with double its weight of phenylhydrazine to 100° , boils the solution for a few seconds, and then lets one drop fall into a beaker containing water made

alkaline with caustic soda, when an orange or golden-yellow coloration is produced. Tannic acid gives a blue coloration changing to yellow. In estimating gallic acid in tannins, it is always necessary to separate it from the tannic acid, which is also present (Spica, Gazz. chim. ital. 31, ii. 201; Harnack, Arch. Pharm. 234, 537; Buchner, Annalen, 53, 537; Hinsdale, Chem. News, 64, 51; Dreaper, J. Soc. Chem. Ind. 1893, 412; Chem. News, 90, 111; Procter and Bennett, J. Soc. Chem. Ind. 1906, 251; Jean, *ibid.* 1900, 382).

GALLIPEÏNE *v.* CUSPARIA BARK.

GALLISIN (iso-MALTOSE) *v.* CARBOHYDRATES.

GALLIUM. Ga. At.wt. 69.9 (Boisbaudran); 70.1 (Richards, Craig, and Sameshima). Is very widely distributed in nature, although always occurring in minute quantities. It is found in various clay ironstones, in hæmatites, in various aluminous and manganese minerals and ores, in some meteorites and meteoric iron, in zinblendes, pyrites, &c. (Hartley and Ramage, Chem. Soc. Trans. 1897, 533). Perhaps the richest source of this metal is the Middlesborough blast furnace metal obtained from the Cleveland clay ironstone, the cast iron containing 1 part of gallium per 33,000 parts of iron. Gallium belongs to the aluminium group of elements, and is occasionally to be detected in commercial aluminium; it is the eka-aluminium predicted by Mendeléeff, and was discovered by Boisbaudran, in 1875, by means of spectroscopic analysis, in the zinblende of Pierrefitte in the Pyrenees (Compt. rend. 1892, 114, 815).

For its electrolytic deposition and purification, see Uhler and Browning, Amer. J. Sci. 1916, [iv.] 42, 389; Richards and Boyer, Nat. Acad. Sci. Proc. 1918, 4, 388; J. Amer. Chem. Soc. 1920, 43, 274. For its qualitative separation and detection, *v.* Browning and Porter, Amer. J. Sci. 1917, 44, 221; J. Amer. Chem. Soc. 1921, 43, 126.

Gallium is a bluish-white, hard, tough, slightly malleable diamagnetic metal; sp.gr. 5.9, sp.ht. 0.080 and of higher sp. resistance than the alkali metals. It fuses at 29.76°, forming a silver-white liquid of sp.gr. 6.096, resolidifying very slowly even at 0°. If, however, a fragment of solid gallium is introduced, it solidifies rapidly in pyramidal monoclinic crystals, and expands on freezing. The expansion on solidification is 0.00531 c.c. per gram. The compressibility of the solid metal is 2.09×10^{-6} . Liquid Ga has a compressibility of 3.97×10^{-6} at 30°. The molten metal, if poured on to a glass, covers the surface with a bright mirror like deposit. The metal is non-volatile at a red heat, is slowly and superficially tarnished in air or water. It is attacked by the halogens, and dissolves in hydrochloric acid and in potash solution with evolution of hydrogen. In nitric acid, it dissolves on warming, with evolution of oxides of nitrogen. It forms liquid alloys with aluminium and indium.

Compounds. *Gallium oxide* Ga_2O_3 is a white powder reduced by hydrogen at a bright red heat, and, according to Winkler (Ber. 1890, 23, 788), also by magnesium: the *hydroxide* is insoluble in water, but soluble in alkalis. *Chlorides*, GaCl_3 , GaCl_2 , an *oxychloride*, *bromides*, *iodides*, *sulphates*, *sulphides*, a *nitrate*, a

series of *alums* $\text{Ga}_2(\text{SO}_4)_3 \cdot (\text{M})_2\text{SO}_4 \cdot 24\text{H}_2\text{O}$, and a *silicotungstate* have been prepared (Dupré, Compt. rend. 1878, 86, 720; Boisbaudran, Ann. Chim. 1877, [5] 10, 126; Wyrouboff, Bull. Soc. franc. Min. 1896, 19, 240). Gallium chloride sublimes at a comparatively low temperature, and may thus be separated from less volatile chlorides.

GALLOCYANINE *v.* OXAZINE COLOURING MATTERS.

GALLOFLAVIN. This dye, which can be fixed on mordanted fibres like alizarin, is obtained by the action of air, *i.e.* oxygen, on alkaline solutions of gallic acid. The process of oxidation depends on the amount of alkali present. In practice, 5 parts of gallic acid are dissolved in 80 parts of alcohol of 96°Tw. and 100 parts of water. The cooled solution is gradually mixed with 17 parts of caustic potash solution of 30°B., stirring all the while, and never allowing the temperature to rise above 10°. It is then exposed to the action of oxygen, either by blowing air through it or by agitating it briskly. The progress of the oxidation shows itself by the liquor assuming at first an olive-green or greenish-brown colour, until finally a crystalline precipitate separates out. When the amount of this precipitate no longer increases, the operation is finished. The mass of crystals is quickly filtered, dissolved in warm water, decomposed with hydrochloric or sulphuric acid, and boiled when the dye is precipitated in the state of glistening greenish-yellow plates. These are washed, and can then be applied for dyeing or printing.

Galloflavin dyes cotton mordanted with alumina greenish-yellow, which turns into a very brilliant yellow by treatment with tin crystals. Wool, mordanted with bichrome, is dyed olive-yellow, copper as mordant gives a dark-brown, and stannous mordant dull-orange. In practice, only chrome mordants are used, and the shades obtained are fairly fast to light, soap, and milling, fast to dilute acids and alkalis, but do not compare favourably with the alizarins. The colour is somewhat sensitive to chlorine.

The formula $\text{C}_{13}\text{H}_6\text{O}_9$ was first suggested for galloflavin (Bohn and Graebe), and subsequently $\text{C}_{12}\text{H}_6\text{O}_8$ (Herzig). The substance crystallises in greenish-yellow leaflets, is sparingly soluble in water, alcohol, and ether, more readily soluble in glacial acetic acid and aniline. The *potassium salt* $\text{C}_{13}\text{H}_4\text{O}_9\text{K}_2$ (B. & G.) is a crystalline body which is insoluble in alcohol and cold water. The *acetyl derivative*

(B. & G.) or $\text{C}_{14}\text{H}_8\text{O}_4(\text{O}\cdot\text{COCH}_3)_4$ (H.) crystallises from benzene or ethyl acetate in white needles, m.p. 230° (B. & G.), 230°–233° (H.); is freely soluble in glacial acetic acid and chloroform, but does not dissolve readily in alcohol or ether. The *chloroacetyl derivative* $\text{C}_{13}\text{H}_5\text{O}_5(\text{O}\cdot\text{COCH}_2\text{Cl})_4$ (B. & G.), is very little soluble in alcohol, ether, chloroform, or benzene, easily soluble in acetic acid, and crystallises in needles; m.p. 210°–212°. Galloflavin, on methylation, yields *tetramethoxygalloflavin* $\text{C}_{12}\text{H}_8\text{O}_4(\text{OCH}_3)_4$ (H.), crystallising in felted, almost colourless needles from acetic acid; m.p. 236°–239°. When this compound is quickly boiled with aqueous potash, and then treated with strong hydrochloric acid, it yields a crystalline substance, *trimethylisogalloflavin*,

$C_{11}H_2O_3(OCH_3)_3COOH$ (H.), difficultly soluble in alcohol, and crystallising therefrom in fine white needles, melting at 253° – 256° , with strong gas evolution. On methylation or esterification, this yields *tetramethylisogalloflavin*

(H.), crystallising from alcohol in long needles; m.p. 232° – 234° . Heated under reduced pressure, trimethylisogalloflavin loses carbon dioxide, and a substance, $C_{11}H_2O_3(OCH_3)_3$ (H.), distils over at 270° – 300° (28 mm. pressure), which sets to a yellowish-white crystalline mass, is difficultly soluble in alcohol, and can be crystallised therefrom in white crystals; m.p. 130° – 134° . On methylating trimethylisogalloflavin with aqueous alcoholic potash and methyl sulphate, and finally with diazomethane, there is obtained a substance, $C_{10}H_2O(OCH_3)_4(COOCH_3)_2$ (H.), crystallising out of methyl alcohol and melting at 92° – 95° . This substance is easily hydrolysed to the corresponding *dibasic acid*

(H.), crystallising from dilute methyl alcohol, and melting at 214° – 215° with gas evolution. This dibasic acid, on heating under reduced pressure, loses carbon dioxide, and a *monobasic acid* $C_{10}H_2O(OCH_3)_4COOH$ (H.) distils over at 260° – 280° (28 mm. pressure), which sets to a solid, and, crystallised from ethyl acetate, melts at 132° – 135° . This series of transformations from tetramethylgalloflavin indicates that it probably contains two lactone bonds, and that galloflavin itself may be represented as:

GAMBOGE *v.* GUM RESINS.

GAMMA (γ) ACID. 2-Amino-8-naphthol-6-sulphonic acid.

GAMMAM. A Tunisian dyestuff of unknown origin.

GANISTER. A local name of unknown origin for a hard siliceous sandstone occurring in the coal-measures of the north of England. Formerly it was employed as a road-stone, but now it is much used for making refractory ganister- or silica-bricks and for the linings of steel furnaces and converters. The name has

been also loosely applied to other siliceous materials used for making fire-bricks. In the typical locality, namely in the neighbourhood of Sheffield, the rock occurs beneath thin seams of coal at a definite horizon—the Ganister group—in the lower coal-measures. The best bed, lying immediately beneath the Hard Mine coal, varies in thickness from a few inches to $5\frac{1}{2}$ feet, with an average of $2\frac{1}{2}$ feet. Here it is a hard compact rock with a very fine and even-grained texture, and consists of sub-angular grains of quartz, mostly 0.15–0.5 mm. across, closely packed together and cemented with secondary silica. No appreciable amounts of mica, felspar, or carbonates are present. The rock thus has the character of a quartzite. It is light to dark grey in colour, and is often iron-stained along the joint surfaces. It breaks with a splintery to sub-conchoidal fracture with sharp edges. Carbonaceous patches and streaks, and fossil tree-roots are embedded in the rock. It consists of 90–95 p.c. of silica with small amounts of alumina, iron oxides, lime, and alkalis. Sp.gr. 2.59. Silica rocks of very much the same nature are widely distributed in most of the coal-fields of England, Wales, and Scotland; e.g. the Dinas rock (or 'clay') from the Vale of Neath in Glamorganshire, which contains as much as 98 p.c. of silica. They pass insensibly, both laterally and vertically, into siliceous fire-clays ('bastard ganister'). The rock is won by quarrying or underground mining, and is crushed, ground, and mixed with lime (1–1½ p.c.) or fire-clay to act as a binder. This mixture is moulded into bricks, which, after drying, are fired at about 1500° , or it is applied directly as a furnace lining, or used for setting the bricks and patching and repairing furnaces. Ganister is also ground to a fine sand for use in casting iron and brass (*v.* Mineral Resources of Great Britain, Mem. Geol. Survey, 1918, vol. vi. (2nd edit., 1920); and 1920, vol. xvi.; A. B. Searle, *Refractory Materials*, London, 1917). L. J. S.

GARANCEUX and **GARANCINE** *v.* MADDER.

GARBAGE FATS. Under the name 'garbage fats' may be comprised all those fats contained in house and other refuse which do not find their way into the sewers. Such refuse is generally collected by the municipalities and destroyed as soon as possible, the primary object being to remove it rapidly from inhabited areas and dispose of it in a sanitary, or at any rate in the least objectionable, manner. The system, in vogue in this country, and rapidly superseding the older method of dumping on waste land, is to destroy the refuse in specially designed destructors, after a rough sorting out of tins, iron pots, old leather, &c., has taken place in the destructor works. Thus all putrescible matter, together with the fat present, is destroyed. Hence efforts have not been wanting to recover the fatty matter. In the United States of America especially methods for the disposal of garbage have been developed. An early process (worked in Buffalo about 1885) consisted in extracting the garbage with light petroleum. This has, however, been superseded by cheaper processes comprised under the term 'reduction processes.' These processes are very similar to the methods used in the rendering of fish oils (see MENHADEN OIL), and slaughter-house greases.

In several cities of America, the Arnold-Egerton process is worked, in which the fatty matter is extracted by purely mechanical means. The garbage is delivered into large digestors, in which the mass is boiled with steam. After boiling at 80 lbs. pressure, the whole mass collects into three layers, the top layer of which forms the separated grease. This grease is sold for the manufacture of low-class soaps and low-class lubricants. It has a dark-brown colour, and is characterised by a large amount of free fatty acids and unsaponifiable matter. Not infrequently it develops an unpleasant odour when kept. J. L.

GARCINIA INDICA (Choisy). A plant belonging to the order *Guttiferae*. The pericarp of the fruit is used at Goa as a spice, and the blood-red acid juice as a lemonade. The seeds yield 30 p.c. of fat, which contains 50 p.c. of stearic acid. The cake left after the removal of the fat contains a fine red colouring matter soluble in water and alcohol (Bovis and Pimentel, Compt. rend. 44, 1355).

GARDENIA GRANDIFLORA. The fruit of the *Gardenia grandiflora*, known as 'Wongsy,' is or was employed in China for dyeing yellow, as an assistant for the production of green colours, and in conjunction with safflower. According to Crookes (Dyeing and Calico Printing, 422), it has not been much used in this country, and the yellow and orange colours it yields are of a somewhat fugitive character.

Rochleder and Mayer (J. pr. Chem. 74, 1) isolated from it pectin, the rubichloric acid (chlorogenin) which is present in Madder, Chay-root and Morinda root (*l.c.*), tannin, and a red amorphous colouring matter apparently identical with the crocin of saffron (*Crocus sativus*). Persoz obtained the colouring matter as a reddish crystalline mass (Crookes, *l.c.*), and found that this dyed cotton when mordanted with alumina, yellow, and when mordanted with iron an olive colour.

In Bancroft's Philosophy of Permanent Colours, i. p. 285, mention is made of the use of the *Gardenia florida* by the Chinese for the dyeing of scarlet under the name of 'unki.'

The Decamalee or Dikamali gum, which is obtained in India from the *Gardenia lucida*, contains, according to Stenhouse and Groves (Annalen, 200, 311), *gardenin* $C_{14}H_{12}O_6$, m.p. 163°-164°, and this was isolated as deep yellow crystals insoluble in water and alkaline solutions.

A. G. P.
GARLIC. *Allium sativum* var. *vilgare* (Döll.). A plant extensively used as a condiment in Spain, Portugal, Northern Africa, and other countries.

König gives as its average composition—

Water	Protein	Fat	Carbohydrates	Fibre	Ash
64.6	6.8	0.1	26.3	0.8	1.4

Among the carbohydrates is included 0.9 p.c. of pentosans. The characteristic odour and flavour of garlic are due to an essential oil, amounting to about 0.2 p.c. of the weight, which consists mainly of allyl sulphide and allyl isothiocyanate, the former largely predominating. A wild species, *Allium vineale*, is a troublesome weed in pastures and meadows, and when eaten by dairy cows imparts its disagreeable flavour to the milk. H. I.

GARNET (Ger. *Granat*; Fr. *Grenat*). A group of minerals differing widely in chemical composition, but all conforming to the general orthosilicate formula $R_3R_2''(SiO_4)_3$, where $R'' = Ca, Fe, Mg, Mn$; and $R''' = Al, Fe, Cr$, or rarely Ti. The following principal types may be distinguished:—

Calcium-iron-garnet	$Ca_3Fe_2Si_3O_{12}$	Andradite
Calcium-chromium-garnet	$Ca_3Cr_2Si_3O_{12}$	Uvarovite
Calcium-aluminium-garnet	$Ca_3Al_2Si_3O_{12}$	Grossularite
Iron-aluminium-garnet	$Fe_3Al_2Si_3O_{12}$	Almandine
Magnesium-aluminium-garnet	$Mg_3Al_2Si_3O_{12}$	Pyrope
Manganese-aluminium-garnet	$Mn_3Al_2Si_3O_{12}$	Spessartite

Only exceptionally is the composition of actual garnet crystals as represented above. As a rule, several, or even all, of these compounds enter into isomorphous mixtures; and whilst there is generally a preponderance of one or other of them, this is not always the case. All the members of the group crystallise in the cubic system, usually with the form of the rhombic-dodecahedron or the icositetrahedron, or a combination of these. The crystals are often rounded or granular in form. There is no cleavage, and the lustre often inclines to resinous in character. Corresponding with the wide range in chemical composition, these minerals exhibit a wide range in colour (yellow, brown, red, green, black, rarely colourless, but not blue), transparency, sp.gr. (3.15 to 4.3), hardness ($6\frac{1}{2}$ -7 $\frac{1}{2}$), and mode of occurrence. They occur as primary constituents of igneous rocks; in gneisses, schists, and crystalline limestones; in veins and encrusting the walls of crevices in rocks. Granular rocks composed wholly of garnet are also known.

The chief application of garnet is as a gemstone, of which there are several beautiful varieties. *Hessonite*, or cinnamon-stone, is a variety of calcium-aluminium-garnet, containing small amounts of ferrous and manganous oxides; its colour is a warm yellowish-red. *Almandine* is deep red, often with a violet tinge. *Pyrope* (Bohemian garnet, 'Cape ruby') is a fiery red. *Rhodolite*, a variety midway between almandine and pyrope in composition, is remarkable for its delicate rhododendron-red colour. *Demantoid* is a calcium-iron-garnet of a rich emerald-green colour and with a brilliant lustre.

Garnet is also used as an abrasive agent, mainly in the form of sand, for sawing and grinding stone and for making garnet-paper (often sold as 'emery-paper'). Owing, however, to its lower degree of hardness, it is of less value than corundum and emery. Practically the whole of the massive garnet used for this purpose is mined in the eastern United States, principally New York, but also Connecticut, Pennsylvania, and North Carolina. The output amounts to about 5000 tons per annum, valued at about 6*l.* per ton. In the garnet-mining district of the Mittlegebirge in northern Bohemia, the small material, left after picking out the stones suitable for cutting as gems, is used for gravelling garden walks. L. J. S.

GARNIERITE. A hydrated silicate of magnesium and nickel, of importance as an ore of nickel. It is soft and earthy, greasy to the touch, and usually of a bright apple-green colour; sp.gr. 2.3-2.8. The composition is variable (SiO_2 , 35-52; MgO , 2-37; NiO , 2-50; H_2O , 10-20 p.c.), and the material is probably

a mixture. It may be regarded as a hydrated magnesium silicate, allied to serpentine, in which variable proportions of magnesium are replaced by nickel. The darker green varieties are sometimes distinguished by the name *noumeite* (from Noumea in New Caledonia), the name garnierite (after Jules Garnier, the discoverer of the New Caledonian nickel ores) being reserved for the lighter-coloured varieties. A chocolate-coloured variety, containing iron, has been called *chocolite* (J. Garland, Nickel Mining in New Caledonia, Trans. Inst. Mining and Metall. 1894, 2, 128, 224). *Nepouite*, from Nepoui, New Caledonia (E. Glasser, Compt. rend. 1906, 143, 1173), is a finely crystalline variety for which the formula is given as $3(\text{Ni}, \text{Mg})\text{O} \cdot 2\text{SiO}_2 \cdot 2\text{H}_2\text{O}$, the amount of nickel oxide ranging from 18 to 50 p.c.

These minerals occur in veins traversing serpentine rocks in the neighbourhood of Noumea, or Numea, the capital of New Caledonia; and, like the serpentine, they have been produced by the alteration of peridotite rocks, the olivine of which contains traces of nickel. Over 100,000 tons of these nickel ores are exported annually from New Caledonia.

Large deposits, forming beds 10 metres in thickness, of the same type of ores occur, also in connection with serpentines and olivine rocks, at Riddles, in Douglas Co., Oregon. The nickel mineral from this locality is sometimes referred to *genthite*, $2\text{NiO} \cdot 2\text{MgO} \cdot 3\text{SiO}_2 \cdot 6\text{H}_2\text{O}$. Other similar occurrences are met with and to some extent mined at Webster in North Carolina, at Texas in Lancaster Co., Pennsylvania (*genthite*), at Revda in the Urals (*revdanskite*), and near Frankenstein in Prussian Silesia (*pimelite*, *alpite*, &c.).

On the New Caledonian ores, see A. Liveridge, The Minerals of New South Wales, &c., 1888, 275; F. D. Power, Trans. Inst. Mining and Metall. 1900, vol. 8, 426, with bibliography; E. Glasser, Ann. des Mines, Paris, 1903, ser. x. vol. 4, 363. L. J. S.

GAS, AIR. When a current of air is passed over or through a volatile liquid hydrocarbon, such as petrol, gasoline, or benzene, the air becomes charged with a certain amount of the vapour from the hydrocarbon and is rendered inflammable, the mixture being known under the name of 'air gas.' Of the various hydrocarbons that have been tried, petrol has proved to be the most useful, on account of its extreme volatility and freedom from impurities which have a slower rate of evaporation.

Petrol is the first distillate from the crude oil as it comes from the oil well, and consists largely of pentane C_5H_{12} , hexane C_6H_{14} , and heptane C_7H_{16} , the first liquid members of the great paraffin group of hydrocarbons. It is volatile, and has a flash-point below the freezing-point of water: one gallon of petrol, on being vapourised, will give 28.4 cubic feet of vapour, whilst a pint of it poured on a level surface will cover about 80 square feet with an inflammable vapour, through which, on coming in contact with a light, a flame will spread; and 100 cubic feet of air can be made highly explosive by the vapour from a pint of petrol.

Attempts to produce an illuminating gas by carburetting air with the vapour of some volatile hydrocarbon, date back to 1841, and until 1889

the mixture was made rich enough to produce a luminous flame. This meant that a large percentage of vapour was required, but on this account, and also by reason of the varying quality of the hydrocarbon employed, as well as the inefficiency of the carburettors, it proved very difficult to maintain the production of a gas of uniform composition, with the result that the amount of light obtained at the burners fluctuated. Owing to these drawbacks, the development of lighting by means of carburetted air remained in abeyance until the introduction of petrol of fairly uniform composition for motor-cars and the extended use of the incandescent mantle turned the attention of inventors once more to the possibilities of the process.

Using an incandescent mantle, there is no need for a rich gas, so that the proportion of hydrocarbon vapour can be reduced to a considerable extent, thus doing away with many of the troubles attending the carburation of the air.

If air be passed over or through a vessel containing petrol, the resulting mixture is of very uncertain composition, as at the commencement the more volatile constituents evaporate very quickly, yielding a gas which is far too rich, whilst at the end of the operation, owing to the loss of these lighter portions, the residue does not evaporate at anything like the same rate, so that the air cannot take up the requisite amount of vapour, and the gas is of poor quality. Moreover, when evaporation takes place, a certain amount of heat is absorbed or rendered latent, which reduces the temperature of the petrol in the carburettor, and as the temperature falls, so it evaporates less readily, thus affecting the composition of the mixture. It is essential, for obvious reasons, that a gas supply, whether for heating, lighting, or power purposes, should be as constant in quality as possible, and this has led to the introduction of a host of devices, the aim of which is to secure a gas of definite and uniform composition.

In the majority of air-gas generators in use at the present time, the incandescent mantle is employed to develop light from a mixture of petrol vapour and air so poor in hydrocarbon that it gives a non-luminous but sufficiently hot flame to raise the mantle to incandescence.

When petrol vapour is added little by little to air, it is found that with 1.2 p.c. of vapour, a flame will just travel through the mixture; with 1.5 p.c., the mixture burns under proper conditions; whilst with 2 p.c., the mixture becomes explosive, increases in explosive force up to 2.6 p.c., and gradually diminishes in explosibility until 5 p.c. of the vapour is present, when it becomes non-explosive and burns quietly once more.

It is clear, therefore, that if a mixture of from 1.5 to 1.8 p.c. of petrol vapour with air can be made, such a gas will burn with a non-luminous flame in a properly constructed burner without the addition of more air, and which will have sufficient flame temperature for use with a mantle, whilst it has the enormous advantage that, if through a leak it should escape into the air, the admixture of more air with it renders it non-explosive instead of, as in the case of ordinary coal gas, giving an explosive mixture.

This property was first utilised by Hooker

in his safety air gas, and has been the objective of all air-gas apparatus makers since his time, as it enables something like 1400 to 1500 cubic feet of air gas to be made from a gallon of petrol, and yields most economical results, as in properly constructed burners such gas will give about 9 candles per cubic foot consumed with an incandescent mantle.

Combustion, with the better qualities of petrol, is represented by the following equation:—

At the present time, air-gas apparatus may be divided into two classes:

(1) Those which give an air gas containing over 5 p.c. of the hydrocarbon vapour, and therefore require the addition of air in a Bunsen burner before combustion in the mantle; and

(2) Those in which the percentage of hydrocarbon vapour is under 2 p.c., and the gas is burnt in burners of proper construction without the addition of more air.

To the first class belong such forms of apparatus as the 'Aërogen,' in which the gas is afterwards burnt with a further addition of air. Such forms of apparatus have been in use on the Continent for many years, in some cases being utilised for the lighting of large villages from a central supply station. To the second class belong by far the largest number of generators, such as those which have from time to time made their appearance under such names as the 'Non-explosive Gas,' the 'Praed,' the 'Eos,' the 'Safety Light,' the 'National,' the 'Globe,' the 'Loco,' 'Solux,' 'Centenary,' and several other systems.

In all these forms of machine, the apparatus is designed automatically to mix or evaporate the petrol with air in the right proportion, no matter whether it supplies a large or small number of lights, and in order to do this it is useless to employ carburettors in which a current of air flows over the surface of or through the petrol, and the best results are obtained by introducing small quantities of petrol into a carburettor of suitable form, where it meets with exactly the amount of air necessary to vaporise it entirely, producing the gas of the required composition. This is done in several ways. In one type of apparatus, a current of air is forced by a fan driven from a hot-air engine through the carburettor, where it meets with the supply of petrol, which is pumped up from a storage tank below the apparatus, and entering the carburettor at the top in the right ratio to the air supply is injected into the current of air as a spray, thus ensuring immediate volatilisation.

In another type of machine, the flow of petrol to the carburettor is regulated by a mercury valve contained in a chamber outside the carburettor. As the level of the petrol in the carburettor sinks, so the mercury seal is opened, allowing more petrol to flow into the carburettor in just sufficient quantity to replace the loss. In a third system, the air is forced in through a rotating meter, the revolving spindle of which works the regulator of the petrol tank. In the carburettor, the petrol flows on to the surface of a sphere or ball, round which the air is made to circulate in such a way as to completely evaporate all the petrol, the mixture

being, at the same time, well agitated by a fan to ensure thorough mixation and uniformity of composition.

Another form of apparatus consists of a multi-chambered turbine arrangement. The petrol and air in definite quantities are admitted into each chamber in succession, and violently agitated therein, with the result that the petrol is almost instantly vaporised, the carburetted air being discharged into a central mixing chamber into which the gas from each chamber flows before it passes off to the holder.

The motive power for the production of the necessary pressure of air can be obtained by the slow descent of a weight, by water power, or, most generally, by a hot-air engine actuated by the combustion of a small portion of the air gas itself.

The drawback to the use of a falling weight is that, unless an abnormal length of fall be arranged for, its period of working is comparatively short before it requires winding up again. Water is reliable, and serves well where a supply is available, but the cost is high if it has to be paid for. The hot-air engine as now made consumes but a very small amount of gas, and is of simple yet reliable construction: it runs noiselessly, and can keep at work for indefinite periods with the minimum of attention.

The burners employed for the combustion of the air gas naturally vary with the quality of gas made, as with gas containing below 2 p.c. of vapour no admission of air before combustion is needed, and the burners have to be packed with small tubes or wire gauze, so that if by any chance an explosive mixture is formed in the generator, owing to the amount of petrol vapour having risen to over 2 p.c., flashing back to the regulating apparatus, and so causing an explosion, would be prevented: with those machines which give a mixture richer than 5 p.c. in vapour, a burner of the ordinary Bunsen type, capable of very delicate adjustment, has to be employed, but in no case must an apparatus be installed in which there is no arrangement, such as a safety chamber, between the burners and the regulating drum for the prevention of a flashback.

With regard to the installation and distribution of the gas, owing to its sensitiveness to atmospheric conditions, great attention should be paid to the arrangement of the falls in the pipes, and siphons should be inserted where there is any chance of a deposit accumulating. It must be mentioned that the chief drawback to petrol-air gas is the very heavy condensation which occurs in the distributing pipes, and in a few instances, where prevailing conditions are amenable to the deposition of moisture, the system has had to be abandoned almost entirely owing to the trouble arising from this cause. This is particularly the case when plants are employed in which heat is employed for effecting vaporisation. It is an advantage to use pipes of rather larger diameter than would be adopted for coal-gas lighting, especially for installations producing a weak gas, as the volume of gas consumed per candle power is more than double that of coal gas, but existing pipes can be utilised in many cases, providing they are not less than $\frac{3}{8}$ inch in bore. As regards the fittings,

the ordinary coal-gas fittings can generally be employed, provided the gas way is of sufficient size to be consistent with the extra volume of gas consumed.

The heating power of air gas is of course dependent upon the percentage of petrol vapour which it contains, and as the different commercial makes of petrol, benzene, &c., which could be employed in such plants vary, it is necessary to know not only the percentage of petrol vapour present, but the source of such vapour. Whereas for lighting alone a gas of low calorific power may be employed, for such purposes as cooking and heating the mixture should be of about 6 p.c. saturation when a gas of about 300 B.Th.U. will be obtained.

The calorific power of standard grades of spirit employed in air-gas machines and internal combustion engines varies between 130,000 and 135,000 B.Th.U. per gallon, density at 15° ranging between 0·68 and 0·72.

The enormous increase in the cost of petrol occasioned by the European war reacted very much to the disadvantage of air gas, for, on the basis that 1 gallon of spirit yields 5000 candle-power hours, the candle hours obtained for 1*l.* amount to only 120 with petrol at 3*s.* 6*d.* per gallon. In contrast to this, it may be mentioned that ordinary coal gas at a price of 3*s.* 6*d.* per 1000 cubic feet yields in the low-pressure inverted incandescent burner so much as 480 candle hours.

V. B. L.

GAS CARBON v. CARBON; also **GAS, COAL.**

GAS, COAL. During the 17th and 18th centuries, several observers noticed the evolution in the neighbourhood of coal-fields of combustible gas, which burned with a luminous flame, and also that a gas of this nature was produced by the distillation of coal in closed vessels, but the first to carry out the process of the distillation of coal for the special purpose of producing a gas for use as an illuminant was William Murdoch, who, in 1792, lighted his house at Redruth by this means. At that time, Murdoch was in charge of James Watt's condensing steam engines recently erected at Cornish mines by Messrs. Boulton and Watt, of which firm he was the representative, and on returning later to the works of Messrs. Boulton and Watt at Soho, Birmingham, he continued his work on the subject, and, probably in 1798, lighted a part of the works with coal gas. Independently of Murdoch, but at a rather later date, Philippe Lebon of Paris also employed for lighting purposes the gas evolved by the distillation of wood, the date of his first patent being 1799.

From 1803 onwards, installations of coal-gas plant were introduced for lighting various houses and factories, largely by Murdoch and Boulton and Watt, but they do not appear to have contemplated the erection of works for a public supply of the gas, although this plan had been advocated already by Lebon. F. A. Winsor or Winzer, a native of Moravia, had become acquainted with Lebon's ideas when in Paris, and on settling later in London, he commenced an agitation for the foundation of a company there for the manufacture and supply of coal gas, and marred though his efforts were by gross extravagance of statement and un-

justifiable claims, they were nevertheless eventually successful in 1810 in obtaining an Act of Parliament for the formation of a Statutory Company in London, which two years later received a charter of incorporation, and still continues under the name of the Gas Light and Coke Co., London.¹

From this time forward, the manufacture and public supply of coal gas has steadily increased, but until the last quarter of the 19th century, the coal gas was almost exclusively employed for illuminating purposes, by utilising the luminosity developed by burning it in open flames, and the quality of chief importance was its illuminating power. During the last 40 years, however, the conditions have completely altered, owing to steadily increasing employment of the gas for the purposes of heating and cooking, and for the production of power by its use in gas engines, for which purposes the calorific power of the gas is the chief factor of importance. Moreover, since the introduction of the incandescent burner by Auer von Welsbach in 1887, this method of lighting, in which a mantle composed of thoria and ceria is heated to incandescence by a Bunsen flame, has, to a very great extent, replaced the open flame burners, the number of which is still steadily decreasing, probably less than 5 p.c. of the gas supplied being now thus used. With the incandescent burner, the light evolved is dependent mainly, though not entirely, on the calorific power of the gas, but has no direct connection with its illuminating power when burnt in open flames, so that at the present time, so far as the great bulk of the gas supplied is concerned, its calorific power is the property of primary importance.

During the last 50 years, great progress has also been made in the manufacture of gas having low illuminating power, and containing a large proportion of inert gases such as nitrogen and carbon dioxide, but which can be produced at a low price and has still sufficient calorific power for employment in gas engines and for furnace heating, and such gas is now also produced in very large quantities, being, in most cases, manufactured at the works where it is required, and not distributed from a central station (*see FUEL*). Here, however, only the production of what is ordinarily known as 'coal gas' will be considered, that is, the gas distributed for public use and capable of being employed at the desire of the consumer for lighting, heating, or power purposes. The magnitude and extent of this industry and the manner in which it has extended during 34 years is shown in the table (p. 307), giving the summary of the figures in the Board of Trade returns from all authorised gas undertakings belonging to 816 statutory gas companies or local authorities for the years 1885, 1909, 1913, and 1919.

This table does not include the production of private companies, but their total output is very small, and would not materially affect the figures. The total amount of coal carbonised by these small private undertakings, some 800 in number, is not more than 500,000 tons annually.

¹ For a full account of the early history, *see A History of the Introduction of Gas Lighting*, by C. Hunt (Walter King).

	Capital or loan authorised	Paid up and borrowed	Tons of coal carbonised	Number of cubic feet of gas made	Number of cubic feet of gas sold	Length of gas mains in miles	Number of consumers	Number of public lamps lighted
	£	£		thousands	thousands			
1885 .	71,863,267	35,513,570	8,378,904	84,637,727	77,393,670	18,967	2,095,025	402,074
1909 .	154,500,093	132,123,284	15,225,320	193,547,394	177,686,943	35,230	6,164,066	712,903
1913 .	163,346,673	139,727,277	16,971,724	224,517,167	206,474,473	39,079	7,103,113	741,703
1919 .	176,353,107	149,978,436	19,033,712	249,566,414	228,537,998	40,109	7,540,133	545,712

In addition to the gas output, coke, tar, and ammonia are also produced in large quantities as by-products. The exact figures for coke and tar are not available, but approximately 7 to 8 million tons of coke and 160,000,000 gallons of tar are now sold annually from gasworks alone. The production of ammonia from gasworks in 1920, calculated as sulphate, was 176,196 tons.

Principles of manufacture. Up to within the last few years, the method of manufacture of coal gas has remained in its general principles almost identical with that employed by Murdoch and his immediate successors (prominent among the latter being Samuel Clegg, senr., and his son, Samuel Clegg, junr.), although in detail and in the magnitude of the operations, great change has taken place. So far as the actual carbonisation of the coal is concerned, Murdoch, after experimenting with different types of retort, settled down to the employment of long, narrow retorts set horizontally, into which the coal was charged all at once in such a manner as to leave a free space above the coal throughout the whole length of the retort, the charge being then allowed to remain in the retort until it was completely carbonised, when the residual coke was raked out and the retort recharged with coal; and this plan is still the one employed in the majority of cases. At first, cast-iron retorts were used, but the rapid wearing out of these, especially when the temperature of carbonisation was increased, soon led to the substitution of fireclay for cast iron, and such fireclay retorts have long been in universal use, except in a few very small works.

The further treatment of the hot volatile products issuing from the retorts to obtain a gas suitable for distribution, still generally follows the lines adopted in the earlier days of the industry. These products are first cooled to approximate atmospheric temperature, when the condensable vapours liquefy, forming tar, and the steam always present in quantity condenses to water, the latter then dissolving part of the ammonia present in the gas as well as other gaseous impurities, especially sulphuretted hydrogen and carbon dioxide. The remainder of the ammonia is removed by washing with water (wet purification). For the further purification of the gas, the latter, after removal of the ammonia, was in the earliest stages of the industry passed through milk of lime, which removes the whole of the sulphuretted hydrogen and carbon dioxide, and some of the carbon disulphide present in small amount, but the use of milk of lime was soon replaced by that of slaked lime in a slightly moist condition (dry purification), placed in layers in a closed purifier constructed in such a manner that the gas filtered through successive

layers of this material. At a rather later date, hydrated ferric oxide, placed in similar purifiers, was employed for the removing the sulphuretted hydrogen, the carbon dioxide being then either separately removed by lime or allowed to remain in the gas.

After the coal-gas industry became firmly established, there was, as already stated, for a long time no material alteration in principle in the manufacture, but very considerable changes took place in the details of the plant and in the construction of apparatus of large size to deal with the constantly increasing demand. Until about 1880, gas undertakings were subjected to but little effective competition from other means of producing artificial light, especially in towns, but from that time, competition has steadily increased, on the one hand from the electric light, and on the other from the introduction of cheap mineral burning oils, and the stimulus of effective competition has resulted in a much more rapid advance, both in the technical aspects of the manufacture of the gas and in the commercial methods adopted in its sale.

The technical advances have, until recently, involved no great alteration of principle, and have consisted generally in improving the efficiency and economical working of the plant employed, and in the introduction of mechanical transport for the large quantities of material which have to be dealt with, including the adoption of labour-saving machinery. Further, the temperatures at which the coal is carbonised have been increased, resulting in a larger yield of gas per ton of coal, and although such gas is of lower illuminating and calorific power, the falling off is much less than the increase in yield, especially as regards the now more important quality of calorific power. In consequence of these changes and the increased use of gas for other purposes than that of lighting, which has resulted in a more uniform demand for gas over the 24 hours of the day and in the summer and winter months, the price of gas had, up to the outbreak of war in 1914, on the average, steadily fallen, in spite of the fact that the cost of the raw materials and the rate of labour remuneration had risen considerably.

The actual price varied very much, according to local conditions, such as the magnitude of the works and its distance from suitable coal supplies, and also with the character of the financial and technical administration of the undertaking, both in the present and in the past. Up to the year 1914, the lowest price charged was 1s. 2d. per 1000 cubic feet for general purposes and 1s. per 1000 cubic feet for power purposes, and except in the case of small undertakings at a distance from the coal-fields, the price rarely exceeded 3s. 6d. per 1000 cubic feet.

Since the year 1914, however, the very

great increase in the cost of coal, plant, materials, and labour has resulted in a corresponding large increase in the cost of gas, and whilst as before the price charged in different parts of the country varies greatly in accordance with local conditions, this now generally amounts to about double the pre-war charge. At the same time a material reduction in the calorific power of the gas has taken place in most cases, partly due to the coal and oil shortage, partly to the difficulty of maintaining the manufacturing plant in efficient repair and of building extensions of plant, and partly owing to the necessity for war purposes of extracting the benzene and toluene content of the gas. Owing to this abnormal state of affairs, the various statutory stipulations as to the calorific or illuminating power of the gas to be supplied by the various gas undertakings were practically suspended during the latter part of the war period. At its conclusion the Fuel Research Board of the Department of Scientific and Industrial Research were asked by the Government to report on the matter of the future control of the industry, and their recommendations, modified in certain details after consideration by the Board of Trade and consultation with the Gas Industry, were made statutory by the Gas Regulation Act of 1920.

By this Act fundamental and far-reaching alterations were made in the conditions under which statutory gas undertakings were to carry on their business. Up to the year 1913, the general principles adopted in the control were as follows: In the case of gas undertakings controlled by Local Authorities, a certain minimum illuminating power was prescribed in the Special Act relating to the undertaking, and, in addition, the maximum price which could be charged per 1000 cubic feet of gas, and the usual clauses with regard to sinking fund for repayment of capital. In the earlier period undertakings owned by companies were treated in a somewhat similar manner, their minimum illuminating power and a maximum price being prescribed, and also a maximum dividend payable. It was also usually provided that any new capital raised by such companies must be sold either by auction or by tender and not issued at its par value. Later the maximum price and maximum dividend clauses were dropped in the case of the majority of the statutory companies, and replaced by the adoption of a "standard price" and "standard dividend," and a sliding scale introduced, whereby for each penny the price of gas was reduced below the standard price, an additional dividend (mostly about $\frac{1}{3}$ th per cent.) was payable above the standard dividend, and *vice versa*, if the price of gas increased above the standard, a similar amount had to be deducted from the dividend payable. These sliding-scale clauses, which made it to the interest of the gas companies to reduce the price to its lowest possible figure, had given general satisfaction up to the outbreak of war in 1914, but the great increase in costs of coal and other materials so increased the cost of gas above the standard price, that the sliding scale resulted in a very great reduction, and in some cases a disappearance of the dividend payable. As a temporary measure, a short Act was passed in

1917 whereby it was enacted that till the end of the war, the sliding scale clauses should not be operative after they had reduced the dividend payable to two-thirds of the standard dividend.

The actual illuminating power prescribed varied considerably with the different undertakings according to the conditions of coal supply and the character of the demand for gas, and in the years just preceding 1913, a few undertakings had received parliamentary sanction for the substitution of a calorific power standard for an illuminating power standard.

The most fundamental change made by the Gas Regulation Act of 1920, is that of the basis on which the gas is charged for. In place of a charge based on the volume of gas (1000 cubic feet) of a specified illuminating or calorific power the charge will in future be made on the number of British Thermal Units (Gross) contained in the gas supplied, or in other words, on the Potential Energy contained in the gas, and all stipulations as to the illuminating power of the gas in open flame burners are repealed. The unit of measurement is taken as 100,000 British Thermal Units Gross, which is defined by the Act as "a therm."

Each undertaking is left free to "declare" what calorific power of gas per cubic foot it will supply, having regard to its local conditions in respect of coal supplies, manufacturing plant, &c., but it must then maintain such declared calorific power as a minimum, under penalty for failure, or give due notice of such alteration and carry out at its own cost any necessary adjustments of consumers' appliances as may be necessary to enable them to use the gas of altered quality with efficiency. The actual volume of gas supplied to consumers will be determined by meters as at present, and the volume of gas shown, multiplied by the calorific power per cubic foot and divided by 100,000, will give the number of therms on which the charge is to be made at the price determined by the Act or Order of the undertaking concerned.

Further, the Board of Trade are authorised to substitute for the maximum price or standard price per 1000 cubic feet of gas specified in the Acts or Orders of each undertaking, a price per therm as nearly as may be corresponding to the former price per 1000 cubic feet, but "with such addition as appears to the Board reasonably required in order to meet the increases (if any) due to circumstances beyond the control of, or which could not reasonably have been avoided by, the undertakers, which have occurred since June 30th, 1914, in the costs and charges of and incidental to the production and supply of gas by the undertakers."

In addition, the former clause as to the absence of sulphuretted hydrogen from the gas is maintained, and a more stringent stipulation as to the minimum permissible pressure of the gas is made, this not to be less than 2 inches of water in any main or service pipe between the main and the meter exceeding 2 inches in diameter. In view of the difficulties caused by the war in carrying out renewals and extension of manufacturing plant and the distribution system, 5 years are allowed before the above pressure stipulations become fully operative.

The Act also stipulated that the Board of

Trade should as soon as possible cause inquiries to be held into two other matters on which opinion was divided, namely, (1) whether any restriction should be made on the percentage of carbon monoxide supplied in gas used for domestic purposes, and (2) whether there should be any limitation in the percentage of incombustible constituents present in the gas. Committees appointed by the Board of Trade have since reported that no restriction is advisable in respect to carbon monoxide. In respect to incombustible constituents, the committee also report that no restriction is advisable at present, but recommend that the matter should be further considered after a period of a few years when more evidence will be available, owing to gas undertakings having had a period of working under the new conditions resulting from the Act of 1920.

As there are over 800 statutory undertakings, each with its separate Act or Order, a considerable period is necessary for the Board of Trade to effect the revision of these, and although progress has been made, only a minority of the undertakings are yet working under the new conditions. Among those which are, there is a considerable difference in the calorific value "declared" which varies from a maximum of 550 B.Th.U. per cubic foot in the case of the South Metropolitan Gas Co., down to 400 B.Th.U.; in the great majority of cases, however, the declared value is between 450 and 500 B.Th.U. Widely varying views are at present held as to the most economical calorific value for the supply, some regarding a much lower calorific power than 400 B.Th.U. as the most advantageous, and a much more extended experience of working under the new conditions will be necessary before a fairly general agreement can be come to between the conflicting views. There is little doubt, however, that the next few years will bring about considerable changes in methods of working from those contained in the present article, both in improvements of old, and development of new methods.

In the United States, and also in Canada, following on the development of the oil-fields and resulting cheap oil supply, the manufacture of coal gas was largely superseded by that of carburetted water gas, i.e. of a mixture of water gas and oil gas of approximately the same illuminating power and calorific power as coal gas, and in 1910 some 80 p.c. of the gas supplied consisted of carburetted water gas; since that date, however, the tendency has been in the direction of increasing the proportion of coal gas supplied. In this country also, from 1890 onwards, many gas undertakings have also manufactured carburetted water gas, which was mixed with the coal gas to an extent not, as a rule, exceeding 40 p.c. of the output of any individual undertaking.

In the year 1913, nearly 24,000 million cubic feet of blue-water gas, and carburetted water gas were made in the United Kingdom or 10·8 p.c. of the total production, and only a very small proportion of this was blue-water gas. Since that date the increasing scarcity and rising price of oil has brought about a large reduction of the amount of oil used in this way, and the addition of blue-water gas without oil enrichment has greatly increased, this being made

either in separate plants or by the introduction of steam into the retorts during carbonisation. In 1919, the total amount of blue-water gas and carburetted water gas produced in separate plants amounted to 38,500 million cubic feet, or 15·8 p.c. of the total production; no figures are available as to the amount of water gas produced by steaming in the retorts, as this cannot be measured separately from the coal gas simultaneously produced, and is consequently included in the coal-gas figures. The amount of oil used, on the other hand, decreased from 58 million gallons in 1913 to 34 million gallons in 1919.

Gas coal. In this country, by far the largest proportion of coal employed for gas-making purposes is of the character known as bituminous caking coal, i.e. a coal which, in addition to yielding a large volume of gas, also forms a plastic mass during the early stages of heating, and then subsequently undergoes carbonisation, and results in the production of a coherent coke of good commercial value. The non-caking bituminous coals, even when yielding a large volume of gas, only give a poor coke, having the same shape and size as the pieces of coal carbonised, and having a low selling value. These are therefore only employed in cases where local conditions are such that non-caking coals are obtainable at a cost sufficiently below that of caking coals, to compensate for the lessened value of the coke produced. This is especially the case in Scotland, where the Scotch splint coals are often of a non-caking or only feebly caking quality.

A further exception to this rule also occurs in the case of cannel coal, which was formerly used in considerable quantity, as, although the coke obtained was almost useless, it gave a very large yield of gas of high illuminating power, and a certain proportion of cannel was therefore used in many works to enrich the gas given by poorer coals to the statutory quality. At the present time, however, very little cannel is employed: firstly, because the increasing scarcity of good cannel caused a rapid increase in its price some 30 years ago, on which account oil from petroleum was largely used in its stead for enrichment, either by making this into oil gas or carburetted water gas and adding these gases to the coal gas. In place of the use of cannel, the low-quality gas was also frequently enriched by carburetting with volatile hydrocarbon vapours, such as the low-boiling paraffins and benzene. In the second place, owing to the lessened importance of illuminating power, enrichment of the gas was largely given up, and the quality reduced to such a figure as can be obtained direct from the caking coals most readily procurable in the locality of the particular gas undertaking.

The rich cannel coals were chiefly obtained from the Wigan coal-field in Lancashire and the Lanark coal-field in Scotland, but the supplies are now largely exhausted. Poorer cannels are found to some extent in most of the other coal districts, but these often give little or no better yield and quality of gas than the bituminous coals, and also give rise to a very low quality of coke, and are therefore only used when the price at which they can be purchased is very low.

It is held by many that, in view of the fact

that cannel coals are capable of giving much higher yields of crude oil when suitably carbonised than can be obtained from coal, cannel coals should be reserved for such crude oil production, and a good deal of experimental work has been carried out in this direction. Up to the present the process of such crude oil production from cannel and similar materials has not been carried out on a sufficiently extended scale to determine fully its commercial practicability.

Chief sources of gas coals. Gas coal occurs in all the coal-yielding areas, but the chief supplies occur in the Newcastle or Durham district, South Yorkshire, Lancashire, Derbyshire, and North Staffordshire. Smaller amounts are obtained from North Wales, South Wales, and Somerset. Generally speaking, in order to reduce the cost of carriage, a gas undertaking obtains its coal from the nearest field producing a suitable quality. In the London district, however, and also for the most part in the south and south-west of England, the main supply is drawn from the Durham field, the greater distance away of these collieries being more than counterbalanced by the fact that the coal is brought for the greater part of the way by coasting steamers instead of by rail, which reduces the rate of carriage.

The coals obtained from the different seams in the same district, and often even from the same seam, vary considerably in their properties from a gas maker's point of view, and with one and the same sample of coal, the gas results also depend greatly upon the conditions under which it is carbonised. Nevertheless, the coals

from each district have, as a rule, certain characteristics which distinguish them from those of other localities. This is especially the case with the coals from the Durham field, these, for the most part, undergoing carbonisation more slowly than the others under similar conditions, and yielding a harder and denser coke. They also yield a thicker tar of higher sp.gr., and in general give a somewhat lower yield of ammonia. The North Staffordshire coals also yield coke of good quality, the gas coke from both these districts being, on the average, superior to that from Yorkshire, Derbyshire, and Lancashire coal.

Valuation of gas coal. The simple elementary analysis of coal, giving the percentages of moisture, carbon, hydrogen, oxygen, nitrogen, sulphur, and ash, affords but very little information as to its value for gas-making purposes. If, however, as first pointed out by Bunte (J. Gasbel. 1888, 31, 895), the figures for moisture and ash be eliminated, and the percentage composition of the actual coal substance calculated, it is possible to judge the general properties of the coal from the figures obtained.

St. Claire Deville published a table (below), giving the results obtained from five typical samples of coal, which were subjected to analysis and gas-making tests in the coal-testing plant of the Paris Gas Works. Coals of Type III (7.5-9.0 p.c. of O in the coal substance) represent the best type of gas-making coals, giving a good yield and quality of gas and also good coke. Coals of Types I and II produce much coke and a poor yield of gas, whilst with Types IV and V the gas results are

	Type I.	Type II.	Type III.	Type IV.	Type V.
100 parts of coal substance contain					
Oxygen	5.56	6.66	7.71	10.10	11.70
Hydrogen	5.06	5.37	5.40	5.53	5.64
Carbon	88.38	86.97	85.89	83.37	81.66
Nitrogen (approx.)	1.00	1.00	1.00	1.00	1.00
Moisture content of air-dried raw coal	2.17	2.70	3.31	4.35	6.17
Total weight of distillation products (p.c.)	26.82	31.59	33.80	37.34	39.27
" " coke	73.18	68.41	66.20	62.66	60.73
Gas, per cent. coal substance	13.70	15.08	15.81	16.95	17.00
Tar	3.40	4.65	5.08	5.48	5.59
Gas liquor	4.58	5.22	6.80	8.62	9.86
COMPOSITION OF THE GAS IN PER CENT. BY VOLUME.					
Carbon dioxide	1.47	1.58	1.72	2.70	3.13
Carbon monoxide	6.68	7.19	8.21	9.85	11.93
Hydrogen	54.21	52.79	50.10	45.45	45.26
Methane and nitrogen	34.37	34.43	35.03	36.42	37.14
Heavy hydrocarbons	3.27	4.01	4.94	5.58	5.54
Specific gravity of the gas.	0.352	0.376	0.399	0.441	0.482
Gas consumption for equal candle power	132.1	111.7	103.8	102.1	101.8

good, but the coke is poor in quality and quantity. The conclusions to be drawn even from such analyses are, however, at most only of a very general nature.

Of greater value and more rapidly carried out is the *proximate analysis* of coal, *i.e.* the determination of moisture, volatile matter, coke, and ash, and, if required, of sulphur, which is objectionable as an impurity. The quantity of volatile matter, *i.e.* loss of weight, exclusive of moisture, when the coal is heated in absence of air (which gives conversely the percentage of coke), varies according to the manner in which the heating is carried out, and to obtain comparable results a standard method of heating must be adhered to, the one usually adopted now in Great Britain and America being that known as the American method (J. Amer. Chem. Soc. 1899, 21, 1122), which is as follows: 1 gram of undried powdered coal is placed in a bright platinum crucible of 20 to 30 grams weight, closed with a well-fitting lid and supported in such a manner that the crucible bottom is 6-8 cm. above the burner top. An ordinary Bunsen burner, having a flame at least 20 cm. long when burning free, is employed for heating, which is continued for 7 minutes. The upper surface of the lid should be free from carbon at the end of the test, but the under surface should remain covered with a black film. The tests carried out in this manner give yields of coke which approximate very fairly to those found in actual practice in gasworks and coke-oven works.

The quantity of volatile matter, excluding moisture, in gas coals usually varies from about 27 to 35 p.c. of the undried coal, or from 29 to 38 p.c. of the actual coal substance, *i.e.* coal, exclusive of moisture and ash.

The actual results obtainable from a coal sample can only be determined by tests on the manufacturing scale, and for this purpose arrangements are made in many works by which one or more beds of retorts can be isolated, and the gas passed through special condensing, purifying, and measuring plant, and either the whole or an average sample of the gas collected for testing; the coke, tar, and ammoniacal liquor also produced are measured in a suitable manner. In large undertakings, a special testing works is sometimes erected, capable of dealing with quantities of coal up to 20 tons a day. Small-scale plants, modelled to represent large-scale practice as nearly as possible, cannot be relied on to give results obtainable in actual practice, as it is impossible to reproduce the conditions sufficiently exactly; but such plants are of use in giving the *comparative* values of different coal for gas-making purposes, and from tests made with different samples in one and the same plant, a fair idea may be obtained of the *relative* values of different samples. Such apparatus also permits of the checking off of deliveries of coal made under contract to see that they agree with the value obtained from the original sample tested in the same plant.

In order to obtain a comparative figure of the value of a gas coal, the number of cubic feet per ton obtained from it is multiplied by the calorific power in British thermal units of 1 cubic foot of the gas, giving the

'calorific multiple,' or the total B.Th.U. per ton in the form of combustible gas obtainable from 1 ton of the coal. Formerly, when illuminating power was the more important consideration, the number of cubic feet obtained per ton is multiplied by the illuminating power, this figure being known as the 'multiple.' In some cases, however, this is expressed in 'sperm value,' *i.e.* the number of lbs. of sperm (as used in the manufacture of the statutory sperm candle), equivalent in light-giving power to 1 ton of coal. This figure is obtained by multiplying the product of yield and illuminating power by 0.00343. For gasworks purposes, the volume of gas is corrected to that of the gas at 30 in. barometer and 60°F., saturated with moisture.

THE MANUFACTURE OF COAL GAS.

The chief manufacturing processes necessarily involved consist briefly in (1) the distillation of the coal; (2) the cooling and condensation of the volatile products; (3) washing the gas for removal of ammonia; (4) purification of the gas from sulphuretted hydrogen; (5) measurement of the gas produced; and (6) its storage in gas holders. The plant required consists of retorts set in suitable furnaces, cooling apparatus for the hot gas, washers, and scrubbers, purifiers, meters, and gas holders, with suitable buildings and accessories.

In order to carry out the manufacture under economic conditions, much depends upon the nature and position of the site. It is not possible to lay down fixed rules with regard to the site to be selected, as generally only a few possible sites are available in suitable positions relative to the district to be supplied, and that which has the least objections to it has to be taken, even if it is by no means ideal. For works of any magnitude, it is, however, essential that the site shall have a good connection with the means of transport, especially with the railway, and, where possible, also with water, as otherwise the costs for bringing in the large quantities of coal required and sending out the coke produced are largely increased; it is also now the practice, wherever possible, to avoid erecting new works in densely populated districts.

In the laying out of the site it is equally impossible to lay down any but the most general rules, as the conditions vary so greatly in almost every case. The object aimed at is to lay out the works in such a manner that advantage is taken where practicable of the existing natural conditions of level or of the relative position of the railway, canal, or wharf, as the case may be, to facilitate the cheap handling of the raw material and finished products, especially of the coal and coke which form much the largest proportion of these. In spacing out the various portions of the plant for carrying out the different processes, sufficient room should be allowed for each, as undue crowding always tends to increase manufacturing costs. Care must also be taken that the plan is such as to allow of the extension of the various portions of the plant, without necessitating the pulling down and re-erecting of the original plant in a different position or undue cramping of the latter.

Fig. 1 gives a diagrammatic representation in plan of the main features of a gasworks capable of making from 10 to 15 million cubic feet of gas per day, and having connection both with rail and water, the works being divided into two completely separate sections, so far as manufacturing plant is concerned; the gas from each section, however, joins together at the inlet to the gas holders, which can be filled from either section. It very rarely happens,

however, that the disposition of the site renders so symmetrical an arrangement possible.

CARBONISATION OF THE COAL.

Broadly speaking, the process of carbonisation, which is by far the most important part of the manufacture, consists in subjecting the coal to distillation in closed vessels from which air is excluded, whereby it is split up into two portions, namely, a volatile portion which escapes from the

FIG. 1.

retort, and by subsequent treatment yields tar, ammoniacal liquor, and permanent gas, and a non-volatile portion consisting mainly of carbon and the ash of the original coal, which remains behind in the retort as a porous mass of coke. The nature and amount of the constituents of the volatile products, as well as the composition and physical properties of the residual coke, depend not only on the nature of the original coal, but also to a large extent on the temperature employed for its carbonisation and on the manner in which the heating is carried out. The nature of the physical and chemical changes which occur is exceedingly complex, and these, so far as they have at present been elucidated,

will be more conveniently considered after a description of the actual process of carbonisation as it is at present carried out in the majority of gasworks.

Manufacture of gas in horizontal retorts.

The material employed for the manufacture of retorts consists at the present time almost universally of fireclay, and for modern carbonising conditions, the quality of the latter should be such that it will withstand temperatures up to 1300° – 1400° , and should not develop serious cracks when subjected to such rapid alternations of temperature as inevitably occur when the hot retort is recharged with a cold mass of coal. The shape of the retorts is long and narrow, the

length being from 9 to 10 feet when the retort is closed at one end, or from 18 to 22 feet when a 'through' retort is employed, closed by a mouthpiece and lid at each end, this last being now the plan mostly adopted in works of medium and large size. The width of the retort varies usually from 18 to 25 inches and the depth from 13 to 16 inches, the size 16-inch by 22-inch being probably used more than any other. The shape of cross section employed varies very

Fig. 2.

considerably; in a few instances, circular retorts are employed (to which, of course, the above-mentioned dimensions of width and depth do not apply), in others oval retorts, but the majority have now a flat bottom and circular top and have approximately the shape of a half-inverted D, \cap , and are commonly known as D-retorts, the corners between the bottom and sides being, however, always rounded, to facilitate the removal of the coke, and to render the retort less liable to crack. The thickness of

Fig. 3.

the retort wall is 3 inches, increased to 4 inches at the end to facilitate the fixing of the iron mouthpiece and lid.

A number of these retorts are fixed horizontally in a single brickwork arch, the number in such a setting varying generally from 6 to 12. The retorts are supported by transverse brick walls, placed at intervals throughout the length of the retort, and extending to the top of the arch enclosing the setting, the method of construction being clearly shown in Figs. 2, 3, 4,

and 5, which give diagrams showing the cross section and three longitudinal sections of a bed of eight through retorts. The gases by which the retorts are heated circulate around the retorts in each of the vertical chambers formed by the cross walls, travelling first upwards along the inner sides of the retorts, and thence over the top of the highest retorts and down along the outer sides of the retorts and away to the chimney.

The method formerly adopted for heating was that of direct firing, a shallow coke fire being maintained on a hearth placed in the centre of the setting below the middle retorts. With such firing the heating of the retorts is effected solely by the sensible heat of the products formed by the combustion of the carbon of the coke by the oxygen of the air, *i.e.* carbon dioxide, nitrogen, excess of oxygen, and in order to get the retorts properly heated in the part with which the gas last comes in contact, it is necessary that the temperature of

Fig. 4.

the latter must not be below about 1000° when they pass away from the setting. As in addition, a considerable excess of air must be used to get complete combustion of the coke, this excess of air likewise passes away to the chimney at a high temperature, resulting in great waste of fuel, and the actual consumption of coke for heating such direct-fired settings amount to 25-30 p.c. weight of coal carbonised.

At the present time, in installations of any size, this method of direct firing has been abandoned in favour of gaseous heating. For this purpose, a deep producer is provided for each bed of retorts, as shown in Figs. 2 to 5, which is charged with hot coke, when required, by allowing the incandescent coke from the retorts to fall directly into it. A limited supply of air (primary air) is admitted below the furnace bars, and passing through the deep layer of coke, the oxygen is converted chiefly into carbonic oxide and to a smaller extent into the dioxide. Steam is introduced along with the primary air, as water is allowed to drip on to the furnace bars to prevent their burning through, and water also evaporates from that kept in the ashpan below the surface, and this steam is largely converted into hydrogen and carbon monoxide in passing through the incandescent

fuel. The presence of steam lowers the temperature of the fuel in the generator, thus reducing wear and tear of the lining, and also prevents the fusion of the clinker formed from the ash, and renders it more readily removable. The composition of the gas varies according to the proportion of air and steam used, but generally approximates to the following example :—

Carbon dioxide	5.2 p.c.
Carbon monoxide	24.4 „
Hydrogen	8.6 „
Methane	0.8 „
Nitrogen	61.0 „

The producer gas thus obtained consists to the extent of about two-thirds of incombustible gases, and is not an ideal one for obtaining very

FIG. 5.

high temperatures; but it is, nevertheless, fully capable of developing the highest temperature required for carbonisation—this being made more easy by reason of the fact that it enters the setting already heated to a very high temperature. Further, as will be seen directly, the air required for its combustion also enters the setting at a moderately high temperature.

In very brief outline, the method of working the setting is as follows: The hot furnace gas collects above the coke, and then passes through nostril holes cut in the furnace arch; one or more nostril holes being placed at the bottom of each of the vertical spaces formed by the cross walls supporting the retorts (*see* Figs. 2 to 5). As it enters the setting, the furnace gas is met by the stream of secondary air necessary for its complete combustion; this being introduced by suitable flues so arranged that a supply of air meets each stream of furnace gas issuing from the nostrils in the furnace arch. Complete combustion of the gas takes place as the streams of furnace gas and air intermix in their circulation around the retorts; the heat thus evolved causing the temperature of the latter to be raised to the required point.

The waste gases leaving the setting have inevitably a high temperature, as they must be sufficiently hot to raise the temperature of the last portions of the retort with which they come in contact to the carbonising temperature required, and if allowed to pass direct to the chimney much loss of heat would ensue. To effect a partial recovery of this heat, the waste

gases, on their way to the chimney, pass through the regenerator, which consists essentially of a series of flues adjacent to and separated by a thin fire-brick partition from a parallel set of flues through which the secondary air is allowed to flow on its way to the setting, travelling in the reverse direction to the waste-gas stream. Much of the heat of the latter is thereby transferred to the secondary air, and thus carried back into the setting, resulting both in economy of fuel and enabling a higher temperature to be obtained with a lower fuel consumption than would otherwise be the case.

The amount of primary air admitted to the furnace and of secondary air to the setting is controlled by suitable slides on the ports of admission and by dampers placed at the outlet of the regenerators. In a setting of through retorts, these last are usually four in number, each taking the waste gas from one quarter of the setting, so that by their adjustment, not only is the total amount of gases drawn through the setting controlled, but also the proportionate amounts drawn into the different parts. By suitable regulation of the primary air slides and dampers, the furnace is made to produce the requisite quantity of gas for the proper heating of the setting, and the secondary air slides are adjusted to supply as nearly as practicable the exact quantity of air required for the complete combustion of the furnace gas. With this method of heating the fuel, consumption is reduced to about one-half that required with direct firing, viz. from 12 to 15 p.c. of the weight of the coal carbonised, whilst simultaneously much higher retort temperatures are attainable.

The charging of the coal into the retort and the withdrawal of the coke produced were formerly always effected by manual labour, the coal being charged with the shovel, or by a scoop run into the retort by hand, and then inverted and withdrawn, the coke being drawn by a rake. This plan is still adopted in small works, where the magnitude of the operations is not sufficient to make the installation of machinery remunerative. In larger works, however, the operations are now usually effected mechanically, a considerable number of machines of different type being at present in use. Limitations of space, however, prevent anything more than a very general description of these machines. In the earlier machines, which were widely adopted, namely, the West and the Arrol-Foulis machines, the existing manual method was closely imitated by mechanical means, the charging machine for the coal inserting the latter by means of a scoop or similar contrivance, and the discharger removing the coke by a mechanically actuated rake; in the West apparatus, compressed air is used as the motive power; and in the Arrol-Foulis, hydraulic pressure. In more recent types of machine different methods are employed. Thus in the De Brouwer apparatus, a stream of coal is projected into the retort at such a high velocity that it is carried to a stop placed at the far end, and then built up in an even layer to the front of the retort; in place of raking out the coke, the plan now being adopted is that of mechanically pushing out the coke from one end, this method being, of course, only applicable to through retorts, which can be

opened at each end. Other machines, such as the Fiddes-Aldridge, are also in use, which effect in one movement the discharge of the coke and the introduction of a fresh charge of coal, and at the present time electrical power is largely employed for actuating retort-house machinery.

In addition to the actual machinery employed for charging the coal and drawing the coke, additional mechanical equipment is also required in the retort house. The coal to be carbonised must not contain lumps of too large a size where machine charging is used, and is therefore dropped into a coal breaker, from which it falls into an elevator, and is raised to a height well above the retort benches, falling from the latter either direct or by means of a conveyor into storage bunkers, from which it is drawn by the charging machines as required. Mechanical conveyors of various types are also frequently employed for removing the coke from the retort house as it is discharged from the retorts, and to carry it to suitable screening machinery for sorting into different grades.

Inclined retorts. In order to utilise the action of gravity in charging and discharging

Fig. 6.

retorts, the horizontal position of the retorts has been abandoned in many installations during the past 25 years, the retorts being set instead at an angle of about 32° to the horizontal, this being approximately the angle of rest of broken coal. Fig. 6 shows a longitudinal section of such a setting of inclined retorts. To charge them, a stop is placed at the lower end of the retort, and a stream of coal admitted at the top, which falls down the retort until it reaches the stop at the bottom, after which, with a properly regulated supply of coal, it builds up in an even layer to

the top of the retort. To discharge the retort after carbonisation is complete, the stop is withdrawn from the bottom, when the coke should fall out by the action of gravity. Usually, however, a certain amount of assistance is required to start the movement, such as pricking with a bar, this being especially the case with retorts which have been at work for some time and have altered in shape.

Inclined retorts were first adopted with practical success by Coze at the Rheims Gas Works in 1885, and have since been installed to a very considerable extent in most countries where the gas industry is established, including Great Britain. Here, however, it has never appeared probable at any time that the inclined retorts would altogether supplant the horizontal retorts, and during recent years but few new installations have been built, the improved machinery for charging and discharging the horizontal retorts having increased the favour with which these are regarded.

The relative advantages of the two systems refer almost exclusively to questions of capital cost, upkeep, and labour charges, and do not materially affect the matter of the yield and quality of gas, as the actual carbonisation of the coal, with proper working, takes place in the same manner in each case, the coal in both being heated in an even layer in the retort, with a considerable amount of free space above the coal, and the sequence of changes which take place from the action of heat is substantially the same in both cases.

Retort-house working. The weight of coal introduced into the retort varies naturally according to the size of the latter, but up to about the year 1900 the weight of charge placed into the retort of the most common size, namely, 20 feet long, 16 inches deep, and 22 inches wide, was between 6 and 7 cwt. (and a proportionate charge in retorts of other sizes); and with such a charge, even with coals which swell considerably during carbonisation, a sufficient amount of free space remained above the mass at the end to permit of the introduction of the rake-head to discharge the coke. The temperature within the retort varies in different works from about 900° to 1250° , the tendency being constantly in the direction of the higher figure, and the time required for the carbonisation of such a charge averages about 6 hours in the case of most caking bituminous coals, but is only about 4 hours with Scotch splint coals. The gas evolved during the first half-hour is somewhat low in quality, but in the succeeding $1\frac{1}{2}$ –2 hours the yield of gas is highest both in quality and quantity. For the remainder of the time, the volume and quality steadily diminish, and when carbonisation is nearly complete, the small volume of gas evolved consists largely of hydrogen, with from 10 to 20 p.c. of methane and some carbonic oxide. In order, therefore, to obtain a stream of gas which is approximately uniform both in quantity and quality, and also to facilitate retort-house working, the retorts are not all charged together, but a certain proportion only are charged at regular intervals of an hour or two hours, according to circumstances, so that the carbonisation in the different retorts is at different stages at any particular time, and the mixture

of gas formed by the combined streams from the retorts keeps more nearly uniform.

Treatment of the hot gases issuing from the retorts. In order to collect the evolved gases, a cast-iron mouthpiece is bolted to the mouth of the retort (or to both mouths of a through retort) having a hinged lid in front, which can be opened for the purpose of discharging the coke and putting in a fresh charge of coal, and then closed so as to form a gas-tight joint. An illustration of a 'self-sealing' mouthpiece in common use is shown in Fig. 7. On the top of the mouthpiece is cast a socket, into which is fixed a vertical pipe of from 4 to 8 inches

diameter, termed the *ascension pipe*, extending upwards above the brickwork of the setting (Fig. 8). By means of the *bridge pipe*, this is connected with the *dip pipe*, which conveys the gas into the collecting main. A separate collecting main is usually now provided for each bed of retorts, the combined gas from each of these passing away by a pipe at the top or side into the *foul main*, by which the gas is conveyed from the retort house to the condensing and purifying plant. Two types of collecting main are in use, namely, the *hydraulic main* and the *dry main*.

In the hydraulic main, which is most

FIG. 7.

commonly employed, the tar and liquor condensed from the gas at this point are allowed to accumulate to such an extent that the dip pipes are sealed in the liquid, this seal then forming an automatic valve, which allows the gas made in the retort to bubble through it into the collecting main, but prevents any gas getting back from that main along the bridge pipe and ascension pipe, when the retort lid is open for purposes of charging. With the dry main the dip pipes are not sealed in the liquid, and in order to prevent gas passing back when the lids are open or air being drawn into the main through the open lid, some method of closing the pipe must be provided which can be operated when the lid is open. Several forms of valve are in use, but are apt to give trouble from the separation of thick tar and carbon on them, and, therefore, in other cases, arrangements are made whereby the dip pipe can be sealed in the liquid whilst the lid is open, and unsealed as soon as this is closed.

Where the hydraulic main is employed, matters are now so arranged in most works that the tar and ammoniacal liquor which separate in that main, are drawn off separately, the tar being taken away from the bottom as it separates, whilst the liquor flows away from an overflow, the height of which can be regulated as desired, the object especially aimed at being to ensure that the dip pipes are sealed in liquor, and not in tar or varying mixtures of tar and liquor. This separate removal of the tar and liquor may be effected in many different ways, a type of

apparatus in common use being the Dillamore tar tower, shown in Fig. 9 (p. 318). This is placed at the end of a bench of retorts as shown, and serves a number of beds. The tar pipe runs from the bottom of each hydraulic main to about the middle of the tower, whilst the lighter ammoniacal liquor flows from a side opening near the upper level of the liquid in the hydraulic main to the top of the tower. The latter is also connected by an equilibrium pipe to the top of the hydraulic main, or foul main, the gas pressure in each being thus maintained the same, under which circumstances the upper level of the liquid is the same in both. The condensed liquor flows from the top of the tower over a weir valve, the height of which can be regulated to give any required depth of seal in the hydraulic main. The tar accumulates in the bottom of the tower, displacing an equal volume of liquor, which flows away over the weir valve, and is run off periodically, care being taken that its upper level never rises above the level at which the tar enters the tower. Whilst running the tar off, liquor must be run in from a tank to the top of the tower at a greater rate than that at which the tar is run off, as otherwise the level of the liquid in the hydraulic main would fall, unsealing the dip pipes.

In order to obtain good results in carbonisation, so far as yield and quality of gas are concerned, it is most essential that the gas pressure in the retort should be maintained as uniform as possible, and only slightly above that of the atmosphere, attention to this point being

second only in importance to that of keeping good and even temperatures of the retorts. The necessity for this arises from the fact that the fire-clay retorts are themselves porous, and also develop cracks through the alternate heating and cooling, and hence, if the pressure within the retort exceeds that of the gases circulating round it to heat it, gas tends to

FIG. 8.

escape through the pores and cracks, and is burnt around the setting and thus lost; and if, on the other hand, the pressure within the retort is materially lower than that within the setting, waste gases, consisting chiefly of nitrogen and carbon dioxide, are drawn into the retort and pass away with the gas made, and lower its quality. In passing over the hot retort walls, the gas, however, always undergoes a certain amount of decomposition, resulting in the deposition of carbon on the walls, which tends to block the pores and small cracks, and thereby to render the retort more gas-tight, the leakage being much higher with a new retort, or immediately after the removal of the crust of 'gas carbon' or 'scurf.' The latter process must be carried out periodically, as it otherwise

becomes so thick as to interfere with the proper heating, as well as with the charging and discharging of the retort, the gas carbon obtained finding a ready sale for the manufacture of electrodes.

A very considerable pressure is required to pass the gas through the condensers, scrubbers, and purifiers, and into the holders, and if the whole of the necessary pressure were thrown on the retort, most of the gas would, in large works, be lost into the setting, and, therefore, in all but very small works a pump or exhaustor is employed to draw the gas from the retorts as it is made, and to force it on through the subsequent apparatus and into the holders. The exhaustor is run in such a manner as to maintain the gas pressure constant in the hydraulic main above the liquor level, and in addition an automatic retort-house governor is also frequently employed to ensure that this pressure is maintained as uniform as possible. Even then, in order to ensure that the pressure in the retort itself is maintained constant, great care must be exercised in maintaining the hydraulic main exactly level, and the dip pipes of equal length, as otherwise the depth to which these are sealed in liquor will vary, and, consequently, the pressure in the retorts, which is equal to that in the hydraulic main less the depth of the seal, will also vary, so that some may be losing gas to the setting and others drawing furnace gas into the coal gas. Where the latter is the case, the pressure in the retorts and ascension pipe is below that of the atmosphere, and, consequently, when the retort lid is opened, air is sucked into the gas through the ascension and dip pipe, thus further reducing its quality.

Even when the hydraulic mains are level and the dip pipes sealed to an equal extent throughout, and the pressure in the hydraulic main is maintained constant, the bubbling of the gas through the liquid causes a rapid oscillation of the pressure within the retort, which may be considerable. By careful attention and regulation of the depth of seal, this oscillation can be very greatly reduced, but never altogether eliminated, and in this respect the dry main, in which there is no seal for the gas to bubble through, has the advantage. On the other hand, the fact that the seal forms an *automatic* valve, which does not require to be operated by the workman when opening and closing the lids, and also that where a dry main is used, more trouble is often experienced in getting the thick tar to flow properly from the mains, especially with some types of coal, has led to the hydraulic main being most frequently adopted in spite of the above objection.

CHEMICAL CHANGES OCCURRING DURING CARBONISATION.

The essential elementary constituents of coal are carbon, hydrogen, and oxygen, and, in addition, smaller amounts of nitrogen and sulphur are always present, as well as varying amounts of mineral matter, which remains behind as ash when the coal is completely burnt. With regard to the chemical constitution of the doubtless numerous compounds present in coal, little definite evidence is as yet available. There is general agreement that the substances have been formed slowly from the large deposits

of vegetable matter of the carboniferous period, the changes taking place generally in absence of or with only limited access of air, and that both temperature and bacterial action have played a part in its production. It is also generally

agreed that the larger proportion of the substances forming the existing coal have been derived from the "cellulosic" constituents of the original vegetable matter, and that the smaller proportion consists of substances

FIG. 9

derived from the waxes and resins of that material. F. Fischer and Schrader (*Brennstoff-Chemie*, 1921, 2, 37) have suggested that the true cellulose of the original matter plays no part in the substances remaining now in the coal, but has been completely resolved into

gases and disappeared, and that the "cellulosic" constituents are derived solely from the lignin content of the original material.

In any case, the compounds as they now exist, whether formed from the woody or the resinous constituents of the original vegetable material,

are of very high molecular weight. Neutral solvents such as alcohol, benzene, &c., extract only exceedingly small amounts of soluble matter from the coal. The basic solvent pyridine is, however, much more effective (Bedson, *J. Soc. Chem. Ind.* 1908, 27, 147; Burgess and Wheeler, *Chem. Soc. Trans.* 1911, 99, 649), have shown that with this solvent varying amounts up to 35 per cent. of soluble matter may be extracted. It is, however, doubtful if this extracted matter consists of substances actually present in the coal, as it is very probable that the chemically active liquid pyridine first effects some resolution of the substances present in the coal into those of lower molecular weight, some of which dissolve in the pyridine. Good gas-making coals generally give a high percentage of such pyridine soluble matter.

The changes which take place when coal is heated in absence of air are exceedingly complicated in character, and result in the production of an immense number of different substances, some gaseous, some liquid, and some solid at the ordinary temperature. The liquid constituents, which condense together in the form of coal tar, are by far the most numerous, the different compounds isolated from it already being numbered by hundreds, and doubtless large numbers of unknown compounds are also present (*v. TAR*). Moreover, both the nature of these substances and their relative amounts in the products vary greatly according to the temperature to which the coal is heated, and the manner in which the heat is applied, and our knowledge of the nature of the reactions occurring during the process is still very far indeed from complete, so that it is only possible as yet to discuss these changes in very broad outline.

When coal is heated, except for evolution of water, and small quantities of oxides of carbon, no apparent change takes place below 300°, but the available evidence points to the conclusion that some changes take place below the apparent point of decomposition which result in the dissociation of many of the substances present into others of lower molecular weight, as many coals and bituminous shales if heated for some time below their apparent decomposition point, yield a largely increased quantity of soluble matter on extraction with neutral solvents. At temperatures varying from 300° to 350° with different coals decomposition commences with evolution of volatile products, the larger proportion of which condenses to liquids at the ordinary temperature, and only a small proportion of which forms permanent gases. These last consist chiefly of carbon dioxide, carbon monoxide, and gaseous hydrocarbons, with little, if any, hydrogen.

By carrying out the decomposition at the lowest possible temperature in a high vacuum, Pictet, Ramsayer and Kaiser obtained a tar from which they were able to isolate a series of hydrocarbons all of which belonged to the cycloparaffin series, the lowest of which was hexahydrofrotluene, C_7H_{14} , and the highest $C_{30}H_{60}$. They were also able to isolate the same hydrocarbons from the extract obtained by long continued extraction of large amounts of Montrambert coal with benzene. Hence it

seems probable that these hydrocarbons are either present as such in coal, or in such a state of combination that they are readily dissociated from the combination. In addition the "vacuum-tar" contains considerable amounts of oxygen compounds; the major portion of these consist of the higher homologues of phenol, phenol itself being absent or present in only minute amount. Acids containing the carboxyl group are also present in small proportion, and a larger proportion of neutral oils containing oxygen whose constitution is unknown.

When the coal is carbonised, whether on the small or large scale, at temperatures not exceeding 400°–450°, the general character of the tar and gas produced is similar to that above described, although, of course, secondary decomposition of the primary products must occur to a somewhat larger extent, these conditions representing what is now generally termed "low-temperature carbonisation." The yield of tar with "gas-coals" varies from about 8 to 10 p.c., and the gas yield from 3000 to 4000 cubic feet per ton of high calorific power, consisting to the largest extent of methane, ethane, &c., and only moderate percentages of hydrogen. The saturated hydrocarbons in the tar are to a large extent of the cycloparaffin series, but some hydrocarbons of the paraffin series are also present. Unsaturated hydrocarbons are also present in quantity, chiefly olefines, but there is always also a fair proportion of those of the C_nH_{2n-2} series, especially of the dienes, as well as cyclopentadiene and its homologues, but unless the temperature exceeds about 600°C., aromatic hydrocarbons are almost entirely absent.

The physical character of the residue varies greatly according to the character of the coal. Where the coal contains constituents which are fusible, the melting of these converts the coal at temperatures rather above 300° into a plastic or semisolid mass, which then undergoes decomposition leaving a porous coherent coke. Where the constituents do not fuse before decomposing the residue remains of the same shape as the original coal. In both cases the residue still contains considerable percentages of volatile matter, and burns in the air with a flame but without production of smoke.

Where the chief object is to obtain smokeless fuel from coal or carbonaceous products, or where the special aim is the maximum production of oil from the material, such low-temperature carbonisation may be advantageous. The yield of gas under these conditions is, however, so low (although of high calorific power) that the employment of such low temperatures is not as a general rule commercially practicable, and for this purpose higher temperatures must be employed when the gas is the chief product required.

In considering the changes which take place at such higher temperatures it is most convenient to deal first only with the carbon and hydrogen of the coal which are the most important constituents from a gas-making point of view. When the closed vessel into which the coal is placed is heated to a higher temperature, it only rises in temperature slowly, and therefore at first only undergoes the above low-temperature decomposition. The further action of heat then brings about fresh changes, both in the above

hydrogen-containing residue and in the volatile substances primarily evolved from the coal. The effect of further heat on the residue is to drive off more hydrogen, which, at temperatures of 700° – 800° , is mostly evolved as methane and free hydrogen, the latter being present in larger proportion, the amount of other gaseous hydrocarbons being very much smaller than in the gas produced at low temperature. The residual coke becomes denser and harder, but at this temperature still contains hydrogen in appreciable quantity, and on raising the temperature to the highest obtainable in practice, an additional yield of gas is procured still consisting of methane and hydrogen, but as the temperature increases the percentage of methane falls and that of hydrogen rises. The higher the temperature to which the residual coke is finally heated, the greater is therefore the yield of combustible gas.

The volatile products first evolved from the coal, consisting chiefly of compounds which are liquid at the ordinary temperature, also undergo further change when a higher carbonising temperature is employed, if they are subjected to the action of this heat before they can escape, the hydrocarbons contained in them yield a large proportion of gases which are permanent at the ordinary temperature, the most important of these being hydrogen, methane, and ethylene. At temperatures above 650° , aromatic hydrocarbons are produced, and if the temperature does not much exceed 700° , only those containing one benzene nucleus, *i.e.* derivatives of benzene itself, appear to be formed in material amount, such hydrocarbons as naphthalene and anthracene being almost entirely absent in the tar formed at these temperatures. The exact manner in which the production of these benzene derivatives occurs is as yet in doubt. It has been suggested that they are formed by loss of hydrogen from the naphthenes present, containing a ready-formed ring of six carbon atoms, or that they are formed by reduction from the phenolic bodies which are simultaneously produced from the oxygenated constituents of the coal. Whilst it is likely that some of the benzene derivatives are produced in these two ways, the fact that at the above temperatures approximately the same extent of production of benzene derivatives occurs with any carbonaceous matter, even from open-chain hydrocarbons, and in absence of any oxygen compounds or of naphthenes, makes it improbable that anything like all of these derivatives are obtained in this manner. Thus when American petroleum containing but little cycloparaffins and phenol, is cracked for the manufacture of carburetted water gas at temperatures of 750° , the proportion of aromatic hydrocarbons found in the tar produced is quite as high as that obtained when oils largely consisting of cycloparaffins are used. The most probable supposition on the evidence at present available, is that at the temperatures which result in the production of the benzene derivatives, the various hydrocarbons undergo decomposition to the extent of producing the single-atom unsaturated hydrocarbons CH_3 , CH_2 , CH , capable of temporary existence, as shown by Sir J. J. Thomson in his positive-ray analysis of methane, and of analogous molecules

such as $\text{C}\cdot\text{CH}_3$, and that the benzene derivatives are produced by the subsequent union especially of these molecules to form the benzene ring, which when once formed is known to be exceedingly stable towards heat. At such temperatures benzene itself forms only a moderate proportion of the aromatic derivatives produced, the homologues with one or more side chains being produced in larger quantity.

As the temperature to which the volatile products are subjected is further raised, there is an increasing tendency to the production of benzene itself by the elimination of the side chains from the toluene, xylene, &c., and simultaneously complex aromatic hydrocarbons containing more than one benzene nucleus make their appearance, and the higher the temperature the larger are both the quantity and the complexity of the products, many of which are now of very high molecular weight, and for the most part infusible and insoluble, and therefore remain suspended in the tar produced, forming what is commonly termed the 'free-carbon' in the tar. Saturated aliphatic hydrocarbons largely disappear, and the quantity of dienes falls, but olefines still remain present in considerable quantity.

At these latter temperatures, the effects on the gas production are by no means altogether favourable, as although some hydrogen is produced in the changes which the volatile products undergo, the simpler gaseous hydrocarbons which form the most important constituents of the gas themselves undergo decomposition into hydrogen and carbon, which last is deposited partly on the coke and partly on the walls of the retorts as 'carbon' or 'scum,' and this material, although of some value, is of greater worth if left in the gas in the form of hydrocarbons. The presence of the solid 'free-carbon' in the resulting tar also greatly increases the difficulty of retort-house working by forming deposits in the mains, &c., which are only removable with difficulty.

The chemical considerations therefore lead to the conclusion that while in order to obtain from coal the maximum yield of energy in the form of combustible gas, it is advisable to subject the latter finally to as high a temperature as possible, so as to drive off the volatile matter completely, the gases and vapours produced in the distillation should only be subjected to a considerably lower temperature than that to which the coke is eventually heated, as too high a temperature results in the separation of carbon, which would otherwise have remained as gaseous hydrocarbons in the gas; thus depreciating both its calorific and illuminating power. On the other hand, it is equally evident that these volatile products must not be subjected to too low a temperature, for in that case the hydrocarbons, &c., produced in the early stages of distillation would not be sufficiently decomposed, and would be lost from a gas-making standpoint—being condensed in the tar.

The remaining constituents of the coal concerned in the production of gas are oxygen, nitrogen, and sulphur. The ash remains in the coke, and need not be further considered here. Oxygen is present in considerable amount in the coal substance; and the coal as used also always

contains either moisture in the free state or in such a loose state of combination that it is given off at temperatures below 100° —the amount varying usually from 1 to 7 p.c. The low-temperature carbonisation first taking place results, as stated above, in the resolution of the oxygen-containing constituents of the coal into carbon dioxide, carbon monoxide, and steam, and condensable compounds of carbon, hydrogen and oxygen largely consisting of the higher phenols. The further action of heat on these last results partly in the elimination of the side-chains and production of lower homologues and of phenol itself, and in addition the action of these on the heated carbon results in some of them losing their oxygen and yielding the corresponding aromatic hydrocarbon. The resulting tar at high temperatures always still contains considerable percentages of phenols, the amount relative to the coal carbonised always increasing as the percentage of oxygen in the coal used increases. As the temperature rises, the carbon dioxide tends to combine more and more with the red-hot carbon present, undergoing reduction to carbon monoxide, and the steam tends also to act on the carbon, with production of water gas; and the higher the temperature to which the gases are heated, especially while in contact with the coke, the greater is the amount of carbon monoxide formed, and the higher also the amount of steam converted into water gas. In high temperature carbonisation, therefore, a small proportion of the oxygen in the original coal is recovered in the tar as phenol, etc., but the bulk of it remains as steam, which condenses out on cooling, and, roughly, about one-fourth is found in the gas as oxides of carbon.

The effect on the nitrogen is similar to that on the hydrogen. At very low temperatures some ammonia is given off, and also substances containing carbon, hydrogen, and nitrogen, which condense in the tar; while a large proportion of the nitrogen remains in the residue. At higher, but still moderate, temperatures, much more nitrogen is given off from the coal, and the above volatile products are largely broken up, with the formation of ammonia and some free nitrogen; and at such temperatures the maximum yield of ammonia is obtained. At still higher temperatures, more nitrogen is evolved from the coke; but the ammonia itself is then largely decomposed into its elements nitrogen and hydrogen, and also reacts with the hot carbon, producing hydrocyanic acid; and, in spite of the more complete elimination of the nitrogen from the coke, the yield of ammonia is decreased. In ordinary gas-works practice in horizontal retorts, only from 14 to 17 p.c. of the nitrogen in the coal is mostly recovered in the form of ammonia (*v. AMMONIA*). Some of the nitrogen is also found in the tar, chiefly in the form of nitrogenous bases, such as pyridine.

The sulphur, too, probably comes off first as compounds with carbon, and hydrogen; and these, when more strongly heated, yield sulphuretted hydrogen, which can be removed from the gas without much difficulty. At still higher temperatures, however, the decomposition of these volatile organic sulphur compounds takes place with formation of larger quantities of carbon disulphide; this compound being also

produced, but probably in much smaller amount, in the gases last driven off from the coke, due to the sulphur still remaining in the latter. High temperatures, especially if allowed to act fully on the volatile products, therefore tend to increase considerably the amount of this impurity, which can only be removed with difficulty.

Both with regard to sulphur and nitrogen, therefore, as well as in the case of the hydrocarbons, it is desirable that the volatile products themselves shall only be heated to a moderate temperature if a maximum yield of the valuable product (ammonia) and a minimum yield of the deleterious impurity (carbon disulphide) is to be obtained. In the case of the oxygen compounds alone does there appear to be any advantage in subjecting these products to a high temperature, owing to the larger proportion of carbon monoxide and smaller proportion of carbon dioxide produced, as well as to the larger amount of steam converted into combustible gas. On the whole, the advantages gained in the latter respect are more than counterbalanced by the deleterious action of such high temperatures so far as the hydrocarbons and the nitrogen and sulphur compounds are concerned.

While, therefore, the effect of heat on coal, and generally on substances containing carbon and hydrogen, is primarily to resolve the compounds into simpler substances, the changes which take place finally are largely synthetical, and new substances are produced in large measure by the combination and interaction of the primary decomposition products, the nature and amount of the new substances formed varying greatly according to the conditions of carbonisation, and especially with the temperature to which they are heated and very greatly with the length of time during which they are exposed to that temperature. In addition to the synthetic production of new hydrocarbons already referred to, others occur in which different constituents are concerned. The formation of carbon monoxide by the action of the dioxide on carbon, and the synthesis of water gas by the interaction of steam and carbon, have been referred to. In addition, there is some evidence that methane may also be formed to a certain extent in the carbonising process by synthesis from hydrogen and carbon monoxide, in accordance with the reversible reaction $\text{CO} + 3\text{H}_2 \rightleftharpoons \text{CH}_4 + \text{H}_2\text{O}$. This reaction occurs almost quantitatively when a mixture of the gases is passed over metallic nickel at 250° (Sabatier and Senderens, *Compt. rend.* 134, 514), and although, as the temperature rises, the reverse reaction takes place in increasing degree, the evidence available points to the conclusion that appreciable amounts of methane are formed in this manner under some conditions during carbonisation.

In the carbonisation of coal in the most usual gas-works practice, the coal, as above described, is placed in a long narrow retort set either horizontally or at an angle of about 32° to the horizontal, leaving a considerable amount of free space above the coal through which the evolved gas must pass to reach the exit pipe at one or both ends of the retort. The carbonisation commences on the outside of the mass—namely, at the bottom and sides—where it is in contact with the heated retort wall, and also

at the top, where it is affected by the heat radiated through the free space from the hot crown of the retort. The coal on the outside first becomes pasty and agglomerates, and then undergoes the low-temperature decomposition already described, the resultant vapours and rich gas escaping fairly readily into the free space above the coal. Here they are subjected to the further action of heat in two ways—namely, by contact with the heated walls of the retorts, and also by the action of the radiant heat rays which are traversing the free space. The net result of their combined action is to raise the temperature of the vapours passing through the free space, and to bring about much change; and the higher the temperature to which the retort walls are heated, the greater is the amount of further decomposition that they undergo.

The further action of heat on the pasty mass on the outside of the charge converts this eventually into coke; heat passing simultaneously further into the charge and converting the layer below into the pasty condition, which is assisted by the condensation on these lower layers of some of the tarry matters formed by the decomposition of the hotter layers above, and the extent to which such condensation occurs doubtless has much influence on the physical properties of the resulting coke. This sequence of changes continues until the heat has penetrated to the centre of the mass, and effected its complete carbonisation. After the first layer of hot coke has been formed, the gases produced from the interior of the charge, in order to escape from the retort, must not only undergo the ordeal of heat in passing through the free space, but also pass through the hot layer of coke on the outside of the charge; and the temperature and area of this coke mass constantly increases as time goes on. Further, as carbonisation proceeds, the rate at which the gas is evolved decreases, and in consequence, its speed through the free space becomes less, and it is exposed to heat there for a greater length of time. From all these causes, the quality of the gas falls off after the first hour, and especially when the carbonisation is approaching completion. The percentages of methane, ethylene, benzene, sulphuretted hydrogen, and carbon dioxide steadily diminish as time progresses, and that of hydrogen steadily increases; while that of carbon monoxide varies less considerably, as shown by the following table, giving the analysis of the gas evolved at different stages from a retort charged with Derbyshire coal, the temperature of carbonisation being about 950°:—

	Hours after commencement				
	½ hour	1½ hrs.	2½ hrs.	3½ hrs.	5 hrs.
Sulphuretted hydrogen .	3.8	3.1	2.8	2.1	1.2
Carbon dioxide .	3.0	2.8	2.6	2.3	1.7
Ethylene and benzene .	8.6	5.2	3.6	2.4	0.0
Oxygen .	0.0	0.0	0.0	0.0	trace
Carbon monoxide .	4.4	5.0	4.9	4.5	3.8
Methane .	49.7	42.0	39.4	37.5	26.3
Hydrogen .	29.8	37.5	42.2	46.2	60.8
Nitrogen (by diff.)	0.7	4.4	4.5	5.0	6.2

Before the introduction of gaseous firing, the retort temperatures obtained in practice did not usually exceed about 900°C., or 1650°F. Under these conditions, the volatile products were not materially overheated, and gas of high illuminating power was produced; while the tar simultaneously formed was fairly fluid, and only contained moderate amounts of the objectionable 'free carbon.' The quantity of naphthalene formed was also not excessive, and that of 'light oils' simultaneously produced was, in most cases, sufficient to wash the naphthalene out of the gas during condensation to a sufficient extent to prevent its subsequent deposition in the solid state in the mains and services. On the other hand, under these conditions, a relatively low yield of gas per ton is obtained, as an appreciable quantity of volatile matter is left in the coke.

When, with the aid of gaseous firing, higher carbonisation temperatures were employed, matters were considerably modified, as the volatile matter of the coal was more completely evolved with the production of a greater volume of gas. But, as we have seen, it follows inevitably that, in a horizontal or inclined retort having a large free space above the coal, the volatile products must also be more strongly heated by an increase in the retort temperature; and, as a result, under these conditions, the gases and vapours undergo a more far-reaching decomposition than before, and a reduction in the quality of the gas is brought about. Some of the hydrocarbons formerly present in the gas are now deposited in solid or liquid form, which either remain in the retort as carbon or are condensed with the tar, and are lost from a gas-making point of view. Simultaneously, other disadvantageous changes occur, inasmuch as the tar produced is thicker and contains much more 'free carbon,' thereby increasing the trouble from stopped ascension pipes and pitched hydraulic mains, and greatly increasing the practical difficulties of retort-house working. Further, the action of these high temperatures on the volatile products increases the production of naphthalene and decreases that of light oils, and renders the cooled gas much more liable to deposit solid naphthalene in the mains and services both on the works and in the district, causing serious trouble both to supplier and consumer.

In spite of these last-named drawbacks, the employment of higher temperatures has, on the whole, proved favourable; the increased yield obtained from the more complete elimination of the volatile matter of the coal having more than counterbalanced these disadvantages. Nevertheless, a process of carbonisation is very desirable, in which the coal itself can be heated to a high temperature without simultaneously causing too great heating of the volatile products; and it is largely with a view to this end that modifications of the method of working have been introduced during the past few years.

From what has been said, it is clear that one of the chief causes of the overheating of the gases and vapours is the existence of a large free space above the coal in the retort. With the horizontal retort, so long as the coke had to be extracted by a rake, worked either by hand or mechanically, a considerable amount of free

space was necessary in order to afford room for the introduction of the rake-head above the coke; but the invention of mechanically propelled pushers, which discharge the coke by pushing from one end of the retort, has done away with the necessity of the free space for the removal of the coke, and has made it possible to put in a much larger charge of coal without increasing the difficulties of discharging the latter. In recent years, therefore, by the introduction of such increased charges, the amount of free space has, in many works, been largely reduced in horizontal retorts, so that the gases and vapours are exposed to a smaller amount of retort surface, and, still more important, owing to the volume of the free space being smaller, they pass through it more quickly, and are exposed to the action of the heat for a shorter time. As the practical result, it is found that the coke produced is larger, a thinner tar containing less free carbon is produced, owing to the lessened overheating, less carbon disulphide is produced, less trouble from naphthalene ensues, and retort-house working is considerably facilitated. Whether the total heat value of the gas obtained from a ton of coal—i.e. the multiple of gas per ton \times calorific power—is greater than can be obtained with the smaller charges, is a matter on which different opinions prevail at present.

On the other hand, owing to the increased thickness of the charge, a longer period must be allowed for its carbonisation if the central core is to be completely carbonised; and beyond a certain weight of charge, varying apparently with different classes of coal, the gas production per retort per 24 hours falls off, or can only be maintained by increasing the carbonisation temperature above that employed with the smaller charges. Such higher temperatures also increase the heat to which the gases are exposed in the free space; but experience seems to show that the effect of such increase is small when the volume of free space is low, or, in other words, that in bringing about decomposition of the volatile products the time during which the gas is exposed to heat is much more important than the temperature of the retort walls.

Carbonisation in vertical retorts. But, while the amount of free space can be in this manner greatly reduced, it is scarcely practicable to eliminate it altogether in horizontal retorts. If, however, the retort is placed in a vertical instead of a horizontal position, this is readily effected; as, in the nature of things, the coal when charged in from the top must completely fill the retort. Although a small amount of free space may be left at the top, matters can be so arranged that this is not too large and that the retort walls at this point are not heated to any great extent. Hence latterly carbonisation in vertical retorts has been much investigated, and is now practised in a steadily increasing number of works.

Intermittent vertical retorts. In the Dessau vertical retort system, patented by Bueb (Eng. Pat. 1393, 1904), the previous practice is adhered to, in so far that the coal is charged into the retort from an overhead hopper all at once, and allowed to remain there until carbonisation is complete, when the coke is discharged by gravity and the retort refilled with fresh coal.

The retorts are either 4 or 5 metres in length, having an oblong cross section with rounded corners and are tapered, increasing in size from top to bottom to facilitate the discharge of the coke. Until recently 10 or 12 retorts were set in rows of two in a setting, each setting being heated by gas from a separate deep producer capable of being filled much above the point at which the producer gases are drawn off, so that it may run for 24 hours without recharging. Fig. 10 gives a vertical section of such a setting

FIG. 10.

and producer, showing clearly the general arrangement of the plant.

As the thickness of the charge is greatest at the bottom, the highest temperature is maintained at this point, with a rather lower temperature in the upper portions where the thickness of the charge is less. The result of this arrangement is that, even at high temperatures, not only is a large yield of gas obtained, but at the same time the tar formed is very fluid, and only contains a small percentage of free carbon. Simultaneously, the naphthalene production is lessened, and that of the lower boiling tar constituents increased, with the result that the naphthalene is sufficiently completely removed from the gas in the ordinary process of condensation, without the adoption of any special treatment, and, at the same time, the amount of sulphur obtained in the form of carbon disulphide is reduced. The yield of ammonia is also higher, and the coke produced is harder and denser than that formed from the same coal in horizontal retorts.

In spite, therefore, of very high retort temperatures, the objectionable overheating which occurs with horizontal retorts having a highly heated free space above the coal, is obviated in such vertical retorts. This is largely due to abolition of this free space, but other conditions also come into play. In the horizontal retorts, after a layer of incandescent coke has been formed on the exterior of the charge,

all gas produced from the unaltered coal in the centre of the charge must find its way out through the incandescent layer, and thus be subjected to considerable heat. In the intermittent vertical retort, the carbonisation also takes place from the periphery inwards, and a layer of incandescent coke is formed in the early stages, but in this case the gas produced from the still uncarbonised coal in the centre of the charge has two possible paths of escape—on the one hand, through the hot coke layer, and on the other, through the cool central core of uncarbonised or partly carbonised coal, and the gas travelling in the latter direction escapes overheating by the hot coke layer. The relative amounts of the gas which travel in each direction is still a matter in dispute, but the evidence available leads to the conclusion that with coals which become pasty on heating, much the largest proportion of the gas travels through the hot coke, as the plastic coal film formed between the carbonised coke and uncarbonised coal in a more or less continuous layer is almost impermeable to gas, and as the greater gas production takes place on the coke side, where it is subjected to the greatest heat, the gases produced find their easiest route to the outlet at the top of the retort through the hot coke layer, which is always broken and fissured. On the other hand, where a non-caking coal is carbonised in vertical retorts, no such plastic layer forms, and with such coals unless the coal itself is very small and lies in a compact mass, the volatile products then mainly pass as formed to the outlet at the top of the retort through the cool core of uncarbonised coal.

In the later form of the Dessau retorts, the length of the oblong cross section has been reduced, and these retorts set in rows of three, which are charged and discharged simultaneously. The reduction in the size of the retort increases the proportion of heating surface to the cubic capacity of the retort, and results in a more rapid carbonisation and increased output of gas, and also a reduced fuel consumption.

Continuous vertical retorts. In this system of carbonisation, the object aimed at is not only to avoid an excessive heated free space above the coal, but also to render the process a continuous one, by the addition of mechanical arrangements whereby the coke is withdrawn continuously, or nearly so, from the bottom of the retort, fresh coal being added to the retort at the top to replace the coke withdrawn, so that the coal to be carbonised slowly travels down the retort, undergoing gradual conversion into coke and gas. The conditions in the retort, therefore, remain approximately constant, and the quantity and quality of the gas evolved remains fairly constant, instead of both falling off as carbonisation proceeds, as is the case with an intermittently charged retort.

The continuous system of carbonisation has been chiefly worked out in this country. Although many experiments in this direction were made in the last century, none met with any degree of success. In the early years of the present century, however, very interesting results were obtained with the Settle-Padfield continuous vertical retort (Eng. Pat. 12552, 1902; 24588, 1903), which showed that excellent carbonising results, so far as yield and quality

of gas and coke were concerned, could be obtained in this manner, although, largely owing to difficulties arising from the shape of retort adopted, the practical difficulties found in working it have prevented its further adoption. At the present time several such continuous processes are in use, the most widely adopted being the Woodall-Duckham system (Eng. Pat. 16497, 1903; 15053, 1907) and the Glover-West system (Eng. Pat. 23650, 1905; 2663, 1907; 7534, 1907; 8572, 1909), a diagrammatic section of each of these plants being shown in Figs. 11 and 12, from which the general arrangement is readily seen. In the Woodall-Duckham retorts, Fig. 11, the discharge of the coke is controlled by the coke-feed roll shown below the retort, which is slowly revolving, and as it rotates allows the coke to fall into the chamber below, from which it is emptied periodically, the speed of the coal through the retort being regulated by varying that of the feed roll. As the coke is removed, the whole mass in the retort falls, leaving a space at the top, which is at once filled by fresh coal introduced from a small hopper above each retort, connected by a valve with the main coal bunker above from which it can be filled with coal as required. The retorts, four of which are placed in a setting, are 25 feet in length, and have a considerable taper to facilitate the downward movement of the mass. The heating is effected by producer gas, which, with the secondary air, enters at the top, the mixed gases passing downwards, the temperature on the outside of the retorts being highest at the top and decreasing to the bottom of the retorts.

In the Glover-West system, Fig. 12, the discharge of the coke is effected in a different manner. At the bottom of the retort is placed a screw conveyor, the pitch of which is less than the angle of rest of the coke, and this is slowly rotated, thus effecting the gradual discharge of the coke into the chambers below, from which it is removed at suitable intervals. As the coke is removed from the bottom, the whole mass of the material in the retort moves downwards, leaving a space at the top which is at once filled from the small hopper at the top of each retort and closed at the top by a gas-tight valve, shutting it off from the main coal bunker above. The small hopper is filled with coal every few hours by opening the valve and allowing it to fill up from the main bunker. The retorts are from 20 to 23 feet in length, and tapered, eight being placed in a single setting. For the purposes of heating, the setting is divided into a number of sections by horizontal division walls, the three upper sections receiving the combined waste gases from the chambers below, and abstracting much heat from these before they pass to the chimney. The next six sections form the heating chambers proper, each receiving a separate supply of producer gas from the furnace, as well as a separate supply of secondary air, and by suitably regulating the supplies, the temperatures in the different sections can be adjusted to that found most suitable for the particular coals carbonised. In the lowest section, the secondary air is admitted on its way to the heating sections, and thereby cools the now carbonised coke passing through the retorts, so that this is discharged in a relatively

cool condition, and requires no quenching, its heat being returned to the setting with the

FIG. 11.

secondary air, effecting a considerable economy in the fuel consumption.

The constant movement of the mass through

the retort in such continuous vertical retorts modifies the conditions of carbonisation to some extent. As with the intermittent retorts, the heat penetrates the mass of coal from the periphery and travels inwards, but the coal is constantly moving downwards, the uncarbonised coal takes the form of an inverted cone, the base of which is at the top, and the apex at a point about two-thirds of the length of the retort below. A small proportion of gas, with much steam, is formed on the inner and cooler side of the layer of decomposing coal, and escapes up through the core of uncarbonised coal, but with a caking coal the bulk of the gas is formed on the hotter outer portion of the decomposing pasty layer and passes up through the surrounding hot coke. Only a limited amount of free space is left at the top. The tar produced is thin and contains but little free carbon, no naphthalene trouble occurs with the gas after condensation, the carbon disulphide is reduced, and at the same time a high yield of gas of good calorific power is obtained. The coke formed from the continuous process is usually less dense than that obtained by intermittent carbonisation in vertical retorts.

Water-gas production in retorts. As already mentioned, admixture of blue water gas to the coal gas is being carried out to an increasing extent. In some instances the water gas is made in a separate plant and introduced into the coal gas stream at varying points, and in others the increased water-gas production is obtained by the addition of steam, to the retorts. Such steaming has been carried out in horizontal retorts by introducing steam below the coke mass throughout the length of the retort, and this has proved a valuable means of maintaining the gas supply during recent periods of coal shortage. The conditions in horizontal retorts are, however, not favourable to the manufacture of any considerable proportion of water gas in this manner, except with production of a high percentage of carbon dioxide in the mixed gas obtained. Vertical retorts, in which the steam has to pass through a much deeper bed of fuel, present much more favourable conditions, and it has long been the practice in the case of intermittent vertical retorts to admit steam to the bottom of the retort during the last 1-2 hours of the charge to increase the production of water gas, and recent requirements have brought about a great increase in the extent of this steaming.

With continuous vertical retorts, small amounts of steam have for a long time been admitted continuously at the bottom of the retort, resulting in the production of small amounts of water gas, and also in preventing ignition of the gas when the bottom doors are opened for the discharge of the coke. During recent years the extent of steam admitted (usually previously superheated) has greatly increased, and very considerable proportions of water gas are now being thus made in these retorts. The changes which occur are, however, not solely confined to the production of water gas, as secondary effects occur to the gas, tar, and ammonia production from the coal itself. This arises from the fact that owing to the increased production, the gases formed in the retort from the coal are thereby driven out of

FIG. 12.

the retort more quickly, and thus exposed for a shorter time to the action of heat, which results in an increased yield of both tar and ammonia from the lessened decomposition occurring. The increased amount of hydrogen in the gas also tends to the production of tar containing a higher proportion of hydrogen. On the other hand, as the water-gas production is endothermic, a greater amount of fuel has to be used to maintain the temperature, and to obtain a low percentage of carbon dioxide in the gas high temperatures must be maintained at the lower portion of the retort; the coke yield is also slightly reduced by reason of the carbon used for water-gas production, and the percentage of ash in the coke obtained slightly increased. The amount of steam which can be added varies greatly with different classes of coal, but with certain kinds of coal, yields of 25,000 of mixed gas having a calorific power of 400 B.Th.U. have been obtained.

Detailed investigations of the process of steaming in continuous vertical retorts have been made by the Investigation Committee of the Institution of Gas Engineers, and by the Fuel Research Board. (Gas Journ. 1920, 150, 640; 1921, 154, 642, 607.)

Carbonisation in larger bulk. Considerable attention has recently been paid, especially in Germany, to the carbonisation of coal for gas-making purposes in much larger bulk than the gas retort, and more in accordance with the practice where metallurgical coke is the product primarily required (*see art. COKE*). In this industry, as the gas is a by-product, the latter is employed for heating the ovens, but as with good working only about half the gas made is required for this purpose, a considerable surplus remains, which is generally used for boiler firing or in gas engines. In the north of England, a considerable amount of this surplus gas is either distributed in the neighbourhood of the ovens for general purposes, or more frequently the gas is sold in bulk to neighbouring gas undertakings, and mixed by them with the gas manufactured by their own plant. Middlesbrough is almost entirely supplied with gas from coke ovens, and a material proportion of the supply of Leeds, Sheffield, and other towns is derived from the same source. In Germany and in the United States an increasing amount of coke-oven gas is employed in this manner.

In the coke-oven industry, the object aimed at is not only the production of coke, but also the utilisation of the slack inevitably produced in the operation of mining. This is in many cases first washed to remove mineral impurities as far as possible, and, when charged into the ovens, lies in a dense mass, which may be 10 tons or more in weight, and has very small interstitial spaces, and is sometimes further specially compressed; moreover, it contains 10 p.c. or more of moisture. Whilst the result of these alterations in the conditions from those in gas retorts effects an improvement in the quality of the coke produced, the gas, as it is formed, has greater difficulty in escaping from the centre of the charge, and the volume produced is usually lower, although it is of good calorific power, provided due precautions are taken to prevent the drawing in of undue amounts of furnace gases or air. The rate of

carbonisation is also naturally much slower, as the larger the bulk in which the coal is charged the smaller is the *ratio* of heating surface per unit weight of coal, which further influences, to some extent, the composition of the resulting gas.

In Germany, particularly during the past few years, extensive experiments have been made with carbonising chambers of rather smaller size than coke ovens, holding from 3 to 6 tons per charge, in which the heating is effected by producer gas manufactured from the coke, and ordinary gas coal is carbonised instead of washed slack. In some of the forms adopted, horizontal chambers are used, and in others, these are provided with a sloping bottom, to facilitate the charging of the coal and discharge of the coke (*see J. Gas Lighting*, 1909, 106, 832). The coke obtained with such chambers is more closely allied to metallurgical coke than to ordinary gas coke, but where ordinary gas coal is used, the results, so far as quality of gas, tar, and ammonia are concerned, do not appear to differ materially from those obtained with intermittent vertical retorts. The relative advantages of such chambers and retorts lie more in connection with questions of the capital and working costs, of the desirability of such large carbonising units for making a uniform quality of gas, for adjusting the gas output to the seasonal variation in the demand for a public supply of gas, and of the suitability of the quality of coke produced to supply the local demand. Since 1911 a few installations of this intermediate type of chambers, between the size of retorts and coke ovens, have been adopted in this country.

The possibility of supplying gas of low calorific power has resulted also in the development of plants for the total gasification of coal, the general principle of which lies in the combination of a vertical retort with a water-gas or mixed gas producer, the coal passing into the producer through the former in which, partly by external heat and partly by the sensible heat of the hot water gas or producer gas passing through it, this is converted into a low-temperature coke before reaching the producer, where it is finally gasified, the mixed gas thus produced having a calorific power of 300-350 B.Th.U. Such plants have been adopted in many gas works in this country as auxiliaries, and also to a considerable extent on the Continent, but detailed and checked reports of their efficiency have not yet been published.

The efficiency of plants of this type would be very largely increased if oxygen were available at a cheap enough rate to be introduced along with steam instead of air into the producer. This matter is fully discussed by Hodsman and Cobb (Gas Journ. 1920, 150, 640).

CONDENSATION OF THE HOT GAS.

The volatile products driven off from the coal issue from the retorts into the mouthpiece, at a high temperature, which may, at times, reach 700°-800°, but this falls very rapidly as the gas passes up the ascension pipe. This arises partly from the fact that the difference in temperature between the gas within and the air circulating around the pipe is very great, and partly because the number of heat units to be

FIG. 13.

FIG. 14.

removed for a given temperature interval is relatively small, being due to the specific heat of the gases, and the latent heat of the tar vapours which condense, both of which are comparatively low. The temperature, therefore, falls rapidly up to the point at which water commences to condense, which is usually about 75° – 80° , and from this point onwards the rate of cooling becomes very slow, chiefly owing to the high latent heat of the steam present. The dew-point is mostly attained by the time the gas reaches the dip pipe, and the temperature of the gas in the hydraulic or dry main, where the streams of gas from the different retorts mix, averages about 60° . By the time the steam commences to condense, by far the greater part of the tar vapours present have liquefied, and, owing to the rapid rate of cooling, these separate in the form of finely divided drops or vesicles, which are carried along with the stream of uncondensed gas mechanically in the form of a dense brown fog. In passing through the hydraulic or dry main, the greater part of this fog (generally from 70 to 80 p.c.) coalesces to form liquid tar, a considerable amount of water also separating here also, which combines with the ammonia and other impurities of the gas, forming ammoniacal liquor, these two liquids being removed in the manner already described. The combined streams from all the collecting mains of the separate setting unite in a trunk main termed the 'foul' main, by which they are conveyed from the retort house to the condensing plant proper, the combined stream having at this point a temperature of 50° – 60° , and still containing much suspended tar fog, amounting in some cases to as much as one-third of the total tar production.

The cooling of the gases to approximately atmospheric temperature is effected by means of either atmospheric condensers or water-cooled condensers. Although many types of the former, differing in external appearance, are in use, the arrangement is in all cases such that the gas is passed slowly through apparatus exposing a large surface to the air, whereby the sensible heat of the gases and the latent heat of the vapours is given up to the air passing over the surface. In the water-cooled condensers water is employed as the cooling medium in place of air. This type of condenser requires a much smaller cooling surface than the atmospheric type, and the temperature to which the gas is cooled can be more readily regulated by controlling the flow of water, provided a sufficient supply of cold water is always available.

Fig. 13 shows the general arrangement of a vertical, and Fig. 14 of a horizontal, atmospheric pipe condenser, the manner of working being readily apparent from the diagram. Fig. 15 gives one section of an annular atmospheric condenser, in which the gas passes through the annular space between the inner and outer pipes, the air circulating not only over the outer pipe, but also ascending up the inner pipe, cooling both surfaces of the annular chambers. The volume of air passing up the inner pipe can be varied by means of the damper shown, and the extent of cooling of the gas regulated to some extent in this way. Fig. 16 gives a vertical and cross section of a water-cooled tubular condenser, the gas passing downwards over the

outer surface of the small pipes, the water travelling up the pipes in the reverse direction to the gas stream, so that the gas leaving the apparatus is finally cooled by the incoming cold water. Many other good forms of both atmospheric and water condensers are in use, but their action is, in general, similar to those described.

When high carbonising temperatures are

FIG. 15.

employed, especially with certain classes of coal, the tar separating in the cold end of the condenser is apt to become semi-solid from crystallisation of naphthalene, eventually causing a stoppage. To avoid this it is convenient to arrange the connections and valves in such a manner that the inlet and outlet can be reversed; the previously cold end then receives the hot gas, and the thick tar becomes fluid and flows to the tar well, so that by periodic reversals of the stream blocks from this cause can be largely avoided.

In this country, where the seasonal changes in temperature are not, as a rule, very extreme, atmospheric condensers are employed to the largest extent, water condensers being employed

frequently in addition to effect the final cooling of the gas. On the Continent, where lower temperatures often prevail in winter and higher in summer, water condensers are more frequently used, and are enclosed in buildings to protect them from extremes of temperature.

In the early days of the manufacture, the only point considered was the simple cooling of the gas, but it was soon found that the manner

ture to which it may be subsequently exposed during distribution, and, at the same time, to remove as completely as possible the vapours of higher-boiling substances, especially naphthalene. The importance of the removal of the latter arises from the fact that it is a solid at the ordinary temperature, and, when present, is liable to be deposited in crystals as the gas cools, and then causes blocks in the subsequent manufacturing plant and in the distribution system, causing great inconvenience. Although the amount of naphthalene in the gas sent out from the works rarely exceeds 15–20 grains per 100 cub. ft., and is usually much less, the deposited naphthalene may, when weather conditions are favourable to its separation, cause the stoppage of hundreds of service pipes in a single night in a large town.

To effect the maximum retention of the lowest boiling-tar constituent, benzene, and the most complete removal of the higher-boiling constituents, the ideal procedure would be to arrange the condensing system so that the whole of the products of condensation flowed back in the opposite direction to the gas, whereby the gas is continually exposed to the solvent action of the liquids condensed from it at a lower temperature, in exactly the same manner as the vapours from a mixture of liquids are treated in a fractionating column in the process of fractional distillation. This principle is, however, very difficult of application in its entirety in the coal-gas manufacture, for many reasons. In the first place, as already mentioned, the separate streams from each retort undergo such rapid cooling before they combine to a single stream, that the tar has largely separated as a fog, which is inevitably largely carried forward mechanically with the gas, instead of travelling in the reverse direction; and, secondly, water also condenses from the gas, and as this does not mix with, and is specifically lighter than, the tar, it tends to cover the surface of the separated tar, and prevent the latter exerting its full solvent action on the substances still present as vapours in the gas. Where the coal is carbonised in larger units, as in coke ovens, the combined streams from the different ovens have a much higher temperature; here a strictly counter-current process is more possible, and Feld has patented a process for the treatment of such gas in a series of mechanical washers, in which the gas is successively washed with the products condensing at a lower temperature, the tar being obtained direct from these in different fractions, corresponding to those obtained in the first distillation of coal tar, and free from water, as the temperature is not allowed to fall to the point at which steam commences to condense (Eng. Pat. 26262, 1905; 20139, 1907; 27567–8, 1907; 9086, 1910). The removal of tar fog from the hot gas from coke ovens at temperatures above the dew-point is also carried out by the Otto process (see art. COKE).

in which the cooling takes place and the temperature to which the condensed tar is cooled in contact with the gas has a very material effect on the illuminating power of the gas produced. This arises from the fact that the illuminating power of the gas is very largely dependent upon the amount of benzene vapour present in it, and the lower the temperature to which the tar is cooled when in contact with the gas, the greater is the proportion of the benzene retained by the tar and the lower that left in the gas. The object aimed at in condensation is, therefore, not merely to cool the gas, but to carry out the cooling in such a manner as to leave in it the maximum amount of benzene vapour that it can retain at the lowest tempera-

The adoption of the counter-current system in gas works in the later stages of condensation, tends to have a beneficial effect, but the extent is only slight, owing to the above-mentioned protective effect of the condensed ammoniacal liquor, the quantity of which is much greater than that of the tar after the gas leaves the hydraulic main. In general, the widest

FIG. 16.

divergence occurs in practice as to the manner in which the condensed tar is allowed to flow, this being sometimes with and sometimes against the gas streams, and sometimes alternately in each direction. It is, however, generally agreed that the tar which separates at the earliest stages, namely, in the hydraulic main, should be removed from contact with the gas before the temperature of the latter is reduced below 30°-35°.

Formerly, when gas of higher illuminating power was made, it was generally regarded as important that the cooling of the gas, at any rate from 60° to about 25°, should take place slowly, if loss of illuminating power was to be avoided. With gas of the quality now usually made, this is, however, of but little influence, rapid cooling in this case effecting but little reduction of the calorific power, provided the temperature is not reduced below 15°-20°; if, however, the gas is at any time cooled in presence of tar much below 15°, decided reduction in calorific power occurs, and too great reduction of temperature in condensation is, therefore, always to be avoided.

During the whole of condensation, including that occurring in the retort house, from 9 to 15 gallons of tar per ton of coal (varying with the nature of the latter and the temperature and method of carbonisation) are separated from the gas, together with a quantity of ammoniacal liquor varying usually from about 10-15 gallons per ton. These both flow together to the well or wells, to which any tar and liquor from the subsequent apparatus also gravitate. The condensed water removes a large proportion of the ammonia from the crude gas (usually about half of the 400-450 grains per 100 cub. ft. contained in the gas issuing from the retorts), and the alkaline ammonia solution also extracts the whole of the hydrochloric acid in the gas formed from the chlorine in the coal, and some of the carbon dioxide, sulphuretted hydrogen, and hydrocyanic acid. The liquor obtained in condensation is termed 'virgin liquor,' that portion formed in the retort house being usually, though not invariably, weak, and containing from 0.5 to 1.5 p.c. of ammonia, whilst that from the condensers is more concentrated, and may contain 4 p.c. or more. The cooled gas mostly contains some 200 grains of ammonia, and 50-100 grains of hydrocyanic acid per 100 cub. ft., from 1 to 2 p.c. of sulphuretted hydrogen, and 1-3 p.c. of carbon dioxide, and in addition also an appreciable amount of tar fog, which has not been removed from the gas in its passage through the condensers, and which, if not previously eliminated, is deposited in the subsequent purifying apparatus, rendering them much less efficient.

Exhausters. The gas pumps, or exhausters, are in the most usual practice placed at the outlet of the condensers, the gas being drawn through the condensers and forced on through the subsequent plant. Various kinds of exhausters are employed, the most popular being those of the Beale rotary type, shown in Figs. 17 and 18. These are automatically controlled by the vacuum in the hydraulic main so as to maintain the latter constant, a service pipe being run from the hydraulic main to a governor in the exhauster house. The latter governor is then

connected with a throttle valve controlling the steam supply to the exhauster, so that the speed at which the latter runs is automatically regulated to give a steady vacuum; or the latter may be run at a constant speed, and the governor

FIG. 17.

connected to a valve on a by-pass main from the inlet to the outlet of the exhauster, allowing more or less gas to flow back from the exhauster outlet to the inlet, according as the rate at which the gas is evolved from the retort falls or rises.

FIG. 18.

Extraction of tar fog. To eliminate the remaining tar fog from the cooled gas, two methods are employed. In the first, represented by the Pelouze-Audouin tar extractor, the gas is divided up into fine streams, which impinge, at a considerable velocity, on a flat surface; the tarry particles adhere to the latter and coalesce to tar which flows away. Fig. 19

FIG. 19.

shows the essential portion of the apparatus, which consists in two plates with a small space between them, the first of which is perforated with fine holes about $\frac{1}{20}$ inch in diameter, and the second with slots, the plates being so fixed that the gas issuing through the small holes impinges on the unperforated portion of the slotted plate. Two such pairs of plates are used in series, and these are arranged to form a bell (Fig. 20), which is sealed in the tar formed, and counterbalanced by weights so that it is free to

rise in the tar. If the amount of gas passing through the apparatus increases, the pressure within the bell tends to increase also, and the latter rises, and thus presents a larger number of holes for the gas to pass through, and *vice versa*, and in this manner the velocity of the gas through the holes is kept approximately constant with varying production of gas. This apparatus is very efficient when properly worked, but is preferably maintained at a temperature of about 30° , as otherwise the deposited tar may become so thick that it cannot flow away, and the apparatus becomes blocked.

FIG. 20.

is fed into the apparatus. A very efficient apparatus of this type is the Livesey washer, the essential feature of which is shown in Fig. 21. It consists of a parallel series of troughs arranged in a cast-iron rect-

angular vessel, the lower portions of which are perforated with holes $\frac{1}{20}$ inch in diameter, as shown, this portion being sealed in ammoniacal liquor. The gas entering at the top passes down between the troughs, and forces some of the liquor through the holes into the interior of the troughs, thus unsealing the holes, through which the gas then bubbles, as well as through the second perforated plate across the width of the trough. The liquor in the trough is broken up into foam, and effects the removal of the tar fog and some ammonia from the gas, the washed gas passing away through the open end of the trough to the gas outlet. With proper working the amount of tar fog can be reduced to below 10 grains per 100 cub. ft., but the amount of ammonia removed varies greatly according to the strength of the liquor used, and the amount passed through the washer. Small amounts of carbon dioxide, sulphuretted hydrogen, and hydrocyanic acid are also removed by the washer.

Wet purification. To effect the complete, or almost complete, removal of ammonia, the gas is next washed with water in suitable apparatus, the washing being conducted on the counter-current principle, the gas meeting a current of water flowing in the opposite direction, so that the liquor leaving the apparatus meets with the gas richest in ammonia, and is thereby worked up to the highest strength possible, whilst the gas leaving the apparatus comes in contact with fresh water, containing little or no dissolved ammonia, and is thereby freed as completely as practicable from it. One of the oldest forms of apparatus for the purpose, which is still largely in use, is the *tower scrubber* (Fig. 22). This consists of a vertical tower of circular section filled with coke, flints, wooden boards on edge, or other material which exposes a large surface to the gas passing through it. Water is mechanically sprayed over the whole of the upper surface of the filling material, and slowly percolates

FIG. 21.

downwards, meeting the ascending gas, and absorbing the ammonia it contains. The gas passes away from the top of the tower, and the liquor flows from the bottom through a siphon or seal-pot to a special tank or direct to the storage well. Such scrubbers are frequently

are employed for filling, but if tar is allowed to get forward into them, their efficiency is greatly reduced, as the down-flowing water then ceases to flow uniformly over the whole surface, but goes in channels, and the gas is not brought in proper contact with the water.

In place of these scrubbers, mechanically actuated rotary washers are now largely used. Several efficient types are in use, one of which, viz. Kirkham, Hulett, and Chandler's 'standard' washer, is illustrated in Fig. 23. This consists of a horizontal cylindrical vessel, divided internally into compartments by vertical plates, the latter having openings, where necessary, to allow of the passage of the gas. In each compartment is a disc keyed to the central revolving shaft, the disc, with the exception of the central portion, being filled with bundles of thin wooden boards or sheet-iron plates, fixed together in such a manner as to allow free passage of the gas over their surface. The gas, in traversing the apparatus as shown by the arrows, passes over this surface, which is kept wetted by revolving through the liquor in the bottom of each compartment, and effects the removal of the ammonia. The washing water enters at the gas outlet end, and flows continuously through each compartment, becoming continuously stronger to the opposite end of the washer, and away from that end by means of a siphon to the storage well. The Holmes washer, which is largely in use, resembles the foregoing in main outline, but special brushes are used to form the necessary washing surface.

During the past ten years centrifugal washers have been employed to an increasing extent, those most frequently used being the Feld, Kirkham-Hulett, Liversedge, and Maclaurin types. All of these consist of a vertical circular tower, divided by horizontal partitions into a number of superimposed compartments. In each of these is a spraying device actuated by a vertical shaft passing up the centre of the tower and driven at sufficient speed by mechanical power, which results in the water entering from the top and falling from compartment to compartment, being broken into fine spray and brought into intimate contact with the gas as it travels upwards to the outlet at the top. The main difference between the various types of machine lies in the form of spraying device adopted.

Provided that the gas is properly cooled, and that the temperature of the incoming water is also low, the quantity of ammonia left in the gas should not exceed 1-2 grains per 100 cub. ft. In hot weather, however, or with insufficient cooling of the gas, this amount may be considerably exceeded, owing to the lessened solubility of ammonia in water at higher temperatures.

Recently in a number of smaller gasworks direct recovery of the ammonia as sulphate has been adopted by passing the gas through sulphuric acid, instead of extracting it with water, and subsequently converting the ammoniacal liquor produced into sulphate. (Moon, *J. Gas Lighting*, 1910, 112, 474; see also *Alkali Inspector's Reports*, 1918, 1919, 1920.) These direct or semi-direct ammonia recovery methods have, however, been much more extensively adopted in connection with by-product coke ovens (see art. COKE).

FIG. 22.

worked in pairs, the first being fed with weak liquor from other parts of the process, but the final washing must always be effected with fresh water if anything like complete elimination of the ammonia is to be effected. Provided the tar fog has been previously removed from the gas, these scrubbers form very effective pieces of apparatus, especially where boards on edge

Fig. 23.

Naphthalene removal. Mention has already been made of the difficulty which arises from blockages both in the plant and mains on the works and on the mains and services in the district of supply, from the deposition of solid naphthalene from the gas. In the early days of the industry, when lower carbonisation temperatures were employed, no difficulty was experienced in this respect, as, although considerable amounts of naphthalene were even then present in the hot gas, the amount of other tar constituents boiling at the same or a lower temperature than naphthalene was sufficient to effect a practically complete washing out of the naphthalene from the gas in the ordinary process of condensation. As carbonising temperature increased, trouble from naphthalene became more and more noticeable, at first only where coals from the Durham coal-field were carbonised, but eventually, with still higher carbonising temperatures, from all classes of coal, and very serious nuisance from naphthalene stoppages took place, both manufacturers and consumers being affected.

The difficulty arises from the fact already discussed, that increased carbonising temperatures, when there is also a considerable free space above the coal in the retort, effect an increase in the production of naphthalene and a decrease in the production of lower-boiling tar oils, the proportion of the latter being then insufficient to effect the complete washing out of the naphthalene from the gas at the

cold end of the condenser, and the gas may, therefore, leave the latter almost saturated with naphthalene vapour at the temperature of the condenser outlet, such gas then becoming supersaturated on further cooling in the works or district of supply, and then under favourable conditions depositing solid naphthalene, mostly in the form of very bulky flaky crystals, a very small weight of which is capable of causing a serious block.

In some cases it has been possible, by modification of the condensing system, to effect a sufficient removal of naphthalene in the latter to avoid further trouble, but the increase in carbonising temperatures during recent years has brought about such a reduction in the amount of light oils produced, that this is now rarely possible, and some further treatment of the gas is therefore requisite in many cases. With vertical retorts, however, and also where horizontal retorts are charged nearly full, a greatly increased production of light oil occurs, and in these cases the ordinary condensation process is, in many instances, sufficient to prevent naphthalene trouble, without any subsequent process.

Two methods of treatment are employed, the one consisting in washing the gas with suitable naphthalene solvents, whereby its amount in the gas is largely reduced, and the second by adding to the gas the vapours of liquids which dissolve naphthalene, and have a somewhat similar vapour pressure. If, after such treatment, any naphthalene subsequently condenses from the gas, a simultaneous condensation of the added vapours occurs, and these dissolve the naphthalene so that the latter condenses in the liquid state, which causes no trouble, as provision is always made for the collection of liquids which may separate, these gravitating down to siphons fixed at intervals at low points in the mains, which are pumped at regular intervals.

To wash the naphthalene from the gas, any of the forms of washer employed for ammonia may be used. As solvent oil, the heavy oil fraction of coal tar, boiling at 270°–350° (green oil), was first suggested by Young and Glover (Eng. Pat. 20125, 1896); but as this oil also dissolves benzene, and would reduce the illuminating power of the gas, from 3 to 6 p.c. of benzene is added to the green oil, which prevents any such action. The same oil was also proposed at a later date in Germany by Bueh, and is largely employed there.

To increase the vapours of liquid hydrocarbons in the coal gas, Bunte and Eitner (J. Gasbeleucht. 1892, 569; 1899, 73) added xylene vapour to the gas, and Colson (Eng. Pat. 17666, 1904) and Bell (J. Gas Lighting, 1904, 88, 98) add the fraction of coal tar boiling chiefly between 170° and 210°. Many other washing oils are used, which frequently act in both the ways above described, partly dissolving naphthalene from the gas, and partly volatilising low-boiling constituents into the gas. Thus, for example, the tar obtained in the manufacture of carburetted water gas is now largely used for the purpose, as this contains a good percentage of light oils, which are largely volatilised into the gas, whilst the residual oil extracts much naphthalene from the gas. In other cases

ordinary paraffin oil is used, some of which also volatilises into the gas.

Botley (Eng. Pat. 9316, 1896) sprays a fine mist of paraffin oil into the gas leaving the works, this spray being carried right to the extreme of the district and also tending to prevent the deposition of naphthalene in the solid state, a similar effect being produced by volatilising paraffin vapour into the gas, which, by its quick condensation, also produces a mist.

The naphthalene washing process is mostly carried out on the cooled gas, either before or after the washing and scrubbing plant; in some cases, however, the washing process with water-gas tar takes place on the hot gas before the condensers, in which case a larger amount of oils is volatilised into the gas from that tar, and partly condenses again in the condensers, and assists in washing out the naphthalene remaining in the gas.

Extraction of 'crude benzole' from the gas.

During the war the benzene and toluene present in the gas were largely extracted for war purposes, and in some instances the extraction is still carried out for the provision of suitable spirit for internal combustion engines. The methods adopted are identical with those normally employed for the recovery of crude benzole from coke-oven gas (*see art. COKE*). As the process simultaneously removes most of the higher boiling vapours of hydrocarbons, including those most efficient in preventing subsequent naphthalene deposition from the gas, it is mostly advisable to add suitable vapours or spray to the gas after the benzole extraction, in the manner mentioned above.

Dry purification. The gas leaving the scrubbers still contains from 0.8 to 2.0 p.c. of sulphuretted hydrogen, and from 1 to 3.5 p.c. of carbon dioxide, together with smaller amounts of other impurities, namely, from 10 to 80 grains of sulphur per 100 cub. ft. as organic sulphur compounds, chiefly carbon disulphide, and from 50 to 100 grains of hydrocyanic acid. Of these the sulphuretted hydrogen, which on combustion is converted into sulphur dioxide, must be removed to an extent which is practically complete, statutory provision being made to this effect in all Acts of Parliament controlling gas undertakings. The carbon dioxide is not in itself deleterious, but was formerly frequently removed, as its presence materially reduces the illuminating power of the gas, each 1 p.c. of carbon dioxide lowering the illuminating power from 3 to 4 p.c. It also lowers the calorific power, but in much smaller proportion (1 p.c. for each 1 p.c. of CO₂ present), and in view of the decreasing importance of illuminating power, the removal of the dioxide is now practised to a much smaller extent than formerly. The removal of the sulphur compounds other than sulphuretted hydrogen cannot be effected completely by any known process, but many undertakings were formerly compelled by statute to reduce the amount of these to a certain maximum limit, varying from 17 to 30 grains per 100 cub. ft. These clauses have been now repealed, but in a number of works a partial or complete removal of the carbon bisulphide is carried out. The hydrocyanic acid is extracted more or less completely along with the sulphuretted hydrogen by all the processes in use, and is not often

found in the purified gas to any very considerable extent. In some undertakings the hydrocyanic acid is extracted at an earlier stage by special processes in order to obtain cyanogen compounds in marketable form, and the methods employed for this purpose will be described later.

Where sulphuretted hydrogen alone is to be removed, the purifying material employed is moist hydrated ferric oxide, the naturally occurring bog iron ore being largely used for the purpose. This contains a sufficient amount of fibrous organic matter to render the mass porous and allow of the passage of the gas through it. Where artificial or natural ferric hydroxides, free from organic matter, are employed, these are mixed with material such as sawdust or wood chips to give the required porosity.

The material is charged in even layers into rectangular cast-iron vessels (Fig. 24) containing wooden grids to carry the oxide, the thickness and number of the layers varying according to the size of the purifier. The latter is then closed by a lid, which, in the diagram shown, is rendered gas-tight by the provision of vertical sides which drop into a water lute cast around the periphery of the purifier; so long as the pressure of the gas within the box does not exceed that equal to the depth of the water

seal, no gas can escape. As, however, serious explosions have occurred owing to escape of gas through the water seal, owing to excessive pressure, the present tendency is to the adoption of luteless lids which are bolted to the purifier and made gas-tight by the insertion of a rubber joint between the purifier and cover.

The purifiers are mostly worked in sets of four, the connections being so arranged that the gas can be allowed to enter any box, and then pass in series through the remaining boxes. Frequently only three boxes are worked in series, the fourth being off for changing the material, or kept in reserve when freshly charged until sulphuretted hydrogen is found to be getting forward nearly to the outlet of the box before it, when the fresh box is put to work, and the first box in the series shut out and recharged with fresh oxide.

The sulphuretted hydrogen acts on the hydrated ferric oxide in two different ways, forming either ferric sulphide or a mixture of ferrous sulphide and free sulphur:

In neutral or faintly acid condition, the reaction takes place according to the second equation, but in slightly alkaline condition ferric sulphide alone is formed, and as the coal gas entering the

FIG. 24.

purifiers always contains traces of ammonia, it is this compound which is chiefly formed in the gas purifiers.

When the mass has ceased to absorb sulphuretted hydrogen, it is removed from the purifier and spread out on the floor in moist condition, with occasional turning over, to expose it to the air, when the ferric sulphide is oxidised, reforming hydrated ferric oxide, with separation of free sulphur. As soon as this reaction is complete, the mass can be returned to the purifier for the extraction of further amounts of sulphuretted hydrogen, this alternate process of fouling and revivification being continued until the mass contains 50-70 p.c. of sulphur, when it is sold for its sulphur content, being chiefly used for sulphuric acid manufacture, one advantage of the material for this purpose being its almost complete freedom from arsenic.

As the crude gas entering the purifiers always contains some oxygen, the revivification of the ferric sulphide to ferric oxide and sulphur always takes place to some extent in the purifier itself, and the length of time for which a purifier will run without changing depends, to a large extent, on the amount of oxygen in the crude gas. All things considered, the volume of oxygen most suitable is rather more than half the percentage volume of the sulphuretted hydrogen in the crude gas; and where the air accidentally getting in

to the gas does not reach this amount, more is added. A still larger addition of air further increases the time the purifiers will run without changing, and consequently the cost for labour, but the extra amount of oxygen and nitrogen remaining in the gas lowers its quality, and if too much oxygen is present the separated sulphur may even fire in the boxes, and, apart from the damage caused in the box, the gas may be badly contaminated with sulphur dioxide. The temperature of the gas passing through the purifiers should not fall below about 15°, as then the action of the oxygen becomes very slow.

Instead of working the rotation of the purifiers in the manner mentioned above, which was formerly universal, modified methods are now frequently adopted. Thus, for example, instead of putting on a fresh box as the last in the series, it is now frequently put on as the first box, where it removes practically the whole of the sulphuretted hydrogen, and the gas coming from the outlet of the two boxes last in the series becomes quite free from sulphuretted hydrogen in a short time, any sulphuretted hydrogen passing from the last purifier during this period being taken up by a 'catch' purifier placed on the common outlet main. At intervals of 24 or 48 hours or more, the last box is made the first box of the series, when the same change

occurs, and this process of 'reversed' rotation continued. Working in this manner, it is often possible to keep the gas free from sulphuretted hydrogen for a very long period, and to obtain a high percentage of sulphur in the spent oxide without removing the material from the box, and, indeed, it often happens that a removal of the material is necessary, not on account of its passing sulphuretted hydrogen, but because the mass has become so dense from separated sulphur, that it requires an undue pressure to force the gas through it. The exact reasons for the longer period of working are not yet quite clear, though it is evident that this method of working enables the oxygen in the crude gas to effect a quicker revivification of the ferric sulphide than is the case with the older method of working.

Purification from carbon dioxide after removal of sulphuretted hydrogen. When the carbon dioxide is required to be removed from the gas after freeing from sulphuretted hydrogen, a similar set of two, three, or four purifiers is employed, into which slaked lime is charged in place of the hydrated ferric oxide. This is prepared by slaking good non-hydraulic lime with water, which is added in sufficient quantity to moisten the slaked lime produced to such an extent that it just balls together when squeezed in the hand. This removes the whole of the carbon dioxide from the gas, the slaked lime being converted into calcium carbonate

Where the gas is free from sulphuretted hydrogen, the spent lime obtained is fairly innocuous, though of very little value, but is sometimes reburnt to lime and again used for purification.

Simultaneous removal of sulphuretted hydrogen, carbon dioxide, and carbon disulphide by means of lime. The dry purification process described above hardly effects the removal of sulphur compounds other than sulphuretted hydrogen to any material extent, and the great bulk of these remains in the purified gas, and much controversy has occurred as to whether these should be removed as far as possible or not. That their removal was desirable if economically practicable was usually admitted, but difficulty lay in the fact that the only process known until recently by which their elimination could be even partially effected at reasonable cost on the large scale had serious drawbacks. This process consists in subjecting the gas to the action of calcium hydrosulphide formed by the action of sulphuretted hydrogen on lime, which absorbs a large proportion of the carbon disulphide, and by which means the total amount of sulphur left in the gas can be reduced to 12-20 grains per 100 cub. ft. The objections to this process are as follows: (1) The spent material consists of a sloppy mass containing calcium sulphide, having a very unpleasant smell of sulphuretted hydrogen, &c., which is perceptible at long distances from the works, and occasions complaints in their neighbourhood, and also in districts through which the material may have to be carted. (2) The discharging of the spent material from the boxes is exceedingly unpleasant to the men employed in the operation, and not unattended with danger to their health. (3)

The process is somewhat uncertain in action, and under some conditions the material may not only not absorb any carbon disulphide from the gas, but may also give off that previously absorbed, thus rendering the amount of sulphur in the gas far higher than it would have been with oxide purification only. (4) Great difficulty is experienced in disposal of the spent material, except in smaller undertakings in agricultural districts, where there is a limited demand for the material for manurial purposes.

Formerly a number of works were statutorily compelled to reduce the total amount of sulphur in their gas below a certain maximum, but these restrictions were abolished as a result of a Board of Trade inquiry held in 1904, under the presidency of Lord Rayleigh, largely on the ground that the above-named disadvantages accruing from the lime process more than counterbalance the advantage derived from the reduction of the sulphur to a lower limit.

In carrying out the lime process, a set of four purifiers, charged with slaked lime, is employed, worked in rotation in a similar manner to the first method described in connection with oxide of iron purifiers. In the first and second boxes carbon dioxide is chiefly absorbed, the remainder along with the bulk of the sulphuretted hydrogen being absorbed in the third and fourth boxes, the calcium hydrosulphide formed in the latter also, under right conditions, absorbing much of the carbon disulphide. The gas from the latter purifier passes to a catch box of oxide of iron, and when the fourth box passes much sulphuretted hydrogen, the box first in series is discharged, recharged with fresh lime, and put on as the last in series.

For the effective removal of the carbon disulphide, one of the most important factors is the amount of oxygen present in the crude gas. If this is excessive, the calcium hydrosulphide is oxidised to thiosulphate, &c., as fast as it is formed, and before it can act on the disulphide, and no removal of the latter occurs; moreover, if the purifiers have been previously extracting the disulphide and the amount of oxygen in the crude gas suddenly rises, not only is no carbon disulphide absorbed, but that previously retained in the lime is given off by the action of the carbon dioxide, and the 'purified' gas may contain three or four times as much disulphide as is present in the gas entering the purifiers. On the other hand, if oxygen is entirely absent, no absorption of carbon disulphide takes place, the most regular results being obtained when the average amount of oxygen present is equal to about one-third of the average volume of sulphuretted hydrogen in the crude gas. Even when this condition is maintained, a good absorption does not invariably occur, and from causes which are at present unknown, a set of purifiers may sometimes cease to absorb the disulphide, and will then usually not recover their activity until they are all recharged with fresh lime.

The exact nature of the compound which combines with the disulphide is not yet known with certainty. It was formerly thought that calcium hydrosulphide combined with it, forming calcium thiocarbonate

but calcium hydrosulphide, and, indeed, all the soluble hydrosulphides, when free from polysulphides, combine very slowly, if at all, with carbon disulphide in absence of oxygen. Veley (Chem. Soc. Trans. 1885, 47, 478) suggests that the active compound is calcium hydroxyhydrosulphide $\text{Ca}(\text{OH})(\text{SH})$, but the writer regards it as much more probable that the real absorbent is calcium disulphide CaS_2 , formed from the hydrosulphide by oxidation:

for although the pure sulphides and hydrosulphides of potassium, sodium, ammonium, and calcium scarcely unite with carbon disulphide at the ordinary temperature, the disulphides of the above metals in all cases combine rapidly and completely with it, forming *perthiocarbonates*, such as Na_2CS_4 (Gélis, Compt. rend. 81, 282; Yeoman, Chem. Soc. Trans. 1921, 119, 38). This supposition explains why some oxygen is necessary for carbon disulphide absorption, as it is required to effect the formation of polysulphide from the primary hydrosulphide, whilst excess of oxygen oxidises the latter to thiosulphate, &c.

Apart from the objections to the process already mentioned, it will be seen that this method involves the complete removal of carbon dioxide from the gas, whether this is otherwise advisable or not, and an economical process which does not necessitate the simultaneous removal of the carbon dioxide is very desirable. Many unsuccessful attempts have been made to devise such a process. Thus Claus (J. Soc. Chem. Ind. 1887, 6, 27; Eng. Pats. 7585, 1886; 3627, 1887) showed that a solution of ammonium polysulphide removed carbon bisulphide, and this has been confirmed by others, but it has hitherto been found that the absorption is not regular, varying from time to time for reasons which have not yet been elucidated. The first action is probably the formation of a solution of ammonium perthiocarbonate $(\text{NH}_4)_2\text{CS}_4$, but this is exceedingly unstable, and readily decomposes, giving off CS_2 . It is, however, capable of undergoing another change, yielding ammonium thiocyanate

and if the conditions under which this change takes place quickly and with certainty could be ascertained, and economically maintained, this should form a cheap process for the purpose.

The Cooper liming process (Eng. Pat. 5713, 1882), in which small quantities of lime are added to the coal before carbonisation, although primarily intended to increase the yield of ammonia, also effects a reduction in the amount of carbon disulphide; but the large-scale experiments with the process made about thirty years ago were abandoned, chiefly on account of the deterioration in the quality of the coke produced. Paterson & Twycross (Eng. Pat. 26772, 1910) have introduced a modified method, whereby a regulated amount of powdered lime is distributed evenly over the surface of the coal on its way to the retort, the powder being made to adhere by the action of a small jet of steam. The process has been at work for some years at the Cheltenham Gas Works, using about 2 per cent. of lime, and has not resulted in any material deterioration of

the coke, and has given an increased yield of ammonia, whilst the amount of sulphur other than sulphuretted hydrogen in the gas has averaged 20 grains per 100 cub. ft., as compared with more than double this amount when the liming is omitted.

It has also long been known that by reheating the gas freed from sulphuretted hydrogen to 300°–350° the carbon disulphide is largely converted into sulphuretted hydrogen, which may then be removed by oxide of iron purification, but until recently practical difficulties in large-scale working prevented its adoption. (For a full account of these methods, see Carpenter, J. Gas Lighting, 1914, 126, 928.) The first successful plant of any magnitude for carrying out the method was that of Hall and Papst at the Oregon Works, U.S.A., where a plant was erected dealing with 4,000,000 cub. ft. of gas per diem, and effected an average reduction of the sulphur from 58 to 17 grains per 100 cub. ft.

As the result of several years' work the South Metropolitan Gas Co., have now worked out a successful and economical process for the complete removal of the carbon disulphide from the gas depending on the passage of the gas heated to 450° over a catalyst (Carpenter, J. Gas Lighting, 1914, 126, 928; Evans, J. Soc. Chem. Ind. 1915, 9). A number of metals, such as iron, nickel, cobalt, and copper may be employed, but the most effective catalyst consists of porous fire-clay impregnated with nickel reduced from the chloride, and this is the one employed in practice, the carbon disulphide under the conditions named reacting with the hydrogen of the gas, yielding sulphuretted hydrogen and carbon:

In carrying out the process, the gas freed from sulphuretted hydrogen passes first through a tubular heat interchanger, where it is heated by the hot gas coming from the catalysing tubes, and thence to a heating chamber in which are assembled the vertical 6-inch tubes filled with the fire-clay-nickel catalyst, maintained at a temperature of 420°–440°. The gas, with the carbon disulphide completely converted into sulphuretted hydrogen, passes through the heat interchangers, giving up a large portion of its heat to the incoming cold gas, and thence, after complete cooling, to oxide of iron purifiers for the removal of the sulphuretted hydrogen.

Apart from the conversion of the carbon disulphide into sulphuretted hydrogen and small amounts of hydrocyanic acid present into ammonia, no material change takes place in the composition of the gas, and its illuminating and calorific powers are substantially unchanged. The carbon deposited from the carbon disulphide accumulates on the catalyst, and is periodically removed by careful burning in a regulated stream of air. No trouble from the 'poisoning' of the catalyst has been experienced.

The process is now successfully at work at the different works of the South Metropolitan Gas Co., the largest installation being capable of dealing with 15,000,000 cub. ft. of gas per diem, and reducing the sulphur to about 8 grains per 100 cub. ft.

Guillet (J. Gas Lighting, 1912, 118, 986)

passes the heated gas, freed from sulphuretted hydrogen, over heated ferric oxide, when the moisture in the gas reacts with the carbon disulphide forming sulphuretted hydrogen and carbon dioxide:

the sulphuretted hydrogen formed being absorbed by the ferric oxide.

Apart from the carbon disulphide, the gas always contains sulphur in the form of other organic sulphur compounds amounting to 4-10 grains per 100 cub. ft., which have not yet been successfully removed. A large proportion of this irremovable sulphur is in the form of thiophen, and, in addition, mercaptans and alkyl sulphides have been detected.

Removal and recovery of cyanogen compounds. It has long been known that crude coal gas contains cyanogen derivatives, and that their quantity tends to increase with increasing carbonising temperatures. The only compound of this kind that has been detected with certainty in the gas is hydrocyanic acid, although it is possible that cyanogen itself may be present in small quantity. The total amount varies considerably at different works, but with the temperatures at present mostly employed, the amount of hydrocyanic acid produced in the gas issuing from the retorts averages about 120-130 grains per 100 cub. ft., of which about one quarter is removed in the virgin liquor during condensation, partly as ammonium cyanide, but chiefly as ammonium thiocyanate, into which the cyanide formed also passes on storage. Smaller amounts are absorbed in a similar manner in the washers and scrubbers, but with high retort temperatures from 90-100 grains of hydrocyanic acid per 100 cub. ft. (equivalent to about 4-4.5 lbs. of crystallised sodium ferrocyanide $\text{Na}_4\text{FeCy}_6 \cdot 10\text{H}_2\text{O}$ per ton of coal) usually remain in the gas entering the purifier.

Where lime alone is used for purification, the hydrocyanic acid is completely absorbed with the other impurities, and converted into calcium thiocyanate; and where ferric oxide is used, the greater quantity is likewise absorbed with formation of insoluble iron ferrocyanides and double ferrocyanides of iron and ammonium (crude Prussian blue) as well as ammonium thiocyanate. The more complete the removal of ammonia from the gas before the purifiers, the greater is the amount converted into ferrocyanide, and the smaller the production of thiocyanate.

The greatly increased demand for cyanide following on the introduction of the McArthur-Forrest cyanide process for extraction of gold from the mine 'tailings,' resulted in many attempts being made for the utilisation of the cyanogen compounds in the crude gas. At first the spent oxide was utilised for this purpose, being sold to chemical manufacturers for its Prussian-blue content, where this reached an amount of 6-8 p.c. A number of processes were also devised for the special recovery of the hydrocyanic acid by extracting it from the gas before the latter reached the purifier. In these processes the hydrocyanic acid is recovered either as (1) ferrocyanide or (2) thiocyanate. For the former, the gas is washed with a solution

containing alkali and ferrous hydroxide, carbonate, or sulphide in suspension, which absorbs the hydrocyanic acid with production of the ferrocyanide of the alkali used, the reaction with ferrous sulphide and sodium carbonate, for example, being:

Where ammonia is used as the alkali, as in the processes of Rowland (Eng. Pat. 22347, 1891), Bueb (Eng. Pat. 9075, 1898), and Lessing (Eng. Pat. 2090, 1907), the gas is treated before the removal of ammonia in a suitable washer with a strong solution of ferrous sulphate, which is converted first into ferrous sulphide and ammonium sulphate by the sulphuretted hydrogen and ammonia of the crude gas, and then yields ammonium ferrocyanide. The latter solution is unstable, and to a large extent combines with the excess of iron present, yielding insoluble double ferrocyanides of iron and ammonium, the proportion of insoluble ferrocyanides produced increasing with increasing strength of the ferrous sulphate solution used. The sludge obtained, containing chiefly crude Prussian blue, with the excess of unused ferrous sulphide, is sold to chemical manufacturers for conversion into saleable ferrocyanide or cyanide.

Where a fixed alkali is used (soda and lime being the only ones available, on account of price), the gas is treated after the removal of ammonia in a washer fed with a mixture of sodium carbonate and ferrous carbonate (Knublauch, Eng. Pat. 15164, 1887), or a solution of ferrous sulphate with excess of lime, when the bulk of the hydrocyanic acid is absorbed and converted chiefly into the soluble sodium or calcium ferrocyanide, only small amounts being converted into insoluble ferrocyanides. The sodium ferrocyanide solution, after filtration from the excess of ferrous sulphide, &c., is directly evaporated and crystallised; the calcium ferrocyanide solution, on the other hand, is unstable when heated, and is preferably first converted into the sodium salt, by addition of the requisite quantity of sodium carbonate, or, if the potassium salt is required, the calcium ferrocyanide solution may be treated with potassium chloride solution, when the sparingly soluble calcium potassium ferrocyanide $\text{CaK}_2\text{FeCy}_6$ is precipitated, and after filtration may be converted into a pure solution of potassium ferrocyanide by addition of the requisite amount of potassium carbonate. In the Davis-Neill process (Eng. Pat. 26566, 1901), the treatment with sodium and ferrous carbonate is carried out before the removal of ammonia from the gas, and the liquor from the washer first distilled to recover ammonia.

In all these processes, a certain amount of hydrocyanic acid is converted into thiocyanate, the proportion formed being greater when ammonia is present, and *carbonyl ferrocyanides* are also usually produced to some extent. Carbonylferrocyanic acid $\text{H}_3\text{Fe}(\text{CO})\text{Cy}$, may be regarded as ferrocyanic acid in which 1 molecule of HCy is replaced by the radical CO , the formation of these salts being doubtless due to the presence of carbon monoxide in the gas treated. They have little or no commercial value, and

accumulate in the mother liquors, being very soluble in water.

For the recovery of the hydrocyanic acid as thiocyanate, according to the British Cyanide Co.'s process (Eng. Pat. 13653, 1901), the gas, whilst still containing ammonia, is passed through a washer containing water or ammoniacal liquor, to which free sulphur is periodically added. The ammonia and sulphuretted hydrogen dissolve in the water, forming ammonium sulphides, which dissolve the sulphur, yielding ammonium polysulphide solution, and the latter absorbs the hydrocyanic acid, forming ammonium thiocyanate. So long as free sulphur is present, the formation of polysulphide and of thiocyanate continues, and a solution can be obtained containing from 3 to 5 lbs. of ammonium thiocyanate per gallon. Except for volatile ammonium salts, such as sulphide, which are expelled on heating, the solution is comparatively pure, and is sold for conversion into cyanide. According to the modification of P. E. Williams (Eng. Pat. 23624, 1909), the gas, freed from tar-fog but containing ammonia, is passed through a purifier charged with spent oxide rich in sulphur, the latter supplying the necessary sulphur for the extraction. Water is periodically sprayed on to the upper surface of the spent oxide and drains to the bottom of the purifiers, and is converted during the passage into a concentrated solution of ammonium thiocyanate by the same series of reactions.

Other purification processes. As already mentioned, a portion of the sulphuretted hydrogen and carbon dioxide is removed along with the ammonia, the solution of the latter in water absorbing these acid gases with formation of ammonium sulphides and carbonates, but the amount of ammonia present is much below that required for their complete removal. Many attempts have been made to modify the scrubbing process in such a manner as to effect the complete removal of these two impurities. Hills (Eng. Pats. 1369, 1868; 934, 1874; 1895, 1875) showed that when the ammoniacal liquor is heated to about 90°, it gives off large quantities of carbon dioxide and sulphuretted hydrogen, but only small amounts of ammonia, the residual liquor then containing large amounts of free ammonia, which may be used for washing a further amount of the acid gases from crude gas. A modification of Hills' method has been described by Holgate (J. Gas Lighting, 1895, 65, 1133). Claus (Eng. Pats. 2838 and 2865, 1881; 4644, 1882; 5959, 1883) combined Hills' process with the continuous distillation of a large amount of liquor, the ammonia being returned to the gas, so that the amount of ammonia in the gas in the scrubbers was four or five times that normally present, and was enabled, on a moderate scale, to effect in this manner a complete removal of the sulphuretted hydrogen and carbon dioxide from the gas, doing away with the necessity for any further dry purification. By washing also with a solution of ammonium polysulphide, the amount of hydrocyanic acid and carbon disulphide was largely reduced. The mixed sulphuretted hydrogen and carbon dioxide evolved from the heated liquor were, after recovery of the ammonia present by washing with water or

acid, mixed with just sufficient air to convert the sulphuretted hydrogen into sulphur and water, and passed through heated ferric oxide in the 'Claus kiln,' the sulphur produced being condensed in suitable chambers.

Great hopes were entertained as to the success of the process, but, unfortunately, the practical difficulties of working which manifested themselves when the process was tried on a larger scale have never been overcome, and at Belfast, where the process was tried for many years, it was not found possible regularly to effect complete removal of the sulphuretted hydrogen, and the loss of ammonia was very considerable (J. Gas Lighting, 1897, 69, 1475).

Processes are at present also on trial with the object of recovering the ammonia from the gas direct as sulphate by utilising the sulphuretted hydrogen of the crude gas as the source of the sulphuric acid. Various methods to attain this end have been patented by Burkheiser (Eng. Pats. 20920, 21763, 1908; 17359, 1910; 16172, 1912), and by Feld (Eng. Pats. 3061, 1909; 5838, 1911; 157, 10147, 1912; Zeitsch. angew. Chem. 1912, 705), but these processes are still in the experimental stage.
